Tremblay *et al*. conclude the phenomena they observed are "likely to prevail with the increasingly deep and frequent seaward retreat of the central ice pack and the greater incidence of upwelling-favorable winds," as described in detail by Yang (2009), and "new production is also bound to rise as winds gain in intensity and upwelling draws deeper into the nutrient-rich, upper Pacific halocline."

6.1.4 Fish

The studies reviewed in this section examine the impact of rising temperatures on marine fish species. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Primary production increases expected to result from future greenhouse gas emissions and their IPCC-projected impacts on climate "will provide opportunities to recover overfished fisheries, increase profitability of fisheries and conserve threatened biodiversity" around Australia.

- The population of one-year-old chum salmon in the Okhotsk Sea "was less during the period from the 1940s to the mid–1970s compared to the period from the mid–1980s to the present." This result "was directly affected by warmer sea surface temperatures associated with global warming."

- There has been a "rapid microevolution for earlier migration timing in" pink salmon in Alaska, which has allowed both the odd- and even-year groups of salmon "to remain resilient to environmental change."

- Despite having low critical thermal maximum temperatures, a geographically diverse group of 11 species of Antarctic fishes "maintained the capacity to increase their heat tolerance through warm acclimation."

- "Adult seahorses show great resilience to heat stress and are not expected to go through any physiological impairment and behavioral change with the projected near-future warming."

- "Tropical marine fishes inhabiting fringing nursery environments may have the upper thermal tolerance necessary to endure substantial increases in sea temperatures."

- Developmental plasticity in fish "may allow adaptation to changing environmental conditions to have delayed effects," and "this may attenuate some of the more severe predictions about organisms' responses to global warming and eutrophication."

Brown *et al*. (2010) noted "effects of climate-driven production change on marine ecosystems and fisheries can be explored using food web models that incorporate ecological interactions such as predation and competition," citing Cury *et al*. (2008). They used the output of an ocean general circulation model driven by a "plausible" greenhouse gas emissions scenario (IPCC 2007 scenario A2) to calculate changes in climate over a 50-year time horizon. They fed those results into a suite of models for calculating primary production of lower trophic levels (phytoplankton, macroalgae, seagrass, and benthic microalgae), and they used the results of those calculations as input to "twelve existing Ecopath with Ecosim (EwE) dynamic marine food web models to describe different Australian marine ecosystems." This protocol ultimately predicted "changes in fishery catch, fishery value, biomass of animals of conservation interest, and indicators of community composition."

The 17 scientists state under IPCC's "plausible

climate change scenario, primary production will increase around Australia" with "overall positive linear responses of functional groups to primary production change," and "generally this benefits fisheries catch and value and leads to increased biomass of threatened marine animals such as turtles and sharks." They note the calculated responses "are robust to the ecosystem type and the complexity of the model used." Brown *et al.* conclude the primary production increases suggested by their work to result from IPCC-envisioned greenhouse gas emissions and their calculated impacts on climate "will provide opportunities to recover overfished fisheries, increase profitability of fisheries and conserve threatened biodiversity."

Drinkwater (2006) reviewed the status of marine ecosystems of the northern North Atlantic in the early twentieth century during a regime shift, which he defined as "a persistent radical shift in typical levels of abundance or productivity of multiple important components of the marine biological community structure, occurring at multiple trophic levels and on a geographical scale that is at least regional in extent." Drinkwater reports, "in the 1920s and 1930s, there was a dramatic warming of the air and ocean temperatures in the northern North Atlantic and the high Arctic, with the largest changes occurring north of 60°N," and this warming "led to reduced ice cover in the Arctic and subarctic regions and higher sea temperatures," as well as northward shifts of multiple marine ecosystems.

The early twentieth century warming of North Atlantic waters "contributed to higher primary and secondary production," Drinkwater notes, and "with the reduced extent of ice-covered waters, more open water allow[ed] for higher production than in the colder periods." As a result, cod "spread approximately 1200 km northward along West Greenland," and "migration of 'warmer water' species also changed with earlier arrivals and later departures." Drinkwater notes, "new spawning sites were observed farther north for several species or stocks while for others the relative contribution from northern spawning sites increased." Also, "some southern species of fish that were unknown in northern areas prior to the warming event became occasional, and in some cases, frequent visitors."

Seo *et al.* (2011) note, "Pacific salmon (*Oncorhynchus* spp.) play an important role as both keystone species in North Pacific ecosystems and as an ecosystem service that provides human food resources for countries of the North Pacific rim," citing Kaeriyama (2008), and they observe the

Hokkaido chum salmon (*O. keta*) experiences a period of critical mortality "characterized by size-dependent mortality and size-selective predation, immediately after seaward migration," citing Healey (1982), Kaeriyama (1986), Kaeriyama and Ueda (1998), and Kaeriyama *et al.* (2007). To determine the effect of global warming on this critical mortality period in the life of Hokkaido chum salmon, Seo *et al.* used multiple regression and path analysis to examine the effects of regional and larger spatial scales of climatic/oceanic conditions on the growth, survival, and population dynamics of the species.

The three researchers from the Faculty of Fisheries Sciences at Japan's Hokkaido University determined growth of one-year-old chum salmon in the Okhotsk Sea "was less during the period from the 1940s to the mid–1970s compared to the period from the mid–1980s to the present," and this result "was directly affected by warmer sea surface temperatures associated with global warming." They add, "the increased growth at age one led directly to higher survival rates and indirectly to larger population sizes."

Bentley and Burgner (2011) studied juvenile sockeye salmon (*Oncorhynchus nerka*) in an Alaskan watershed that had experienced a 1.9°C increase in summer water temperature over the prior 46 years. They hypothesized the warming of the region "would have resulted in a corresponding increase in fish metabolism, and thus potential consumption rates, that would increase infestation rates of the tapeworm *Triaenophorus crassus.*" They tested their hypothesis by comparing infestation rate data for *T. crassus* collected between 1948 and 1960 with similar data obtained in 2008 and 2009 from the Wood River system of Bristol Bay, Alaska.

The two U.S. researchers from the University of Washington's School of Aquatic and Fishery Sciences say in "comparing the average summer air temperature to the parasite prevalence of juvenile sockeye salmon, we found no significant relationship over the fifteen years of collected data." They also report in "evaluating the influence of average summer air temperature on the parasite infestation rates of juvenile sockeye salmon, we again found no significant relationship for either parasite abundance or parasite intensity," and "when we compared the 13 years of historic parasite prevalence to equivalent data collected in 2008 and 2009, we did not find a statistically significant positive long-term trend in the data." Bentley and Burgner write, "the parasite abundance of examined sockeye salmon smolts also did not exhibit a statistically significant long-term

trend using the eight years of historic data and the two years of contemporary data." They report, "evaluating the relationship between time and parasite intensity produced similar results as the other five comparisons, with there not being a statistically significant positive relationship." Bentley and Burgner conclude their data demonstrate "the complex effects of warming have not summed to generate a measurable change in the infestation rates of juvenile sockeye salmon in the Wood River system."

Kovach *et al*. (2012) studied salmon in Auke Creek, a small lake-outlet stream near Juneau, Alaska, where there have been complete daily counts of all adult pink salmon migrating into the creek since 1971. They used "phenotypic data on migration timing, archived genetic samples and data from a marker locus, the allele frequencies of which were experimentally altered more than 30 years ago, to determine whether change in migration timing in a population of pink salmon has a genetic basis (i.e., microevolution)." The three researchers determined both even- and odd-year adult pink salmon that spawn in the warming Alaskan stream are migrating into fresh water nearly two weeks earlier than their predecessors did 40 years ago. They also found experimental data "support the hypothesis that there has been directional selection for earlier migration timing, resulting in a substantial decrease in the late-migrating phenotype (from more than 30% to less than 10% of the total abundance)." They also report, "from 1983 to 2011, there was a significant decrease—over threefold—in the frequency of a genetic marker for late-migration timing, but there were minimal changes in allele frequencies at other natural loci."

Kovach *et al*. say "these results demonstrate that there has been rapid microevolution for earlier migration timing in this population," and this has allowed both the odd- and even-year groups of salmon "to remain resilient to environmental change," as also was demonstrated by Kinnison and Hairston (2007). They note, "population abundance in 2011 was the second highest on record," further indicating the salmon of Auke Creek are "persisting through rapid temperature warming."

Aurelio *et al*. (2013) examined "the effect of environmental warming on the metabolic and behavioral ecology of a temperate seahorse, *Hippocampus guttulatus*." They compared routine metabolic rates, thermal sensitivity, ventilation rates, food intake, and behavioral patterns at the average spring temperature (18°C), the average summer temperature (26°C), the temperature that seahorses

often experience during summer heat wave events (28°C), and the temperature of a near-future warming (+2°C) scenario (= 30°C) in Portugal's Sado estuary.

The 10 scientists state "both newborn juveniles and adults showed significant increases in metabolic rates with rising temperatures," with newborn juveniles being "more impacted by future warming via metabolic depression." In addition, "in adult stages, ventilation rates also increased significantly with environmental warming, but food intake remained unchanged." They report, "the frequency of swimming, foraging, swinging, and inactivity did not significantly change between the different thermal scenarios." Aurelio *et al*. conclude "adult seahorses show great resilience to heat stress and are not expected to go through any physiological impairment and behavioral change with the projected near-future warming," but juveniles in their early life stages "display greater thermal sensitivity and may face greater metabolic challenges."

Bilyk and DeVries (2011) note "most animals do not have a static heat tolerance; rather it changes in response to their recent thermal history through acclimation." They continue, "given the long residence of Antarctic fishes in constant freezing seawater, this plasticity had long been thought either lost or marginal (Brett, 1970)." They say "understanding the heat tolerance of Antarctic fishes and its plasticity is critical for understanding the threat to this cold adapted fauna," especially "given the future predicted increases in water temperatures in the southern Ocean from global climate change."

Bilyk and DeVries employed the critical thermal maximum (CTMax) methodology—the temperature at which an animal loses the ability to escape from constant rapid warming (Paladino *et al*. 1980)—"to survey heat tolerance in a geographically diverse group of eleven species of Antarctic fishes acclimatized to the cold water temperatures of their natural habitats." They also used this methodology on eight of the species "following warm acclimation to 4°C, which when compared to their environmental CTMaxs provided a measure of the plasticity of their heat tolerance," as these fish "had been caught or held at temperatures below -0.9°C."

The researchers found "when acclimatized to their natural freezing water temperatures, environmental CTMaxs ranged from 11.95 to 16.17°C," and when the eight further-studied species were warm-acclimated to 4°C, "all showed a significant increase over their environmental CTMaxs, with several showing plasticity comparable in magnitude to some far more eurythermal fishes." Bilyk and DeVries write,

"despite their low CTMaxs, all the Antarctic species maintained the capacity to increase their heat tolerance through warm acclimation," and when this capacity was quantified, it showed "a surprising level of thermal plasticity at low temperatures," which they say was surprising "given the presumed loss of selection for thermal flexibility that has long been assumed in this fauna."

Eme *et al*. (2011) write, "temperate fishes have been considered especially vulnerable to changing climate conditions," and "increasing water temperatures may also threaten shallow-water marine fishes inhabiting nursery environments, like tropical mangroves and seagrass beds." To evaluate these hypotheses, the authors "used critical thermal methodology to quantify critical thermal maxima (CTmaxima) of juvenile squaretail mullet (*Liza vaigiensis*) and juvenile crescent terapon (*Terapon jarbua*) captured from shallow seagrass nursery areas around Hoga Island, southeast Sulawesi, Indonesia."

The three U.S. researchers report groups of mullet acclimated to a constant temperature of 37°C, as well as temperature cycles of 35–39°C or 37–41°C, all displayed statistically similar mean CTmaxima of 44.7, 44.4, and 44.8°C, respectively. They found terapon acclimated to a constant temperature of 37°C or a temperature cycle of 37–40°C both displayed mean CTmaxima of 43.8°C. Eme *et al*. conclude "terapon and mullet demonstrate exceptional tolerance to high temperatures," and "it seems likely that shallow-water sea surface temperatures would have to be much higher to adversely affect these and other shallow water marine fishes (Eme and Bennett, 2009)," as these "exceptionally high CTmaxima afford mullet and terapon a significant measure of protection against changing habitat conditions." The scientists write, "despite diverse independent origins across taxa, fishes may share a common suite of physiological adaptations allowing them to survive periodic exposure to high environmental temperature (Hochachka and Somero, 2002; Somero, 2010)," and "exceptional thermal tolerance may be common throughout the biodiverse shallow waters of the Indo-Pacific." They conclude, "tropical marine fishes inhabiting fringing nursery environments may have the upper thermal tolerance necessary to endure substantial increases in sea temperatures."

In a controlled laboratory experiment, Donelson *et al*. (2012) reared the offspring from eight wild-caught damselfish (*Ancanthochromis polyacanthus*) for two generations, "in present day (+0.0°C) and predicted future increased water temperatures (+1.5°C and +3.0°C) to test their capacity for metabolic acclimation to ocean warming." After three months, the authors assessed the responses in resting metabolic rate (RMR) relative to maximum metabolic rate (MMR) for each individual. They used this "metabolic performance" measure to characterize changes in the ability of each fish to perform aerobic activities (which would include functions such as behavior, growth, and reproduction) at its summer average water temperature (+0.0°C) and above (+1.5°C and +3.0°C).

The experiment revealed second-generation offspring had superior metabolic performance at all temperatures when their parents had been reared to maturity at a temperature of +1.5°C or +3.0°C. In addition, one pair of damselfish (i.e., one particular genetic lineage) contributed many more second-generation offspring that did well at +3.0°C than did the other wild parents: 75% of all fish that reproduced at +3.0°C were the offspring of wild pair #41. In contrast, wild pair #41 contributed 57% of offspring reproducing at +1.5°C and only 44% of those reproducing at +0.0°C. Thus, in addition to acclimation occurring within two generations, there was rapid selection of genotypes (and associated phenotypes) tolerant of higher temperatures. Donelson *et al*. conclude "this study provides evidence that, contrary to some expectations, a tropical marine species has the capacity for acclimation and adaptation to temperature increases over timescales much shorter than the rate of anthropogenic climate change," and "the discovery that advantageous offspring phenotypes are produced within two generations could indicate that some tropical marine species are more capable of coping with global warming than has been suggested."

Grenchik *et al*. (2013) note "tropical ectotherms are predicted to be especially sensitive to global warming because they may possess a narrow thermal tolerance range as a result of having evolved in a relatively stable thermal environment." They say having a narrow thermal tolerance range would mean "tropical species tend to live close to their thermal optimum," so "even relatively small increases in temperature could lead to declines in individual performance," because "as water temperature increases, so does the cost of maintaining basic cell function (resting metabolic rate, RMR; Bret, 1971)."

Grenchik *et al*. reared newly settled juveniles of the tropical damselfish *Pomacentrus moluccensis* for four months in four temperature treatments: current-day summer average (28.5°C) and up to 3°C above the average (29.5, 30.5, and 31.5°C). The three Australian researchers found the RMRs of fish reared

at 29.5 and 31.5°C were "significantly higher than the control group reared at 28.5°C," and "fish that developed in 30.5 and 31.5°C exhibited an enhanced ability to deal with acute temperature increases." They conclude, "this study shows that there is capacity for thermal acclimation during development, with individuals reared from an early age at some temperatures able to modify their physiology to maintain RMRs at near present-day levels," and this developmental thermal acclimation "may assist coral reef fish to cope with increases in water temperature without a substantial loss to performance."

Simpson *et al.* (2011) write, "marine ecosystems in the northeast Atlantic have warmed particularly rapidly, with mean sea temperatures in the North Sea and Celtic-Biscay Shelf regions increasing between 1982 and 2006 by 1.31°C and 0.72°C, respectively," four times faster than the global average. They considered these regions and timeframe to be ideal for determining how real-world fish respond to real-world warming. The researchers "assessed the full impacts of warming on the commercially important European continental shelf fish assemblage using a data-driven Eulerian (grid-based) approach that accommodates spatial heterogeneity in ecological and environmental conditions."

They analyzed "local associations of species abundance and community diversity with climatic variables, assessing trends in 172 cells from records of >100 million individuals sampled over 1.2 million km^2 from 1980–2008." They contrasted this work with the climate envelope approach, which relies on macro-ecological analyses of the effects of climate change on marine fish assemblages that do not account for "constraints on distributional shifts due to population dependence on essential habitat, such as favored substrates, appropriate predator and prey fields, and close proximity to nursery grounds, all of which are often unknown and difficult to quantify."

The seven scientists say they discovered "responses to warming in 72% of common species, with three times more species increasing in abundance than declining." These trends were "reflected in international commercial landings," where landings of nine species identified as declining in warm conditions fell by half during the period of their study, whereas landings of 27 species identified as increasing in warm conditions rose by 2.5 times. They write, this "profound reorganization of the relative abundance of species in local communities occurred despite decadal stability in the presence-absence of species," such as would have been suggested by the climate envelope approach on a larger spatial scale.

Simpson *et al.* conclude their "finding of stability in presence-absence of species over decadal periods, but significant temperature-driven responses in local species abundance and assemblage composition, suggests that climate envelope models based on species presence-absence alone will not predict the most ecologically and economically significant effects of climate change."

Lloyd *et al.* (2012) write, "at a broad geographical scale, species richness and diversity decrease as latitude increases both north and south of the equator," and in marine systems this distribution pattern "has been linked most consistently to variation in sea temperature," primarily via studies conducted in north-temperate seas, such as those of Fisher *et al.* (2008) and Hiddink and Hofstede (2008). Noting there is a paucity of such studies from the Southern Hemisphere, Lloyd *et al.* analyzed measurements of sea surface temperature and spear-fishing records pertaining to 84 species of marine fish personally harvested by one of their team. This analysis was performed for each day of diving over the years 1989–2007, during which time interval there was a 0.47°C increase in mean sea surface temperature, which rose from an average of 23.36°C for the period 1989–1996 to an average of 23.83°C for 2002–2007.

The five Australian researchers report over the specified time interval, "the proportion of the catch made up by temperate species, in terms of both the number and mass of fish, consistently decreased, whereas the proportion of the catch made up by tropical species consistently increased between the two time periods," and "the contribution of broadly distributed species to the overall catch remained approximately the same." In addition, "average species richness and diversity increased 33 and 15%, respectively, between the two time periods." These findings, the authors write, "are broadly consistent with a predicted poleward shift in species ranges and a predicted increase in species richness and diversity with increasing sea temperature," confirming "large-scale climate change causing a widening of the tropical belt and subsequent ocean warming is having a profound impact on marine species abundance patterns and community composition at a local scale in the sub-tropics."

Capelin (*Mallotus villosus*) are small, short-lived forage fish that are the primary prey of many top predators in northern marine ecosystems. They typically spawn in one of two specific habitats with divergent temperature regimes: beach (warm, variable) and deep water (demersal: cool, stable). In recent years there has been some concern about how

capelin may respond to projected global warming.

In 2009 and 2010, Davoren (2012) investigated "the influence of temperature on spawning habitat selection in coastal Newfoundland by quantifying habitat-specific temperature, population-level habitat use, and individual-level movements of male capelin via acoustic telemetry." The Canadian researcher reports "capelin spawned only at beaches in 2009, when temperatures were significantly colder and frequently fell below suitable ranges at demersal sites, whereas demersal sites were predominantly used under opposing conditions in 2010." She remarks "males detected in both habitats primarily dispersed from the initial habitat when temperatures routinely fell outside of suitable ranges," noting "this movement often involved traveling long distances (11.0–32.7 km) against currents, suggesting energetic costs."

Davoren writes, "overall, temperature appeared to be an important environmental cue for habitat selection by capelin," and she concludes, "the flexible use of spawning habitats under divergent temperature conditions suggests that capelin have a high capacity to respond to and possibly tolerate predicted ocean-climate change."

Zambonino-Infante *et al*. (2013) note rising temperatures typically cause "a monotonic decrease in dissolved oxygen concentration in numerous coastal and estuarine ecosystems around the world, resulting in the increased frequency, intensity and length of hypoxia episodes in shallow areas," with a primary consequence of these phenomena being the progressive widening of the gap between the availability of dissolved oxygen in the coastal water and the metabolic demand of various marine animals. Zambonino-Infante *et al*. studied the common sole (*Solea solea*), which inhabits shallow marine areas highly exposed to environmental changes, to see "whether temperature and trophic conditions experienced during the larval stage had delayed effects on life-history traits and resistance to hypoxia at the juvenile state," thereby examining "the combined effect of global warming and hypoxia in coastal waters, which are potential stressors to many estuarine and coastal marine fishes."

Their analysis showed "warmer larval temperature had a delayed positive effect on body mass and resistance to hypoxia at the juvenile stage," which "suggests a lower oxygen demand of individuals that had experienced elevated temperatures during larval stages." Zambonino-Infante *et al*. say "this study clearly demonstrates that environmental conditions experienced during early developmental stages are important in controlling environmental adaptation performance at later life stages." They state "sole that had experienced elevated temperatures during their early-life exhibited higher body masses and tolerance to hypoxia, probably through long-term programming of metabolic pathways," noting "such a cohort effect on growth performance and hypoxia tolerance could have major implications for population dynamics." They conclude, "developmental plasticity in animals may allow adaptation to changing environmental conditions to have delayed effects," and "this may attenuate some of the more severe predictions about organisms' responses to global warming and eutrophication."

6.1.5 Other Marine Species

In studying the impact of rising temperature on other marine species, researchers have made some important findings that challenge the projections of IPCC on this matter. As listed in the bullet points below and discussed further in the body of this section, such findings include:

- Single environmental metrics, such as air temperature, are not sufficient for making projections of the impacts of climate change.

- Caution should be applied when interpreting results from laboratory-based studies, which are often incapable of mimicking conditions in the real world and often yield results quite different from those observed in nature.

- Warmer temperatures capable of reducing sea ice density and cover reduce the risk of narwhal mortality.

- Intertidal marine species along Australia's east coast have easily withstood a significant climatic warming of ~1.5°C over the past 60 years without having to migrate poleward.

- Thermal heterogeneity within marine habitats must be fully understood in order to properly interpret and ascribe patterns of biogeographic response to climate change.

- Offspring of female turtles grew larger and survived better at hotter incubation. The increased heat tolerance appears to be genetically based.

Helmuth *et al*. (2011) note "virtually every physiological process is affected by the temperature of an organism's body, and ... with the advent of new molecular and biochemical techniques for studying organismal responses to thermal stress ... there has been a renewed interest in the effects of temperature extremes on the ecology and physiology of organisms given the observed and forecasted impacts of global climate change." Using a simple heat budget model that was ground-truthed with approximately five years of *in situ* temperature data obtained by biomimetic sensors, Helmuth *et al*. (2011) "explored the sensitivity of aerial (low tide) mussel body temperature at three tidal elevations to changes in air temperature, solar radiation, wind speed, wave height, and the timing of low tide at a site in central California USA (Bodega Bay)."

The six U.S. scientists found "while increases in air temperature and solar radiation can significantly alter the risk of exposure to stressful conditions, especially at upper intertidal elevations, patterns of risk can be substantially reduced by convective cooling such that even moderate increases in mean wind speed (~1 m/sec) can theoretically counteract the effects of substantial (2.5°C) increases in air

temperature." They also found "shifts in the timing of low tide (+1 hour), such as occur [when] moving to different locations along the coast of California, can have very large impacts on sensitivity to increases in air temperature," noting, "depending on the timing of low tide, at some sites increases in air temperature will primarily affect animals in the upper intertidal zone, while at other sites animals will be affected across all tidal elevations." In addition, "body temperatures are not always elevated even when low tide air temperatures are extreme," due to "the combined effects of convective cooling and wave splash."

Helmuth *et al*. say their findings suggest the timing and magnitude of organismal warming "will be highly variable at coastal sites, and can be driven to a large extent by local oceanographic and meteorological processes." They "strongly caution against the use of single environmental metrics such as air temperature" for "making projections of the impacts of climate change." Moreover, caution should be applied in interpreting the findings of laboratory-based studies, which often do not mimic conditions in the real world and therefore can yield results and implications quite different from those observed in the real world.

Byrne *et al*. (2011) studied the thermotolerance of the planktonic life phase of sea urchin *Heliocidaris erythrogramma* along the southeast coast of Australia, where sea surface temperatures (SSTs) have risen by 2.3°C over the past 60 years. They employed experimental treatments ranging from 18 to 26°C, with the latter value representing a 3 to 4°C increase above recent ambient SSTs. They found "development success across all stages (gastrula, 24 h; larva, 72 h; juvenile, 120 h) decreased with increasing temperature," and they acknowledge "significant deleterious effects were evident at +3 to 4°C." They also report, "larvae that developed through the early bottleneck of normal development at 26°C metamorphosed successfully," and there was a 25% decrease in planktonic larval duration (PLD) of the larvae in the highest of the temperature treatments. In parallel studies of progeny derived from the northern and southern parts of the coastline, they found "northern embryos had significantly higher thermotolerance."

The five researchers say ocean warming may be advantageous to *H. erythrogramma* larvae "through early settlement and reduction of the vulnerable planktonic period." They also state the higher thermotolerance of the species' northern embryos "provides the possibility that *H. erythrogramma* populations might keep up with a warming world through pole-

ward migration of thermotolerant propagules, facilitated by the strong southward flow of the East Australian Current." They conclude "due to its extensive latitudinal distribution, its potential developmental thermotolerance and independence of its lecithotrophic larvae from exogenous food and the need to make a functional skeleton, *H. erythrogramma* may be particularly robust to ocean change."

Laidre and Heide-Jorgensen (2005) used a combination of long-term satellite tracking data, climate data, and remotely sensed sea ice concentrations to detect localized habitat trends of the narwhal (*Monodon monoceros*) in Baffin Bay between Greenland and Canada—which is home to the largest numbers of the world's narwhals—to study the species' vulnerability to ongoing and projected climate change. The two researchers write, "since 1970, the climate in West Greenland has cooled, reflected in both oceanographic and biological conditions (Hanna and Cappelen, 2003)," with the result "Baffin Bay and Davis Strait display strong significant increasing trends in ice concentrations and extent, as high as 7.5% per decade between 1979 and 1996, with comparable increases detected back to 1953 (Parkinson *et al*., 1999; Deser *et al*., 2000; Parkinson, 2000a,b; Parkinson and Cavalieri, 2002; Stern and Heide-Jorgensen, 2003)."

Laidre and Heide-Jorgensen report, "cetacean occurrence is generally negatively correlated with dense or complete ice cover due to the need to breathe at the surface," and "lacking the ability to break holes in the ice," narwhals are vulnerable to reductions in open water availability, as has been demonstrated by ice entrapment events "where hundreds of narwhals died during rapid sea ice formation caused by sudden cold periods (Siegstad and Heide-Jorgensen, 1994; Heide-Jorgensen *et al*., 2002)." These events are becoming more likely as temperatures continue to decline and sea ice cover and variability increase; the researchers found the latter two trends to be "highly significant at or above the 95% confidence level." They conclude, "with the evidence of changes in sea ice conditions that could impact foraging, prey availability, and of utmost importance, access to the surface to breathe, it is unclear how narwhal sub-populations will fare in light of changes in the high Arctic." Clearly, warmer temperatures capable of reducing sea ice cover would benefit narwhals, making them less vulnerable to death from the cold.

Poloczanska *et al*. (2011) resurveyed a historical census of rocky-shore marine fauna that had been conducted in the 1940s and 1950s, to ascertain whether there had been subsequent latitudinal changes in the distribution and abundance of intertidal marine species consistent with global climate change along Australia's east coast, which, as they demonstrate, "has undergone rapid warming, with increases in temperature of ~1.5°C over the past 60 years." Their survey was conducted at 22 rocky-shore sites located between 23 and 35°S latitude, stretching across 1,500 km of coastline.

Of the 37 species the authors encountered that had distributional data available from both time periods, "only six species showed poleward shifts consistent with predictions of global climate change." Four others moved in the opposite direction "inconsistent with expectations under climate change," and the rest "showed no significant changes in range edges." The seven scientists state a combination of wave exposure, local currents, and the presence of large sand islands—"not temperature"—"is the primary factor influencing biogeographic distributions along the subtropical east coast of Australia."

The contemporaneous study of Seabra *et al*. (2011) supports this conclusion, describing how intertidal marine species can easily withstand significant climatic warming without having to migrate poleward. They examined the relative magnitudes of local-scale versus large-scale latitudinal patterns of the intertidal body temperatures of robolimpets (Lima and Wethey, 2009): autonomous temperature sensor/loggers mimicking the visual aspect and temperature trajectories of real limpets. These temperatures were measured at 30-minute intervals for recurring periods of 170 days at 13 exposed or moderately exposed rocky shores along 1,500 km of the Atlantic coast of the Iberian Peninsula, where they were attached to steep rocky surfaces—both north-facing (typically shaded) and south-facing (sun-exposed)—at three tidal heights covering the entire vertical range inhabited by real-life limpets.

The "most relevant finding" of the study, the four researchers write, was "sunny versus shaded differences were consistently larger than the variability associated with [a] the seasons, [b] shore-specific characteristics (topography, orientation, wave exposure, etc.) and [c] shore level." Seabra *et al*. say these findings emphasize the importance of analyzing temperature variability at scales relevant to the organisms being studied, "since the usage of sea surface temperature (SST) derived from remotely sensed data to model the distribution of intertidal species may be missing key environmental features," especially since their results "clearly show that other factors than SST play a much stronger role in

determining the body temperatures of these organisms." They also suggest "the observed temperature variability may explain the weak correlations found in many studies modeling the distribution of intertidal species using SST data (e.g. Lima *et al.*, 2007b), which negatively impacts attempts of forecasting distributional changes in response to predicted climate warming."

Seabra *et al.* further state "habitat heterogeneity as determined by surface orientation and, to a lesser extent, height on the shore may provide thermal refugia allowing species to occupy habitats apparently inhospitable when considering only average temperatures," and "this may be important for understanding range shifts contrary to global warming predictions (e.g. Lima *et al.*, 2007a, 2009; Hilbish *et al.*, 2010)." Thus, they emphasize again "thermal heterogeneity within habitats must be fully understood in order to interpret patterns of biogeographic response to climate change."

Webster *et al.* (2011) note sponges comprise a major component of coral reef macrofauna and play key ecological roles, including providing habitat for other invertebrates and complex microbial symbioses, citing Bell (2008). Concerned that projected increases in air and sea surface temperatures of up to 4°C by 2100, as suggested in IPCC (2007) report, will have a direct and significant impact on sponges and their holobionts, Webster *et al.* "assessed the effect of elevated seawater temperature on bacterial communities in larvae of the Great Barrier Reef sponge, *Rhopaloeides odorabile*," in a series of laboratory experiments to "compare the thermal thresholds for the different life history phases of this model sponge species."

Although *R. odorabile* adults were previously observed to experience significant negative repercussions above 32°C, the four researchers found their larvae exhibited "a markedly higher thermal tolerance," with no adverse effects detected at temperatures up to 36°C, and their microbial communities "were conserved at temperatures up to 34°C." The Australian scientists state, "we demonstrated that sponge larvae maintain highly stable symbioses at seawater temperatures exceeding those that are predicted under current climate change scenarios." Given the likelihood both the sponge and its holobionts would experience considerable adaptive evolution between now and the end of the twenty-first century, it is safe to say predicted global warming would have little or no impact on their survival and normal functioning.

Weber *et al.* (2012) note, "temperature has a profound effect on hatching success, embryonic development and sex in marine turtles," and these effects have logically led to "growing concerns regarding the impacts of climate warming on their reproductive success." Weber *et al.* tested for "local adaptation in an island-nesting population of green turtles (*Chelonia mydas*) where incubation temperatures vary dramatically among closely adjacent nesting beaches," one with pale sand (Long Beach, LB) and one with dark sand (Northeast Bay, NEB) that was consistently 2–3°C warmer than the pale sand beach only 6 km away. They employed "a combination of *in situ* and common-garden approaches to compare survival (as a measure of fitness), developmental rates and size at hatching for offspring of LB and NEB females at different incubation temperatures, while simultaneously accounting for egg-mediated maternal effects."

The six scientists report the offspring of female turtles nesting on the naturally hot (black sand) beach "survived better and grew larger at hot incubation temperatures" compared with the offspring of females nesting on the cooler (pale sand) beach. These differences, they write, were caused by "shallower thermal reaction norms in the hot beach population, rather than shifts in thermal optima, and could not be explained by egg-mediated maternal effects." They conclude "the results of the common-garden experiment suggest that the increased heat-tolerance of NEB turtles has a genetic basis."

Weber *et al.* also say their results suggest "marine turtle nesting behavior can drive adaptive differentiation at remarkably fine spatial scales," and "previous studies may have underestimated the extent of adaptive structuring in marine turtle populations that may significantly affect their capacity to respond to environmental change." They conclude, whereas "global warming is predicted to have multiple deleterious effects on the reproductive success of marine turtles, including the loss of nesting beaches to rising sea levels, increasingly feminized populations and reduced hatching success," their results suggest "in at least one of these respects, marine turtles have the capacity to adapt to warmer temperatures."

Doonan *et al.* (2012) write, "*Katharina tunicata*, commonly known as the Black Katy Chiton, is an abundant intertidal grazer with a limited pelagic larval stage of approximately six days (Paine, 1992)," which is distributed along the Pacific coast of North America from Alaska's Aleutian Islands to southern California, where it is "an important regulator of intertidal ecosystems." They say the species "has recently suffered declines in localized parts of its

range as a result of exploitation by humans and sea otters." Noting it is also "under threat from the effects of climate change," they sought to determine "whether local-scale barriers to gene flow could potentially compromise the dispersal capacity of the species in the face of climate change." They "used nuclear single-nucleotide polymorphisms and mito-chrondrial DNA sequencing to elucidate fine-scale patterns of genetic variation between populations of the Black Katy Chiton separated by 15–150 km in southwest Vancouver Island."

The four UK researchers from Queen's University in Belfast report, "both the nuclear and mitochondrial data sets revealed no genetic differ-entiation between the populations studied," and "an isolation-with-migration analysis indicated extensive local-scale gene flow, suggesting an absence of barriers to dispersal." They write, "population demographic analysis also revealed long-term popu-lation stability through previous periods of climate change associated with the Pleistocene glaciations," and at the Pleistocene-Holocene transition of approx-imately ten thousand years ago, as discussed by Fields *et al*. (1993). Doonan *et al*. conclude, "taken together, the current evidence of high dispersal and a lack of biogeographic barriers to gene flow, coupled with the signature of long-term population stability through previous periods of climate change, suggest that this dispersal potential may act as a lifeline for *K. tunicata* as their southerly habitats rapidly warm, and a poleward migration is required for survival," citing Graham *et al*. (2010).

In an ecosystem-level study, Stuart-Smith *et al*. (2010) state, "despite increasing scientific and public concerns [about] the potential impacts of global ocean warming on marine biodiversity, very few empirical data on community-level responses to rising water temperatures are available." They undertook "a study of sub-tidal reef communities over a decadal time scale, comparing data on fishes, macroinvertebrates and macroalgae collected at 136 sites, spanning hundreds of kilometers around the island of Tasmania (southeastern Australia) in the early to mid 1990s, with data from the same sites in 2006/2007."

This region, they write, "has experienced relatively rapid warming during the last century as a consequence of a strengthening of the warm East Australian Current (Ridgway, 2007)," which mani-fested "an increase in sea surface temperature of 2.28 ± 0.35°C per century for the period 1944–2002 (Ridgway, 2007), which is considerably more rapid than the global mean of 0.6 ± 0.2°C per century estimated by Smith and Reynolds (2003), and a mean

increase in surface air temperature of 0.6–0.8°C (Salinger, 2005; Hansen *et al*., 2006)." The warming around this part of Tasmania has been more than three times greater than the global mean, making this region a prime location to examine the impacts of rising temperature on marine species in the real world.

Contrary to their expectations, the four researchers discovered "Tasmanian shallow rocky reef communities have been relative stable over the past decade," despite the "substantial rise in sea surface temperature over this period" and the "continuation of a considerable warming trend in oceanographic conditions over the last 50 years." They report, "the northeast and southeast bioregions, which are most influenced by the East Australian Current and hence have experienced the greatest warming over the last century, appeared to have actually changed very little," adding, "not only were Tasmanian reef communities remarkably similar between 1994 and 2006 in a multivariate sense, but univariate community characteristics such as species richness and total fish abundance were also consistent."

Poloczanska *et al*. (2013) "investigated the peer-reviewed literature that addresses the question of whether or not climate change impacts marine ecological phenomena, and found 208 studies of 857 species and assemblages." From these reports they extracted "1,735 observations of the following types of response: distribution, phenology, abundance, community change, calcification and demography," for which "either regional or global climate change was considered as a driver."

The 20 researchers report, "from this database, 81–83% of all observations for distribution, phenol-ogy, community composition, abundance, demo-graphy and calcification across taxa and ocean basins were consistent with the expected impacts of climate change." They add, "of the species responding to climate change, rates of distribution shifts were, on average, consistent with those required to track ocean surface temperature changes." The findings of this massive review of the relevant scientific literature indicate Earth's marine life is well-equipped to deal with predicted changes in the global ocean environ-ment and are, in fact, already doing so.

Linares *et al*. (2013) note, "several studies have provided evidence that thermal stress affects the growth, survival and physiology of tropical and temperate macro-invertebrate species," but "few studies have focused on sub-tidal temperate species and the potential differential thermal tolerances of

populations dwelling under contrasting temperature conditions." Linares *et al*. assessed "the role that environmental history plays in the response of the temperate gorgonian *Eunicella singularis* to thermal stress," comparing populations dwelling in the coldest and warmest areas of the NW Mediterranean Sea.

The four researchers report, "*E. singularis* populations from both areas exhibited a high resistance to thermal stress," but "populations from warmer areas had an increased tolerance to thermal stress," such that "the upper thermal limits found for cold and warm populations were 28 and 29°C, respectively." Linares *et al*. conclude by noting their results "agree with results for other Mediterranean anthozoans (Rodolfo-Metalpa *et al*. 2006; Torrents *et al*., 2008) and tropical corals (Middlebrook *et al*., 2008), demonstrating thereby that shallow populations (acclimated to warm temperature conditions) have a higher tolerance to thermal stress than deep populations."

6.2 Freshwater Warming

The vast majority of studies examining the potential effects of CO_2-induced global warming on aquatic life are focused on marine life, but some scientists have conducted research on the impacts of elevated temperature on freshwater species. The following bulleted key findings indicate the cautious optimism this research suggests, and the findings are discussed in greater detail thereafter.

- Increases in water temperature at Lake Zurich from 1977 to 2008 have resulted in an increase in the number of phytoplankton species and phytoplankton families.

- Annual bass growth is positively and significantly correlated with annual temperature metrics, revealing above-average growth during the warmest and driest years.

- Golden perch growth rates likely will increase in

southerly Australian populations due to warmer temperatures and a lengthening of the growing season.

- Over the past two decades, when IPCC claims Earth warmed at a rate and to a degree unprecedented over the past millennium, the majority of French fish—plus some newcomers to the country's streams and rivers—thrived under warmer water conditions, increasing in both species numbers (diversity) and population size.

- Many predictions of the impact of climate change on aquatic life assume a species-specific response to changing environments, yet substantial differences in thermal plasticity have been observed between populations within species, enabling some populations to cope effectively with changes in the environment that other populations cannot tolerate. The probability of climate-induced species extinctions is much lower than what is often projected.

- Three species of freshwater mussels can adjust their individual critical thermal maximum (the upper temperature at which the onset of behavioral incapacitation occurs) upwards in response to periodic heat waves or significantly warmer years.

In contrast to IPCC-based projections, modest warming has been shown to be highly beneficial to some freshwater species.

Pomati *et al*. (2012) explain that among human impacts on aquatic biodiversity, eutrophication has caused a number of undesirable environmental effects worldwide, including "a general reduction in species richness (Smith and Schindler, 2009) and a loss of ecosystem resilience against further degradation (Folke *et al*., 2004)." They indicate "lake restoration programs in many regions started at the peak of the eutrophication period (late 1970s, early 1980s)," but the resulting reduction in nutrient loading "coincided with rising temperature from climate warming," citing Van Donk *et al*. (2003) and Jeppesen *et al*. (2005), so we currently have "limited understanding of how combined climate change and reduction in nutrients affect species richness, ecosystem functioning or resilience."

Pomati *et al*. analyzed physical and biological parameters in Lake Zurich on the Swiss Plateau just north of the Swiss Alps at depths of 0, 1, 2.5, 5, 7.5, 10, 12.5, 15, 20, 30, 40, 80, 120, and 135 meters that had been collected monthly over a number of decades

by the Zurich Water Supply Company, focusing on data from 1977 to 2008. The five scientists discovered increases in water temperature (0.24°C/decade at the lake surface; 0.13°C/decade near the lake bottom) and spatial (depth) heterogeneity were the best predictors of phytoplankton richness, as the number of phytoplankton species increased from about 40 to 100 and the number of phytoplankton families increased from approximately 25 to 45. They note phytoplankton richness and spatial heterogeneity had the strongest effects on zooplankton richness.

The researchers write, "our analysis highlights that climate warming and re-oligotrophication may favor an increase in spatial (depth) heterogeneity in the water column of deep lakes, enhancing the potential for phytoplankton species co-existence and an increase in plankton richness." They conclude, "although our study focuses on a single lake, the responses we have documented may be common at least throughout lakes within the European peri-alpine climatic region," citing Buergi and Stadelmann (2002), Buergi *et al*. (2003), and Anneville *et al*. (2005).

Morrongiello *et al*. (2011) analyzed the yearly growth increments laid down in the otoliths—aragonite ($CaCO_3$) structures in fish that are used for acoustic perception and balance, also known as earstones—of populations of a native fish species (the golden perch) living in two artificial impoundments (Lakes Mokoan and Eppalock) near their southerly distribution limits in central Victoria, Australia. Over a 15-year period that both predated and encompassed a significant supra-seasonal drought, the authors determined "fish growth declined as water levels in the lakes dropped during the drought," but "this effect was offset by increased growth in warmer years." It was in fact more than offset; based on the relationships they found in their data, future projections of mean annual growth of two-year-old golden perch in Lakes Mokoan and Eppalock in the year 2070, respectively, increase by 14.9% and 17.2% under low CO_2 emission and 56.5% and 58.6% under high CO_2 emission scenarios compared with 1990 CO_2 levels. The Australian scientists conclude, "despite climatic models predicting significant declines in future water availability, fish growth may increase due to a disproportionate lengthening of the growing season." They forecast "golden perch growth rates in southerly [Australian] populations may increase as warmer conditions associated with climate change will lengthen the growing season and make these high [southern] latitude habitats more favorable."

Rypel (2009) applied tree-ring techniques to the

otoliths of 397 largemouth bass (*Micropterus sal-moides* Lacepede) to explore potential relationships between annual bass growth and various climate metrics in the southeastern USA, as manifest in six rivers and seven reservoirs in Georgia, Alabama, and Mississippi sampled during the summers and autumns of 2005–2008. Rypel reports, "results from multiple regressions suggested that on average roughly 50% of the annual variability in largemouth bass growth was attributable to climatic variations," with annual growth indices typically being found to be "above-average during the warmest, driest years, and below-average during the coldest, wettest years," because "annual bass growth was significantly negatively correlated with annual precipitation metrics, and significantly positively correlated with annual temperature metrics."

These findings indicate the warming and drying that are predicted by models to occur in many places will benefit largemouth bass because an increase in temperature generally "stimulates metabolism, and enhances growth rates of fishes," Rypel writes, citing Beitinger and Fitzpatrick (1979) and Brander (1995).

Poulet *et al*. (2011) write, "over the past 200 years, owing to the industrial and agricultural revolutions, various new and intense pressures have been applied to freshwater ecosystems resulting in the decline of many species both in range and number (Maitland, 1995)." Of these additional threats, they highlight five: overexploitation, water pollution, flow modification, destruction or degradation of habitat, and invasion by exotic species, citing Dudgeon *et al*. (2006). Poulet *et al*. used the extensive electrofishing database of the French National Agency for Water and Aquatic Environment to evaluate time trends of 48 freshwater fish taxa at 590 sites across France over the period 1990–2009, to assess the recent and ongoing net impact of these modern threats to the fish of France.

The three French researchers found "species richness increased steadily from the beginning of the monitoring period," and "the number of species displaying a significant increase in spatial distribution or abundance was greater than those showing a significant decrease." They write, "these results are in agreement with recent findings which describe an increase in the number of species and density of fish communities in large French rivers over the past 25 years," citing Daufresne and Boet (2007). They add, "predictions about the future distribution of 30 common fish species in French streams in 2008, suggested increases in local species richness and in occurrences of the majority of species (Buisson *et al*.,

2008)," and they note "both studies described population growth of warm and cool water species in response to global warming."

Over the past two decades, when IPCC claims Earth warmed at a rate and to a degree unprecedented over the past millennium or two, the majority of French fish, plus some newcomers to the country's streams and rivers, thrived under warmer water conditions, increasing in both species numbers (diversity) and population size.

While not all aquatic species may respond in such a positive manner, there is little reason to accept IPCC's model-based projections of widespread future species decline (and possible extinctions) in response to CO_2-induced global warming. A growing body of evidence demonstrates the ability of aquatic life to adapt and evolve to overcome challenges imposed by rising water temperatures.

Seebacher *et al*. (2012) note "within-individual plasticity (acclimation) counteracts potentially negative physiological effects resulting from environmental changes and thereby maintains fitness across a broad range of environments." They write, "the capacity for the acclimation of individuals may therefore determine the persistence of populations in variable environments."

They "determined phylogenetic relationships by Amplified Fragment Length Polymorphism (AFLP) analysis of six populations of mosquitofish (*Gambusia holbrooki*) from coastal and mountain environments and compared their capacity for thermal acclimation." The six scientists demonstrated mosquitofish populations "are divided into distinct genetic lineages and that populations within lineages have distinct genetic identities." They report, "there were significant differences in the capacity for acclimation between traits (swimming performance, citrate synthase and lactate dehydrogenase activities), between lineages, and between populations within lineages," demonstrating "there can be substantial variation in thermal plasticity between populations within species." They conclude "similar responses are likely to be found in other species that comprise structured populations."

Noting "many predictions of the impact of climate change on biodiversity assume a species-specific response to changing environments," Seebacher *et al*. argue, "this resolution can be too coarse and … analysis of the impacts of climate change and other environmental variability should be resolved to a population level," because their findings suggest some populations of a species may be able to cope with a change of climate with which others cannot,

thereby preventing the otherwise-inevitable climate-induced extinction of the species.

Gailbraith *et al.* (2012) studied thermal adaptation of three species of freshwater mussels (*Alasmidonta varicosa*, *Elliptio complanata,* and *Strophitus undulatus*) that had been acclimatized to a water temperature of either 15 or 25°C. The temperature of the water in which the mussels were immersed was gradually raised at a rate of 0.35°C per minute, until the researchers observed the onset of extreme gaping, a periodic valve movement resulting in the rapid opening and closing of the mussels' shells that indicates their impending demise. The authors thus studied the mussels' critical thermal maximum (CTM), defined as the upper (warm) temperature at which the onset of behavioral incapacitation (usually loss of equilibrium) occurs—in the words of Gailbraith *et al.* quoting Hutchison (1961)—"the animal loses its ability to escape from conditions that will promptly lead to its death." Although it sounds like a fixed, immutable value for a given species, the CTM has been proven to be a function of temperature itself.

The three U.S. researchers report, "responses varied by species, but mussels acclimated to 25°C generally had a higher CTM than mussels acclimated to 15°C." For one of the three species (*E. complanata*), they observed the effects of acclimation and another variable (aeration) were interactive, leading them to conclude "combinations of environmental stressors may influence thermal tolerance" and "such responses vary among species." They note results similar to theirs "are well documented for other freshwater organisms, particularly for fish (Becker and Genoway, 1979; Elliott, 1981) but also for the zebra mussel, *Dreissena polymorpha* (McMahon and Ussery, 1995; Lutterschmidt and Hutchison, 1997)."

Although multiple factors may thus come into play in determining an animal's current CTM, it is evident from the results of Galbraith *et al.* that some degree of warming above that species-specific value can at times lead to a longer-term increase in the species' CTM. In the case of global warming, the evidence suggests species may adjust their individual CTMs upward in response to periodic heat waves or significantly warmer years.

Crozier *et al.* (2011) note "environmental change can shift the phenotype of an organism through either evolutionary or non-genetic processes," but "despite abundant evidence of phenotypic change in response to recent climate change, we typically lack sufficient genetic data to identify the role of evolution." They studied the potential role of rapid evolution by investigating the drivers of a long-term trend toward earlier upstream migration date in adult sockeye salmon (*Oncorhynchus nerka* Walbaum) that currently migrate up the Columbia River 10.3 days earlier than they did in the 1940s. Noting water temperature records in the lower river showed a rise of 2.6°C in mean July temperature since 1949, the researchers "developed a functional model relating survival during upstream migration to temperature on the basis of the results of recent studies that tracked individual fish through the migration," after which they "hindcast this function over the historical record to estimate the putative selection differential over the time series." Thereafter, they "assembled a set of possible environmental drivers of interannual variation in migration timing from the literature" and used "a state-space modeling framework to combine selection and these environmental variables as covariates to explain mean population migration date in a formal time-series analysis," employing "model-selection techniques to determine which factors best predicted annual migration timing."

The three researchers from the Northwest Fisheries Science Center in Seattle, Washington (USA) determined "an evolutionary response to thermal selection was capable of explaining up to two-thirds of the phenotypic trend" they observed, and "adaptive plastic responses to June river flow explain most of the remainder." Crozier *et al.* note the amount of evolutionary change they calculated to have taken place "is typical of numerous studies of contemporary evolution," citing Hendry and Kinnison (1999) and Kingsolver *et al.* (2001). They suggest evolutionary change "will play an important role in protecting species from extinction during ongoing climate change, as demonstrated in recent simulations of evolution in Fraser River sockeye salmon," citing Reed *et al.* (2011). They conclude, "directional environmental changes are very likely to induce more rapid evolution in the future."

6.3 Ocean "Acidification"

6.3.1 Introduction

As the air's CO_2 content rises in response to increasing anthropogenic CO_2 emissions, more CO_2 dissolves in the surface waters of the world's oceans. Theoretical reasoning, some of it reviewed in Section 6.3.1.2 below, suggests the pH values—a negative or inverse measure of the acidity of water—of the planet's oceanic waters should be gradually decreasing.

By some estimates, the globe's seawater has declined by about 0.1 pH unit relative to what it was in preindustrial times, and model calculations imply there could be an additional drop somewhere in the neighborhood of 0.3 to 0.7 pH by the year 2300. IPCC and others refer to this small potential change in oceanic pH and its presumed impacts on aquatic life as "ocean acidification." That term, however, is misleading and deceptive. The world's oceans are currently basic (or alkaline), with an average pH of around 8.1, and there is no chance future anthropogenic CO_2 emissions will ever cause the oceans to become acidic (pH less than 7). The general public, not scientifically trained, naturally interprets the phrase literally and assumes rising atmospheric CO_2 is turning the world's oceans, lakes, and streams into a dangerous acid that is harming (or will harm) marine life.

IPCC characterizes the projected pH reduction as a cause for great concern, because it has been postulated to harm calcifying marine life such as corals, not only by reducing the calcifying rates of marine organisms but also by impeding the responses of other growth and developmental parameters of these organisms. The ocean chemistry aspect of this ocean acidification hypothesis is rather straight-forward, but it is not as solid as model projections make it out to be. Some researchers, including Pieter

Tans, senior scientist at the National Oceanic and Atmospheric Administration (NOAA) Earth System Research Laboratory in Boulder, Colorado (USA), have published papers suggesting the drop in oceanic pH will not be nearly as great as IPCC and others predict. Figures 6.3.1.1 and 6.3.1.2 illustrate Tans' analysis.

The first of the two figures depicts much of the past and projected history of fossil-fuel carbon utilization, together with historical and projected atmospheric CO_2 concentrations to the year 2500, as calculated by Tans (2009). As the figure shows, the air's CO_2 concentration is expected to peak well before 2100 and at only 500 ppm, as compared to the 800 ppm predicted in one of IPCC's scenarios. It is
Figure 6.3.1.1. Past and projected trends of fossil-fuel carbon utilization and the atmosphere's CO_2 concentration. Adapted from Tans (2009).

also worth noting that by the year 2500, the air's CO_2 concentration should actually drop back to about what it is today.

When these emission estimates are calculated for their expected reductions of oceanic pH, as shown in Figure 6.3.1.2, the projected pH change at 2100 is far below what IPCC estimates. The pH projections from Tans' data also suggest a recovery to values near those of today by the year 2500, a striking contradiction of IPCC's estimates. (Tans' research is described in more detail in the next section.)

The increase of CO_2 in the air should lead to additional weathering of terrestrial carbonates and dissolution of marine carbonates, which would increase delivery of Ca^{2+} and CO_3^{2-} to the oceans and largely compensate for the CO_2-induced decrease in
Figure 6.3.1.2. Past and projected trends of oceanic pH based on fossil-fuel carbon utilization estimates from Tans (2009) and IPCC's A2 scenario.

oceanic calcium carbonate saturation, further suggesting IPCC's projections of ocean acidification may be exaggerated. In addition, as with all phenomena involving living organisms, the introduction of life into the ocean acidification picture greatly complicates things, as several interrelated biological phenomena must be considered; when they are, it becomes much more difficult to draw such sweeping negative conclusions as IPCC does.

As the research reviewed in the subsections below demonstrates, the rising CO_2 content of Earth's atmosphere may be a beneficial phenomenon with many positive consequences for the oceans as well as other aspects of the environment (Idso, 2009).

Before proceeding into those specifics, however, we provide a brief discussion of changes in oceanic pH, followed by some additional considerations of ocean chemistry.

6.3.1.1 Assessing and Projecting Changes in Oceanic pH

Based on four theoretical constructs—a geochemical model, an ocean general-circulation model, an IPCC CO_2 emissions scenario for the twenty-first century, and a projected logistic function for the burning of Earth's post-twenty-first century fossil-fuel reserves—Caldeira and Wickett (2003) calculated the atmospheric CO_2 concentration could approach 2,000 ppm around the year 2300, leading to a surface seawater pH reduction of 0.7 unit, a change they describe as being much more rapid and considerably greater "than any experienced in the past 300 million years." This long time interval makes the phenomenon sound truly catastrophic, especially as IPCC claims this "ocean acidification" phenomenon will impede the process of calcification in corals and other marine life. In judging the plausibility of this scenario, it is important first to know whether the acidification phenomenon is really severe and unprecedented.

In a special issue of *Oceanography* published in December 2009, Feely *et al*. (2009) review what is known about the current pH status of the world's oceans and what can likely be expected by the end of the current century. The three researchers write, "estimates based on the Intergovernmental Panel on Climate Change business-as-usual emission scenarios suggest that atmospheric CO_2 levels could approach 800 ppm near the end of the century," and "corresponding biogeochemical models for the ocean indicate that surface water pH will drop from a pre-industrial value of about 8.2 to about 7.8 in IPCC A2 scenario by the end of this century." They warn, as a result, "the skeletal growth rates of calcium-secreting organisms will be reduced" and conclude, "if anthropogenic CO_2 emissions are not dramatically reduced in the coming decades, there is the potential for direct and profound impacts on our living marine ecosystems."

In the same issue of *Oceanography*, Tans (2009) presents a much different take on the subject. He begins by noting the anthropogenic component of the air's CO_2 concentration "depends primarily on the total amount emitted, not on the rate of emissions,"

and "unfortunately, IPCC reports have not helped public understanding of this fact by choosing, somewhat arbitrarily, a rather short time horizon (100 years is most commonly used) for climate forcing by CO_2."

"Instead of adopting the common economic point of view, which, through its emphasis on perpetual growth, implicitly assumes infinite Earth resources," Tans notes the cumulative extraction of fossil-fuel carbon currently stands at about 345 gigatons of carbon (GtC), and there appears to be another 640 or so GtC of proven reserves, yielding a total original reserve of about 1,000 GtC, from which he proceeds with his analysis.

The past and projected history of fossil-fuel carbon utilization, together with historical and projected atmospheric CO_2 concentrations out to the year 2500, as calculated by Tans, is presented in Figure 6.3.1.1 above. According to the data presented there, Tans shows the air's CO_2 concentration peaking well before 2100 at only 500 ppm, as compared to the 800 ppm Feely *et al*. take from IPCC. By the year 2500, the air's CO_2 concentration drops back to about what it is today, according to Tans' analysis.

Based on his more modest projections of future atmospheric CO_2 concentrations, Tans finds the projected pH reduction of ocean waters in the year 2100 to be only one-half of the 0.4 value calculated by Feely *et al*., with a recovery to a reduction of slightly more than 0.1 pH unit by 2500, which is less than the range of pH values typical of today's oceans (8.231 in the Arctic Ocean minus 8.068 in the North Indian Ocean equals 0.163, according to Feely *et al*.). Graphical data presented by Pelejero *et al*. (2010) depict interannual pH variations in the North Atlantic Ocean near Bermuda ranging from a high of approximately 8.18 to a low of about 8.03 at various times over the years 1984 to 2007 (Bates, 2007), further demonstrating large pH variations are occurring in some ocean basins as a result of seasonal seawater variability.

Even greater natural pH variability is evident on both shorter and longer time scales in still other of Pelejero *et al*.'s graphs. Over a mere two days in July 2001 on a Molokai (Hawaii) Reef flat, for example, seawater pH ranged from a high of 8.29 to a low of 7.79 (Yates and Halley, 2006). Over a period of about a decade in the mid-twentieth century, the pH at Arlington Reef in Australia's Great Barrier Reef system ranged from a high of approximately 8.25 to a low of about 7.71 (Wei *et al*., 2009). These natural and recurring pH declines (0.50 and 0.54) are greater than the 0.3 to 0.4 decline IPCC expects to occur between now and the end of the century, and much

greater than Tans' estimate of about 0.2.

Hofmann *et al*. (2011) state "natural variability in pH is seldom considered when effects of ocean acidification are considered," and they suggest this omission is disturbing because "natural variability may occur at rates much higher than the rate at which carbon dioxide is decreasing ocean pH," which is about 0.0017 pH unit per year, according to Dore *et al*. (2009) and Byrne *et al*. (2010). They contend "ambient fluctuation in pH may have a large impact on the development of resilience in marine populations," noting "heterogeneity in the environment with regard to pH and pCO_2 exposure may result in populations that are acclimatized to variable pH or extremes in pH."

Hofmann *et al*. recorded continuous high-resolution time series of upper-ocean patterns of pH variability with autonomous sensors deployed at 15 locations from 40.7303°N to 77.8000°S latitude and from 0 to 166.6712°E longitude and 0 to 162.1218°W longitude, over a variety of ecosystems ranging from polar to tropical, open ocean to coastal, and kelp forest to coral reef. The 18 researchers report their measurements revealed "a continuum of month-long pH variability with standard deviations from 0.004 to 0.277 and ranges spanning 0.024 to 1.430 pH units." This variability was "highly site-dependent, with characteristic diel, semi-diurnal, and stochastic patterns of varying amplitudes."

Hofmann *et al*. write, "these biome-specific pH signatures disclose current levels of exposure to both high and low dissolved CO_2, often demonstrating that resident organisms are already experiencing pH regimes that are not predicted until 2100." These facts suggest the current real-world heterogeneity of the world's oceans with regard to pH and pCO_2 exposure may already have "result[ed] in populations that are acclimatized to variable pH or extremes in pH," such as those that have been predicted to be the new norm in 2100. Lower ocean pH levels may therefore not mature in the way projected by IPCC, a conclusion Loaiciga (2006) shares, having written years earlier, "on a global scale and over the time scales considered (hundreds of years), there would not be accentuated changes in either seawater salinity or acidity from the rising concentration of atmospheric CO_2."

Marine photosynthesis may also reduce CO_2-induced lowering of ocean pH levels lower ocean pH levels, as it tends to increase surface seawater pH, countering the tendency for pH to decline as the air's CO_2 content rises, as demonstrated by Lindholm and Nummelin (1999). This phenomenon has been found to dramatically increase the pH of marine bays,

lagoons, and tidal pools (Gnaiger *et al.*, 1978; Santhanam, 1994; Macedo *et al.*, 2001; Hansen, 2002) and significantly enhance the surface water pH of areas as large as the North Sea (Brussaard *et al.*, 1996).

Middelboe and Hansen (2007) studied a wave-exposed boulder reef in Aalsgaarde on the northern coast of Zealand, Denmark, plus a sheltered shallow-water area in Kildebakkerne in the Roskilde Fjord, Denmark. As one would expect if photosynthesis tends to increase surface-water pH, the two researchers found "daytime pH was significantly higher in spring, summer and autumn than in winter at both study sites," often reaching values of 9 or more during peak summer growth periods vs. 8 or less in winter. They also found "diurnal measure-ments at the most exposed site showed significantly higher pH during the day than during the night," sometimes reaching values greater than 9 during daylight hours but typically dipping below 8 at night, and "diurnal variations were largest in the shallow water and decreased with increasing water depth."

In addition to their own findings, Middelboe and Hansen cite Pearson *et al.* (1998), who found pH averaged about 9 during the summer in populations of *Fucus vesiculosus* in the Baltic Sea; Menendez *et al.* (2001), who found maximum pH was 9 to 9.5 in dense floating macroalgae in a brackish coastal lagoon in the Ebro River Delta; and Bjork *et al.* (2004), who found pH values as high as 9.8 to 10.1 in isolated rock pools in Sweden. Noting "pH in the sea is usually considered to be stable at around 8 to 8.2," the two Danish researchers conclude "pH is higher in natural shallow-water habitats than previously thought."

Liu *et al.* (2009) note, "the history of ocean pH variation during the current interglacial (Holocene) remains largely unknown," and it "would provide critical insights on the possible impact of acidification on marine ecosystems." Working with 18 samples of fossil and modern *Porites* corals recovered from the South China Sea, the nine researchers employed ^{14}C dating using the liquid scintillation counting method, along with positive thermal ionization mass spec-trometry to generate high-precision δ^{11}B (boron) data, from which they reconstructed the paleo-pH record of the past 7,000 years, as depicted in Figure 6.3.1.1.2.

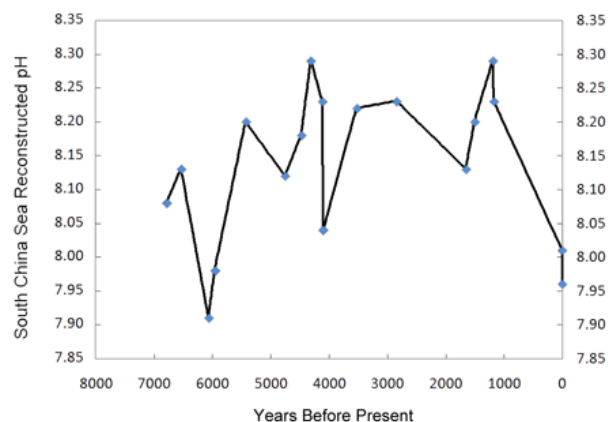
As the figure illustrates, there is nothing unusual, unnatural, or unprecedented about the two most recent pH values. They are not the lowest of the record, nor is the rate of decline that led to them the greatest of the record. This strongly indicates these recent values have little to do with the nearly 40%


Figure 6.3.1.1.2. Reconstructed pH history of the South China Sea. Created from Table 1 of Liu *et al.* (2009).

increase in the air's CO_2 concentration that occurred over the course of the Industrial Revolution. As for the prior portion of the record, Liu *et al.* note there is also "no correlation between the atmospheric CO_2 concentration record from Antarctica ice cores and δ^{11}B-reconstructed paleo-pH over the mid-late Holo-cene up to the Industrial Revolution."

Further insight comes from the earlier work of Pelejero *et al.* (2005), who developed a more refined history of seawater pH spanning the period 1708–1988 (depicted in Figure 6.3.1.1.3), based on δ^{11}B data obtained from a massive *Porites* coral from Flinders Reef in the western Coral Sea of the southwestern Pacific. These researchers also found "no notable trend toward lower δ^{11}B values." They discovered "the dominant feature of the coral δ^{11}B record is a clear interdecadal oscillation of pH, with δ^{11}B values ranging between 23 and 25 per mil (7.9 and 8.2 pH units)," which they say "is synchronous with the Interdecadal Pacific Oscillation."
Figure 6.3.1.1.3. Reconstructed pH history of Flinders Reef of the Western Coral Sea of the Southwestern Pacific. Adapted from Pelejero *et al.* (2005).

Pelejero *et al*. also compared their results with coral extension and calcification rates obtained by Lough and Barnes (1997) over the same 1708–1988 time period. As best as can be determined from their graphical representations of these two coral growth parameters, extension rates over the last 50 years of this period were about 12% greater than they were over the first 50 years, and calcification rates were approximately 13% greater over the last 50 years.

Wei *et al*. (2009) derived the pH history of Arlington Reef (off the north-east coast of Australia). Their data show a 10-year pH minimum centered at about 1935 (which obviously was not CO_2-induced) and a shorter, more variable minimum at the end of the record (which also was not CO_2-induced). Apart from these two non-CO_2-related exceptions, the majority of the data once again fall within a band that exhibits no long-term trend.

Numerous scientific studies have demonstrated atmospheric CO_2 enrichment stimulates pH-boosting photosynthesis in marine micro- and macro-algae (see Sections 6.3.2 and 6.5.1). This phenomenon suggests anything else that enhances marine photosynthesis—such as nutrient delivery to the waters of the world's coastal zones (i.e., eutrophication)—may do so as well, as Borges and Gypens (2010) have found.

Employing an idealized biogeochemical model of a river system (Billen *et al*., 2001) and a complex biogeochemical model describing carbon and nutrient cycles in the marine domain (Gypens *et al*., 2004), the two researchers investigated "the decadal changes of seawater carbonate chemistry variables related to the increase of atmospheric CO_2 and of nutrient delivery in the highly eutrophied Belgian coastal zone over the period 1951–1998." They write, "the increase of primary production due to eutrophication could counter the effects of ocean acidification on surface water carbonate chemistry in coastal environments," and "changes in river nutrient delivery due to management regulation policies can lead to stronger changes in carbonate chemistry than ocean acidification," as well as changes "faster than those related solely to ocean acidification." They add, "the response of carbonate chemistry to changes of nutrient delivery to the coastal zone is stronger than ocean acidification."

Given its failure to account for the full spectrum of important phenomena that affect ocean acidification, IPCC's current assessment of potential impacts on aquatic life should be considered far more uncertain and much less extreme than IPCC claims it to be.

6.3.1.2 Some Thoughts on Ocean Chemistry

Contributed by Tom V. Segalstad
Associate Professor of Geochemistry
(Resource- and Environmental Geology)
University of Oslo, Norway

The "acidification" of the ocean—or rather its potential progression toward less alkaline conditions—is postulated to result in serious consequences to marine life, including the dissolution of lime shells of various marine organisms. However, the foundation of the ocean acidification scare is disputed and challenged in the scientific literature as indicated in the multiple peer-reviewed studies referenced throughout Sections 6.3–6.5. The present section approaches and critiques the hypothesis from a geochemical perspective.

Water (H_2O) in the ocean is about one pH unit alkaline. Water protolyses as:

$$H_2O \leftrightarrow H^+ + OH^- \text{ [1]}$$
The ordinary hydrogen atom (H) has one proton and one electron. When the hydrogen's electron is lost to the hydoxyl (OH^-), the remaining H^+ is just a proton. This dissociation of water is called protolysis: the formation of a proton from water.

The concentration of such protons in water determines its acidity or alkalinity. A high concentration is typical of acids, while a dominance of hydroxyl is typical of alkalies. Water is considered neutral (neither alkaline or acidic) when concentrations of H^+ and OH^- are equal. In thermodynamics the concentration is commonly expressed as activity—a thermodynamic concentration, denoted "a".

pH ("power of hydrogen") is a measure of the acidity of water, defined as the negative logarithm to the activity of H^+ (a_{H+}):

pH ≡ - log a_{H+} [2]

The protolysis constant for the chemical reaction for water protolysis, equation [1], has a value of $\sim 10^{-14}$ at 25°C. At this temperature, the pH has a range up to 14 units, with a value of 14 representing the most alkaline waters, a value of 7 indicating neutral water, and values below 7 for acidic waters. The protolysis constant varies with temperature (and somewhat by pressure), so the value for neutral water changes with changing temperatures. Dissolved gases and solids also can change the pH of water.

6.3.1.2.1 The Assertion of Ocean Acidification

Oceanic pH varies naturally with latitude and ocean depth across Earth. Hence, no single value exists to define oceanic pH. For instance, the pH of surface waters in the western Pacific Ocean varies from around 7.8 to 8.5 between 60°N and 60°S. Although significant pH variations can occur both above and below this range, ocean water is generally characterized as alkaline. And because pH units of measure fall on a logarithmic scale (each pH unit change requires an order of magnitude change in the activity of H^+), large additions of gases and/or dissolved solids into water are needed to induce significant changes in pH.

Some researchers assert ocean waters have become less alkaline (by about 0.1 pH unit) since preindustrial times (e.g., Caldeira and Wickett, 2003). Ocean waters are projected to experience a further pH decline of 0.1–0.2 unit during the next decennia, and a reduction of 0.5–0.7 by the year 2100, caused by anthropogenic CO_2 (NIVA, 2008).

In its first assessment report, published in 1990, IPCC claimed anthropogenic CO_2 has a long lifetime in the atmosphere, of between 50 and 200 years. This long lifetime, according to IPCC, accounts for the modern rise in atmospheric CO_2, which they assert is caused by anthropogenic CO_2 emissions accumulating in the air year after year. Solomon *et al.* (2009) suggest an even longer residence time for anthro-pogenic CO_2 in the atmosphere, estimating it may be more than 1,000 years, where the CO_2 content flattens out asymptotically towards infinity in their model. Other researchers have provided contrasting findings. Many scientific papers, for example, contend the atmospheric CO_2 lifetime (halflife) is much shorter, at around five years (Bolin and Eriksson, 1959), that a similar lifetime is found for oceanic CO_2, and that natural processes play a far more significant role

influencing the atmospheric content of CO_2 than previously thought (e.g., Segalstad, 1992; 1996; 1998; 2008; 2009; Starr, 1993; Rohde, 2000).

It is important to note the dissolution of CO_2 in water is governed by Henry's Law, evidenced by the fact there is approximately 50 times more CO_2 dissolved in the ocean than in the atmosphere at present. It is this vast mass of dissolved CO_2 in the ocean that holds the regulating power—not the relatively small amount of CO_2 contained in the air. Furthermore, the chemical reaction speeds involved in the dissolution of CO_2 are high, as is the ocean circulation speed in the upper parts of the ocean.

The ocean acidification hypothesis also ignores the presence of vast amounts of dissolved calcium in the ocean: the upper 200 m of ocean water contains enough dissolved calcium to bind all anthropogenic CO_2 as precipitated calcium carbonate (in the ocean) without affecting the ocean's pH (Jaworowski *et al.*, 1992a; Segalstad, 1996; 1998). The ocean acidification hypothesis also ignores or downplays other oceanic buffers (pH stabilizing reactions), the thermodynamic stability of solid calcium carbonate in ocean water, and photosynthesis by marine biological systems. Many assertions of ocean acidification are based on a methodology that has been called into serious question. For example, the Norwegian Institute for Water Research (NIVA, 2008) built its assertions of ocean acidification on a paper by Haugan and Drange (1996), who derived their claims from the work of Spivack *et al.* (1993). This latter group of authors presented a proxy history of the ocean's pH over the past 21 million years that used boron isotopes in foraminifera from only five dated boron isotope analyses. This methodology was challenged by Lemarchand *et al.* (2000), who found the boron isotopes in foraminifera represent changes in the marine boron isotope budget rather than changes in the ocean's pH. Claims that the oceans are presently "acidifying," if based on boron isotope measurements, are highly questionable, if not altogether invalid.

6.3.1.2.2 The Geochemistry of CO_2

Depending on physical conditions, CO_2 can both rapidly dissolve and de-gas in water. This is succinctly demonstrated in the making of carbonated sodas canned by breweries and the degassing of the dissolved CO_2 to the air with time upon opening the soda container.

The dissolved CO_2 first hydrolyzes with the water

into carbonic acid, H_2CO_3. Next, the carbonic acid protolyzes in two steps, first producing H^+ and dissolved bicarbonate HCO_3^-, and next producing H^+ and dissolved carbonate CO_3^{2-}. With the presence of vast amounts of dissolved calcium Ca^{2+} in the ocean, calcium combines with dissolved carbonate or bicarbonate (the dominating dissolved carbon species in the ocean) to form solid calcium carbonate. In simple terms, this process explains how and why some marine organisms form solid calcium carbonate shells. And it further explains how and why the chemical sedimentation of precipitated calcium carbonate can occur to make limestone (or dolomite) on the ocean floor.

Budyko *et al.* (1987) has pointed out periods of maximum carbonate precipitation (as limestone and dolomite) tend to occur at times of intense volcanism (releasing vast amounts of CO_2 from Earth's interior). These periods also tend to correspond with periods of higher atmospheric CO_2, highlighting a geochemical path of CO_2 that initiates from Earth's interior, degasses from volcanoes to the atmosphere, dissolves into the oceans, and precipitates solid marine carbonate rocks on the ocean floor. The chemical reactions for these processes are illustrated below, where (g) = gas, (aq) = aqueous (dissolved in water), and (s) = solid. The protolysis of the water must be added to the system because the ocean water is alkaline, dominated by hydroxyl OH^-. By adding all the partial reactions in this system, the total net reaction for the marine precipitation of solid calcium carbonate from the air's CO_2 and dissolved calcium in ocean water can be obtained:

CO_2 (g) $\leftrightarrow$ CO_2 (aq)	dissolution [3]
CO_2 (aq) + H_2O $\leftrightarrow$ H_2CO_3 (aq)	hydrolysis [4]
H_2CO_3 (aq) $\leftrightarrow$ H^+ + HCO_3^- (aq)	1st protolysis [5]
HCO_3^- (aq) $\leftrightarrow$ H^+ + CO_3^{2-} (aq)	2nd protolysis [6]
Ca^{2+} (aq) + CO_3^{2-} (aq) $\leftrightarrow$ $CaCO_3$ (s)	precipitation [7]
2 H^+ + 2 OH^- $\leftrightarrow$ 2 H_2O	protolysis [1]
CO_2 (g) + Ca^{2+} (aq) + 2 OH^- $\leftrightarrow$ $CaCO_3$ (s) + H_2O	total net reaction [8]

The Law of Mass Action ensures when all these chemical reactions have been accounted for in the total net reaction (and when increasing the amount of a gas, CO_2, in the air), calcium carbonate (solid) will be stabilized in the ocean, because the chemical reaction will be forced in the direction from left to right. This result is the opposite of what is commonly asserted (that solid calcium carbonate would be dissolved by the increasing amount of CO_2 in the air).

A simple example of this equation is seen in the oft-demonstrated school chemistry experiment of blowing one's exhaled breath (CO_2 gas) through a straw into a reaction tube with dissolved calcium hydroxide $Ca(OH)_2$ in water. Solid calcium carbonate precipitates out into the solution within seconds, providing a good visual of what happens in the ocean when gaseous CO_2 dissolves in the ocean, where there is an ample supply of dissolved calcium and hydroxyl.

6.3.1.2.3 pH Stabilizing Reactions in the Ocean

A "buffer" can be defined as a reaction system that modifies or controls the magnitude of an intensive (mass independent) thermodynamic variable, such as pressure, temperature, concentration, pH (acidity), etc. The ocean's carbonate system acts as a pH buffer through the presence of a weak acid (H_2CO_3 and its protolysis products) and a salt of the acid ($CaCO_3$). The pH of the water can be calculated as:

$$pH \approx [\log K + a(CO_2,g) + a(Ca^{2+},aq)] / -2 \qquad [9]$$

where K is the chemical equilibrium constant, and a the activity (thermodynamic concentration). At the ocean surface the $a(Ca^{2+},aq)$ is much larger than the $a(CO_2,g)$. Therefore the alkalinity is the determining factor for the pH, and not the activity (or the fugacity or the partial pressure) of atmospheric CO_2 (Charlson and Emerson, 2000).

In his book on geochemical thermodynamic calculations, Bethke (1996) shows that in a system with only water and CO_2, without mineral buffers present, more than a doubling of the amount of CO_2 in the air above the water surface will lead to a pH decrease of less than 0.4 pH unit. He further demonstrates this is within the natural variation, and thus nothing to worry about.

The ocean is not chemically uniform. Colder water will have a naturally lower pH, because the protolysis constant for water changes with temperature. An upwelling ocean current with colder water, or movement of water from higher latitudes, may lead to a somewhat lower pH within the natural variation—without an anthropogenic influence.

It is also important to note when solid calcium carbonate is brought into the system, a change in the amount of CO_2 gas alone cannot change the pH,

because of the buffer action of the calcium carbonate. Thermodynamic calculations on an ocean water composition in equilibrium with calcium carbonate at 25°C show the pH would have to be lowered by 2 units in order to dissolve the calcium carbonate at this temperature. This means the H^+ concentration would have to be increased by 2

Figure 6.3.1.2.1. A phase diagram for the system CO_2—H_2O—$CaCO_3$ at 25°C and water composition of average sea water. The blue stability fields show the stability of different aqueous species for given pH and log activity of bicarbonate. The green star indicates the sea water position, within the $CaCO_3$ stability field. The diagram was constructed using the program package "The Geochemist's Workbench," by Craig Bethke.

logarithm units, i.e. 100 times (see Figure 6.3.1.2.1).

When adding more CO_2 (g), more bicarbonate will be produced. Yet as the phase diagram illustrates (Figure 6.3.1.2.1), such a CO_2 addition will only stabilize $CaCO_3$ even more—the star in the figure (denoting the sea water composition) would move upward. Furthermore, the star would have to be moved out of the $CaCO_3$ (s) stability field in order for calcium carbonate (calcite) to be dissolved. This is impossible to do by adding CO_2 (g) when calcium carbonate is present (Segalstad, 2008). Hence, the pH of ocean water appears to be well buffered with respect to adding more CO_2 to the atmosphere. At 0°C the pH would have to be lowered 1.5 pH units for solid calcium carbonate (calcite) to be dissolved.

The carbonate buffer is not the only pH buffer

acting in the ocean. The ocean has a set of other mineral-buffer-reactions, such as the buffer:

$$CaAl_2Si_2O_8 \text{ (s)} + 2H^+ + H_2O \leftrightarrow Al_2Si_2O_5(OH)_4 \text{ (s)} + Ca^{2+} \text{ (aq)} \qquad [10]$$

This anorthite feldspar ↔ kaolinite buffer has a buffering capacity 1,000 times larger than the ocean's carbonate buffer (Stumm and Morgan, 1970). There are also clay mineral buffers, plus a calcium silicate ↔ calcium carbonate CO_2 buffer (MacIntyre, 1970; Krauskopf, 1979) [for simplicity]:

$$CaSiO_3 \text{ (s)} + CO_2 \text{ (g)} \leftrightarrow CaCO_3 \text{ (s)} + SiO_2 \text{ (s)} \qquad [11]$$

All these buffers act as a "security net" under the CO_2 (g) ↔ $CaCO_3$ (s) buffer. Together they constitute an almost infinite buffer capacity (Stumm and Morgan, 1970; Segalstad and Jaworowski, 1991).

The last two buffers mentioned are slower than the CO_2 (g) ↔ $CaCO_3$ (s) buffer at low temperatures. But their reactions are fast at the hot mid-ocean ridges, where temperatures can reach several hundred degrees C. There is no shortage of dissolved calcium in the ocean water, because this element is constantly being added from weathered surface rocks to the ocean by rivers, and by water-rock interactions at hot mid-ocean ridges.

Rainwater has a pH of about 5.7 (Krauskopf, 1979), because of the acidity caused by dissolution and protolysis of atmospheric CO_2. All the acidic rain supplied to the ocean water through the millennia have not changed the ocean's pH of near 8, which also supports the notion of strong pH buffering in ocean water (Pytkowicz, 1972).

6.3.1.2.4 Carbon Isotopes and Mass Balance Calculations

Stable $^{13}C/^{12}C$ isotope ratios, expressed as $\delta^{13}C$ vs. PDB, provide the only way to determine unequivocally the fraction of anthropogenic CO_2 in the atmosphere. The natural atmospheric CO_2 reservoir has $\delta^{13}C \approx$ -7‰ when in isotopic equilibrium with marine HCO_3^- (aq) and $CaCO_3$ (s). CO_2 gas from burning of fossil-fuel and biogenic materials has $\delta^{13}C \approx$ -26‰ (Ohmoto and Rye, 1979; Deines, 1980).

IPCC identifies 280 ppmv (ppm by volume) as the preindustrial CO_2 value, but that may be arbitrarily influenced by the selection of low-value

CO_2 data from ice cores (where measured values up to 7,400 ppmv were omitted), as well as from the mismatching of contemporary measurements with different ages (Jaworowski *et al*., 1992a; 1992b). IPCC claims the rise in CO_2 to 353 ppmv in 1990, and 379 ppmv in 2005, is due only to anthropogenic CO_2 (IPCC, 1990; 2007).

The $\delta^{13}C$ value reported for atmospheric CO_2 was -7.489‰ in December 1978, decreasing 10 years later to -7.807‰ in December 1988 (Keeling *et al*., 1989). If the resultant decrease were solely the product of mixing natural CO_2 with CO_2 produced from the burning of fossil fuels or plants (~79% / ~21% CO_2 mix; lifetime 50–200 years; IPCC, 1990), the current atmospheric CO_2 $\delta^{13}C$ value should be -11, much lower than reported (Segalstad, 1992; 2008).

The December 1988 atmospheric CO_2 composition has been computed for its 748 Gt C (Gt = 10^{15} g) total mass and $\delta^{13}C$ value of -7.807‰ for three components: (1) natural fraction remaining from the preindustrial atmosphere, (2) cumulative fraction remaining from all annual fossil-fuel CO_2 emissions, and (3) carbon isotope mass-balanced natural fraction. The masses of component (1) and (2) were computed for different atmospheric lifetimes of CO_2 (Segalstad, 1992).

The result fits a lifetime of about five years, in agreement with ^{14}C studies (see Sundquist, 1985; Segalstad, 1998; 2009; for further references). The mass of all past fossil-fuel and biogenic emissions remaining in the current atmosphere was -30 Gt C or less; i.e. a maximum of around 4% of the total, corresponding to an atmospheric concentration of approximately 14 ppm. The implication of the five-year lifetime is that approximately 135 Gt C (18%) of the atmospheric CO_2 is dynamically exchanged each year (Segalstad, 1992; 1996; 1998; 2008).

The above calculations also demonstrate that over this 10-year period (1978–1988), at least 96% of the atmospheric CO_2 is attributed to non-fossil-fuel sources, and this percentage has not likely varied much in the years since. Hence, it is clear marine degassing and juvenile degassing from sources such as volcanoes must be much more important for the atmospheric CO_2 budget than the burning of fossil-fuels and biogenic materials. IPCC has failed to recognize this conclusion.

6.3.1.2.5 Can Anthropogenic Carbon Double the Atmospheric CO_2 Content?

Many models suggest there is enough fossil carbon on Earth that, if burned, would raise the atmospheric CO_2 concentration to two or more times its preindustrial value. There are reasons to conclude such an increase may never occur.

The equilibrium partition coefficient for the CO_2 distribution between the atmosphere and ocean is approximately 1:50 (Revelle and Suess, 1957; Skirrow, 1975), given by Henry's Law and the Henry's Law Constant. This partition coefficient can be used to set an upper limit for how much the CO_2 concentration will rise in the atmosphere if all available fossil carbon fuel (coal, petroleum, gas) were burned.

To permanently double the current level of CO_2 in the atmosphere under chemical equilibrium conditions, the atmosphere would have to be supplied with approximately *51 times* the present amount of CO_2 if equilibrium should be attained, in order to keep the partition coefficient (air:sea = 1:50) constant according to Henry's Law. At the double amount of CO_2 in the air, the new ratio would have to be 2:100. In other words, an increase of one unit CO_2 in air leads to an increase of 50 units CO_2 in the sea; thus a total of 51 units has to be supplied. All available fossil fuel carbon amounts to 11 times the amount of carbon in today's atmospheric CO_2 (Jaworowski *et al*., 1992a). Therefore, mankind does not have enough fossil fuel to double the current level of atmospheric CO_2 under equilibrium conditions, all other factors held constant.

If the total fossil fuel reservoir of 7,200 Gt C were burned during the next 300 years, only the dissolved organics (carbon pool of about 1,000 Gt C) would consume all manmade CO_2 by their photosynthesis, because this period covers 6 to 15 turnovers of the upper-ocean pool of dissolved organic carbon, based on radiocarbon (^{14}C) studies. However, the vast oceanic dissolved inorganic carbon reservoir of 38,000 Gt C indicates the sea is a much more powerful sink for atmospheric CO_2. Hence, it is unlikely a permanent doubling of the amount of atmospheric CO_2 is attainable by human activities. See Jaworowski *et al*. (1992a) for further details and references.

6.3.1.2.6 Conclusion

Brian Mason (1966) wrote in his textbook, *Geochemistry* (3rd edition), "The ocean may thereby act as a self-balancing mechanism in which most of the elements have reached an equilibrium concentration."

That statement remains valid, as seen through a considerable constancy of sedimentation and pH over many past hundreds of millions of years. The circulation of CO_2 among the atmosphere, ocean, and biosphere is a fast exchange, with an average measured lifetime (half-life) for one atmospheric CO_2 molecule of about five years (Bolin and Eriksson, 1959; Segalstad, 1992; 1996; 1998; 2008; 2009; Starr, 1993; Rohde, 2000).

According to Mason, "it is apparent that the oceans, by controlling the amount of atmospheric CO_2, play a vital part in maintaining stable conditions suitable for organic life on the Earth." As the material above demonstrates, physical chemistry and thermodynamics provide strong reasons for questioning the validity of the so-called ocean "acidification" hypothesis, especially when considering the vast buffering capacity of the ocean's many buffering mechanisms.

6.3.2 Effects on Marine Plants

6.3.2.1 Phytoplankton

6.3.2.1.1 Coccolithophores

Coccolithophores are single-celled algae and protists found throughout the surface euphotic zones of the world's oceans. They contain chlorophyll, conduct photosynthesis, and possess special plates or scales known as coccoliths, which they create through calcification. This section reviews the results of studies that address how they may be affected by a possible decline in ocean pH levels in a CO_2-enriched world of the future. Several of the findings challenge the alarming negative projections of IPCC, as noted in the bullet points below and further discussed in the main portion of the section.

- Shifts in dominance among species of coccolithophores or clones within a species have been found to occur as the air's CO_2 content rises, which may enable the species to function much as they do today—if not better—in a high-CO_2 world of the future.

- Contemporary evolution likely will help to maintain the functionality of microbial processes at the base of marine food webs in the face of projected lower pH levels.

- Various coccolithophore species appear able to track the environmental value of ocean pH in real time.

- There is evidence the coccolithophore *Calcidiscus leptoporus* has adjusted successfully to the 80 ppm CO_2 difference between preindustrial and the present, as well as the 180 ppm CO_2 difference between glacial times and the present.

Riebesell (2004) notes a doubling of present-day atmospheric CO_2 concentrations "is predicted to cause

a 20–40% reduction in biogenic calcification of the predominant calcifying organisms, the corals, cocco-lithophorids, and foraminifera." But he also notes "a moderate increase in CO_2 facilitates photosynthetic carbon fixation of some phytoplankton groups," including "the coccolithophorids *Emiliania huxleyi* and *Gephyrocapsa oceanica*." In what constitutes a major challenge to the model-based claim atmospheric CO_2 enrichment will harm such marine organisms, Riebesell suggests "CO_2-sensitive taxa, such as the calcifying coccolithophorids, should therefore benefit more from the present increase in atmospheric CO_2 compared to the non-calcifying diatoms."

Leonardos and Geider (2005) grew a non-calcifying strain (PML 92A) of the marine cocco-lithophorid *Emiliania huxleyi* (Lohmann) Hay & Mohler in chemostats-cyclostats aerated with air of either 360 or 2,000 ppm CO_2 under both high- and low-light conditions in seawater either replete with or deficient in nitrogen and/or phosphorus, while measuring a suite of physical and biochemical properties of the coccolithophorid populations and the media in which they lived. They found "increased atmospheric CO_2 concentration enhances CO_2 fixation into organic matter," but "only under certain conditions, namely high light [HL] and nutrient limitation." Under N-limited conditions, for example, they found particulate organic carbon (POC) "was greatest under HL and elevated CO_2 (by up to 46% relative to HL and ambient CO_2)." Their work also revealed "the increase in POC was a consequence of both an increase in cell density and an increase in the cell organic carbon content."

The two UK researchers state "enhanced CO_2 uptake by phytoplankton such as *E. huxleyi*, in response to elevated atmospheric CO_2, could increase carbon storage in the nitrogen-limited regions of the oceans and thus act as a negative feedback on rising atmospheric CO_2 levels." According to their calculations, if the results obtained for *E. huxleyi* are indicative of the effects of CO_2 on primary production in other N-limited phytoplankton, changes of the magnitude they measured in *E. huxleyi* due to increased CO_2 could increase export production of the oligotrophic ocean by an amount equivalent to the estimated postindustrial increase in the terrestrial carbon sink.

Leonardos and Geider state their findings are "consistent with the response of primary productivity to manipulation of aqueous phase CO_2 in the oligotrophic North Atlantic (Hein and Sand-Jensen, 1996)," where increases in primary productivity "of

up to 100% were observed, although the average increase was 15% to 19%." They note "stimulation of carbon fixation by elevated CO_2 had already been documented for nutrient-limited lake phytoplankton (Urabe *et al*., 2003)."

Working with two previously untested cocco-lithophores—*Calcidiscus leptoporus* and *Coccolithus pelagicus*—which they describe as two of the most productive marine calcifying species, Langer *et al*. (2006) conducted batch-culture experiments in which they observed a deterioration of coccolith production above as well as below present-day CO_2 concentrations in *C. leptoporus*, and a lack of a CO_2 sensitivity of calcification in *C. pelagicus* over an atmospheric CO_2 concentration range of 98–915 ppm. Both observations, they write, "refute the notion of a linear relationship of calcification with the carbonate ion concentration and carbonate saturation state," as various scientists proposed early on.

With respect to *C. leptoporus*, Langer *et al*. observed that at both higher and lower CO_2 concentrations than those of today, the proportion of coccoliths showing incomplete growth and mal-formation notably increased. To determine whether this takes place in the real world, the seven scientists studied coccolith morphologies in six sediment cores extracted along a range of latitudes in the Atlantic Ocean. They report changes in coccolith morphology similar to those "occurring in response to the abrupt CO_2 perturbations applied in our experimental treatments are not mirrored in the sedimentary record." This finding indicates, as they suggest, "in the natural environment *C. leptoporus* has adjusted to the 80 ppm CO_2 and 180 ppm CO_2 difference between present, preindustrial and glacial times, respectively."

The team of researchers from Germany and the United Kingdom write, "it is reasonable to assume that *C. leptoporus* has adapted its calcification mechanism to the change in carbonate chemistry having occurred since the last glacial maximum," suggesting as a possible explanation for this phenomenon "the population is genetically diverse, containing strains with diverse physiological and genetic traits, as already demonstrated for *E. huxleyi* (Brand, 1981, 1982, 1984; Conte *et al*., 1998; Medlin *et al*., 1996; Paasche, 2002; Stolte *et al*., 2000)." They also state this adaptive ability "is not likely to be confined to *C. leptoporus* but can be assumed to play a role in other coccolithophore species as well." Langer *et al*. conclude such populations "may be able to evolve so that the optimal CO_2 level for calcification of the species tracks the environmental

value." The authors conclude "genetic diversity, both between and within species, may allow calcifying organisms to prevail in a high CO_2 ocean."

Working with the same sediment core, Halloran et al. (2008) analyzed the size distribution of $CaCO_3$ particles in the less-than–10-µm sediment fraction over the past quarter-century. They found a history of "changing particle volume since the late 20th century consistent with an increase in the mass of coccoliths produced by the larger coccolithophore species," leading them to conclude "in the real ocean the larger coccolithophore species increase their calcification in response to anthropogenic CO_2 release." The four researchers state this positive calcification response "could be attributed to an alleviation of CO_2 limitation in species that partly rely on the diffusive supply of dissolved carbon dioxide for photo-synthesis, as demonstrated by a rise in photosynthetic efficiency with increasing carbon dioxide in cultures of E. huxleyi (Rost et al., 2003)."

Stoll (2009) addressed the speculative claims of scientists promoting the view "ocean acidification in response to excess carbon dioxide in the atmosphere could become a problem for marine organisms, especially those that make skeletons or shells out of calcium carbonate," including the coccolithophorids that are, by volume, the most important shell pro-ducers. She had a much more optimistic view of the subject, thanks in large part to the research findings of Langer et al. (2009).

The latter scientists—from France, Germany, Spain, and the Netherlands—grew four strains of the coccolithophore Emiliania huxleyi in dilute batch cultures of seawater with carbonate chemistries characteristic of those expected to prevail beneath an atmosphere with CO_2 concentrations ranging from approximately 200 to 1,200 ppm, while they measured particulate organic carbon content, par-ticulate inorganic carbon content, and organic and inorganic carbon production. They found the four strains "did not show a uniform response to carbonate chemistry changes in any of the analyzed parameters and none of the four strains displayed a response pattern previously described for this species." In light of these findings, other aspects of their earlier studies (Langer et al. 2006, 2007), and the diverse findings of others who had used different strains of the species, the five scientists conclude "the sensitivity of different strains of E. huxleyi to acidification differs substantially" and "likely has a genetic basis."

Stoll agrees with that assessment. She notes the work of those who foresaw disastrous consequences typically "precludes the kind of natural selection and adaptation that might occur over decades and centuries in the ocean." Langer et al. (2009) state "shifts in dominance between species and/or between clones within a species might therefore be expected," as the air's CO_2 content continues to rise; but they note far too often "the possibility of adaptation is not taken into account."

Stoll notes the great genetic diversity that exists in the real world, both among and within species, "is good insurance in a changing ocean." It can be interpreted as evidence coccolithophorids are well prepared for whatever the future may bring, for as Langer et al. (2006) state, "genetic diversity, both between and within species, may allow calcifying organisms to prevail in a high CO_2 ocean." That appears to be the consensus of most studies that have moved on from theoretical speculation to the intermediate crucible of laboratory experimentation and the final test of real-world observation.

Beaufort et al. (2011) note "culture experiments investigating the physiological response of cocco-lithophore calcification to increased CO_2 have yielded contradictory results between and even within species," citing Riebesell et al. (2000), Langer et al. (2006), Iglesias-Rodriguez et al. (2008), and Langer et al. (2009). They investigated 180 surface-water and 555 sediment-core samples encompassing a wide spectrum of present and past oceanic conditions, some stretching back in time as much as 40,000 years.

The 13 researchers report, "significant overall correlations of coccolith mass with pH and pCO_2$ were recorded, but with notable regional variations, indicating that these parameters are not solely responsible for the observed trend." They also report some cultured strains of coccolithophores "are capable of maintaining calcification (degree and/or rate) over certain carbonate-chemistry ranges, a phenomenon that could contribute to localized within-sample deviations from the broad trend linking coccolith mass to carbonate chemistry." The results indicated changes in the relative abundance of taxa were "predominantly responsible for the decrease in coccolith mass with ocean acidification that was seen in modern samples."

Beaufort et al. also note, "in Patagonian-shelf and Chilean upwelling waters with low CO_3^{2-}, in which the overall trend would predict low coccolith mass," they detected "an unexpectedly highly calcified Emiliania huxleyi morphotype," and "the relative abundance of this morphotype increased with decreasing pH along the Pacific transect towards Chile." Noting "coccolith morphotype is thought to be subject to genetic regulation (Langer et al., 2009),"

they state "this highly calcified *E. huxleyi* morphotype may be a genetic entity with an adaptation enabling it to calcify heavily in the relatively acidic upwelling waters."

The scientists conclude "the presence of highly calcified *E. huxleyi* in CO_2-rich modern waters demonstrates that prediction of future responses is unlikely to be straightforward," and "such complexity could account for the lack of an obvious overall direction in the response of coccolithophore calcification over a potentially analogous ocean acidification event about 55 million years ago at the Palaeocene-Eocene Thermal Maximum," citing Gibbs *et al.* (2006).

Fiorini *et al.* (2011) measured the growth rates of three coccolithophores (*Emiliania huxleyi*, *Calcidiscus leptoporus,* and *Syracosphaera pulchra*) in laboratory batch cultures in their haploid and diploid life stages, while they were growing in filtered seawater maintained in equilibrium with air containing either 400 or 760 ppm CO_2. For all three species, "the growth rate was consistently higher at elevated pCO_2," but "the response of other processes varied among species." Calcification rates of *C. leptoporus* and *S. pulchra*, for example, did not change at elevated pCO_2, whereas this important process was increased in the case of *E. huxleyi*. They also found these CO_2-induced impacts were most pronounced in the haploid stage.

Fiorini *et al.* state these effects "must be taken into account when predicting the fate of coccolithophores in the future ocean." The European scientists write, "the phenotypic and physiological differences of the two life stages allow each species to use two different niches to exploit a wider range of ecological conditions (Cros *et al.*, 2000), to limit the competition in the utilization of resources (food, light) inside the species and to rapidly escape negative selection pressures exerted on one stage such as grazing, parasitic attack, viral infections (Frada *et al.*, 2008), or abrupt environmental changes (Noel *et al.*, 2004)." In this way, they continue, "the survival of a species is ensured by one life stage when the environmental conditions do not favor the development of the other life stage (Houdan *et al.*, 2005)."

Lohbeck *et al.* (2012) note the present understanding of the sensitivity of marine life to lower ocean pH levels has been based primarily on short-term experiments that often depict negative effects. Suggesting phytoplanktonic species with short generation times "may be able to respond to environmental alterations through adaptive evolution," they studied "the ability of the world's

single most important calcifying organism, the coccolithophore *Emiliania huxleyi*, to evolve in response to ocean acidification in two 500-generation selection experiments."

The three German researchers grew freshly isolated coccolithophore genotypes from Bergen, Norway, in batch cultures for more than 500 asexual generations at three different atmospheric CO_2 concentrations—ambient (400 ppm), medium (1,100 ppm), and high (2,200 ppm)—where the medium CO_2 treatment was chosen to represent the atmospheric CO_2 level projected for the beginning of the next century. They conducted a multi-clone experiment designed to provide existing genetic variation that "would be readily available to genotypic selection," plus a single-clone experiment initiated with one "haphazardly chosen genotype," where evolutionary adaptation would require new mutations.

Compared with populations kept at ambient CO_2 partial pressure, Lohbeck *et al.* found those selected at increased CO_2 levels "exhibited higher growth rates, in both the single- and multi-clone experiment, when tested under ocean acidification conditions." Calcification rates were somewhat lower under CO_2-enriched conditions in all cultures, but the research team state they were "up to 50% higher in adapted [medium and high CO_2] compared with non-adapted cultures." They conclude "contemporary evolution could help to maintain the functionality of microbial processes at the base of marine food webs in the face of global change."

The marine biologists say the swift adaptation processes they observed may "have the potential to affect food-web dynamics and biogeochemical cycles on timescales of a few years, thus surpassing predicted rates of ongoing global change including ocean acidification." They also note "a recent study reports surprisingly high coccolith mass in an *E. huxleyi* population off Chile in high-CO_2 waters (Beaufort *et al.*, 2011)." This observation, they write, indicates "across-population variation in calcification, in line with findings of rapid microevolution identified here."

Lohbeck *et al.* suggest "contemporary evolution could help to maintain the functionality of microbial processes at the base of marine food webs in the face of global change." Writing about this development in a *News & Views* item in the same issue of *Nature Geoscience*, Collins (2012) notes, "marine microbes, with their large population sizes and fast division rates, are certainly going to evolve over a timeframe of decades," and "we can expect that future

coccolithophore populations will be shaped by a combination of species succession and adaptive evolution."

McCarthy *et al*. (2012) note diatoms are a type of algae, most of which are unicellular, that serve as primary producers in various marine food chains. They investigated how diatoms might respond to continued increases in the air's CO_2 content, since they are responsible for about 40% of current marine primary productivity (Field *et al*., 1998). The team of four Canadian researchers grew the coccolithophore *Emiliania huxleyi* and two strains of the diatom *Thalassiosira pseudonana* under low light in turbidostat photobioreactors bubbled with air containing either 390 ppm or 750 ppm CO_2, finding "increased CO_2 led to increased growth rates in all three strains" and "CO_2 thus had a fertilization effect on all species, enhancing growth rates 20%–40%." They observe, "total cellular protein did not change between ambient and 750 ppm CO_2 treatments," but "cellular RUBISCO content showed a 2- to 3-fold increase with [elevated] CO_2 in both *E. huxleyi* and in the coastal diatom strain."

McCarthy *et al*. note the CO_2 fertilization effect on the growth rates of *T. pseudonana* and *E. huxleyi* provides these species with increased competitive ability. They conclude their results suggest "there could be a net increase in capacity for primary productivity at 750 ppm CO_2, at least with regard to small diatoms and coccolithophores in coastal environments," where the two types of phytoplankton provide the bulk of current marine primary productivity.

Smith *et al*. (2012) write, "laboratory studies are unrealistic in many respects and, because of their typically short timescales, preclude the possibility of evolutionary adaptation to the imposed change, a key uncertainty in OA [ocean acidification] research," citing Gattuso and Buddemeier (2000), Langer *et al*. (2006), and Ridgwell *et al*. (2009). They decided "to complement laboratory experiments with observational studies of coccolithophores living in the natural habitats to which they are evolutionarily adapted."

Focusing on two morphotypes (over-calcified and normal) of the world's most abundant coccolithophore species (*Emiliania huxleyi*), Smith *et al*. assessed their numbers, along with seawater carbonate chemistry and other environmental variables, at monthly intervals between September 2008 and August 2009 along a 1,000 km route, including over deep oceanic waters in the Bay of Biscay. They found a pronounced seasonality in the morphotypes of *E. huxleyi*. "Surprisingly," they write, "the over-calcified morphotype was found to dominate the *E. huxleyi* population in winter," even though seawater pH and $CaCO_3$ saturation were lowest in winter. The heavily calcified form of *E. huxleyi* dominated dramatically, shifting from less than10% of the total *E. huxleyi* population in summer to more than 90% of the population in winter.

Smith *et al*. acknowledge their findings "do not suggest that the changing carbonate chemistry was necessarily responsible for this shift in morphotypes." But "if it was not, then the alternative is that carbonate chemistry is not the sole and overriding control over coccolithophore calcification." This, they write, should "seriously call into question" the contention "ocean acidification will lead to a replacement of heavily-calcified coccolithophores by lightly-calcified ones."

Jin *et al*. (2013) note, "as a key group of oceanic primary producers, coccolithophores play a crucial role in the global carbon cycle, not only in terms of photosynthesis but also by producing calcium carbonate in the form of extracellular plates." They note coccolithophores are "important in the sulfur cycle in terms of dimethyl-sulphide (DMS) production (Malin and Erst, 1997)," which leads to enhanced cloud formation and the reflectance back to space of increased amounts of incoming solar radiation, which tends to cool the planet.

The three researchers also note the particulate inorganic carbon (PIC) produced by coccolithophores in the surface ocean sinks to deep in the sea; this phenomenon, known as the carbonate pump, "is a critical part of the global carbon cycle and has a major feedback effect on global climate (Hutchins, 2011)." Jin *et al*. grew in a laboratory environment the coccolithophore *Gephyrocapsa oceanica* for approximately 670 generations in water in equilibrium with both ambient and CO_2-enriched (1,000 ppm) air, with the latter treatment reducing the water's pH to a value of 7.8.

Jin *et al*. found "high CO_2-selected cells showed increases in photosynthetic carbon fixation, growth rate, cellular particulate organic carbon (POC) or nitrogen (PON) production, and a decrease in the C:N elemental ratio, indicating a greater up-regulation of PON than of POC production under ocean acidification." They note these findings are "in good agreement with a recent study in which *E. huxleyi* positively adapted to increased CO_2 levels," citing Lohbeck *et al*. (2012). Jin *et al*. conclude their data indicate "the coccolithophorid could adapt to ocean acidification with enhanced assimilations of carbon and nitrogen."

The experimental findings and real-world observations discussed above suggest coccolithophores are well-equipped to deal with whatever decline in ocean pH levels may be on the way.

6.3.2.1.2 Cyanobacteria

Cyanobacteria—also known as blue-green algae, blue-green bacteria, or Cyanophyta (the smallest of which, less than two micrometers in diameter, are typically referred to as picocyanobacteria)—obtain their energy through photosynthesis and are thus important primary producers in many areas of the world's oceans, as well as significant components of the marine nitrogen cycle. This section briefly reviews studies that address how they may be affected by lower ocean pH levels in a CO_2-enriched world of the future, as noted in the bullet points below and further discussed in the main body of the section.

- Ocean acidification enhances the productivity of one of the world's most important diazotrophic (N-fixing) cyanobacteria (*Trichodesmium erythraeum*) in N-limited oligotrophic regions of the world's oceans, providing more essential nitrogen to support greater amounts of higher-order marine animal life.

- The same is true of the unicellular diazotrophic cyanobacterium *Crocosphaera*, recognized as being perhaps equally as important as *Trichodesmium* to the global ocean's nitrogen cycle.

- Acidification-induced increases in photosynthesis and N_2 fixation by both types of cyanobacteria may stimulate productivity in N-limited oligotrophic regions and thus provide a negative feedback on rising atmospheric CO_2 levels.

- The potentially toxic cyanobacterium *Cylindrospermopsis raciborskii* becomes less profuse as atmospheric CO_2 concentrations rise.

Arguing cyanobacteria "should be one of the focus points regarding biological responses to the rise in atmospheric CO_2 concentration," Lu *et al.* (2006) studied physiological changes in phycocyanin (PC)-rich and phycoerythrin (PE)-rich *Synechococcus* strains of picocyanobacteria under atmospheric CO_2 concentrations of 350, 600, and 800 ppm in batch cultures maintained in one-liter glass flasks under a

12-hour:12-hour light:dark regime for periods of 12 days, measuring physiological parameters related to the growth and well-being of the picocyanobacteria. They found the growth of the PE strain was unaffected by atmospheric CO_2 enrichment, but the PC strain grown at 800 ppm CO_2 experienced a 36.7% increase in growth compared to when it was grown at 350 ppm CO_2.

The PC strain showed no significant change in carbohydrate content over the CO_2 range investigated, but the PE strain exhibited a CO_2-induced increase of 37.4% at 800 ppm CO_2. The PC strain exhibited a 36.4% increase in its RNA/DNA ratio between 350 and 800 ppm CO_2, and this ratio, Lu *et al.* write, "provides a good estimate of metabolic activities and has been used extensively as a biochemical indicator of growth rate in a variety of marine organisms." In both *Synechococcus* strains, cellular pigment contents were generally greater in the CO_2-enriched treatments than in the ambient-air controls. At day 12 in the PE strain, for example, they averaged more than 70% greater at 800 ppm CO_2 than at 350 ppm CO_2.

These results clearly indicate both strains of the *Synechococcus* picocyanobacteria benefited greatly from the extra CO_2, albeit in different ways. In comparing the different responses of the two strains, Lu *et al.* conclude, "the PC strain would probably benefit more than the PE strain from future increases in atmospheric CO_2 concentration," but "differences in photosynthetic characteristics may allow the coexistence of the two picocyanobacterial strains through a subtle form of niche differentiation," citing Ernst *et al.* (2003) and Stomp *et al.* (2004). Consequently, there is reason to believe the continuing rise in atmospheric CO_2 content will lead to a significant increase in primary production and nutrient cycling throughout the world's oceans, driven by the positive impacts of "acidification" on these very tiny organisms.

Levitan *et al.* (2007) note, "among the principal players contributing to global aquatic primary production, the nitrogen (N)-fixing organisms (diazotrophs) are important providers of new N to the oligotrophic areas of the oceans." They cite several studies demonstrating "cyanobacterial (phototrophic) diazotrophs in particular fuel primary production and phytoplankton blooms which sustain oceanic food-webs and major economies and impact global carbon (C) and N cycling." They examined how the ongoing rise in the air's CO_2 content might impact these relationships, exploring the response of the cyanobacterial diazotroph *Trichodesmium* to changes in the atmosphere's CO_2 concentration. They studied this particular diazotroph because it contributes more than 50% of total marine N fixation.

The eight Israeli and Czech researchers grew *Trichodesmium* IMS101 stock cultures in a YBCII medium (Chen *et al.*, 1996) at 25°C and a 12-hour:12-hour light/dark cycle (with the light portion of the cycle in the range of 80–100 μmol photons m^{-2} s^{-1}) in equilibrium with air of three CO_2 concentrations (250, 400, and 900 ppm, representing low, ambient, and high concentrations, respectively). They continuously bubbled air of the three CO_2 concentrations through the appropriate culture vessels throughout various experimental runs, each lasting a little over three weeks, while they periodically monitored a number of diazotrophic physiological processes and properties. They found *Trichodesmium* in the high CO_2 treatment "displayed enhanced N fixation, longer trichomes, higher growth rates and biomass yields." In the high CO_2 treatment there was "a three- to four-fold increase in N fixation and a doubling of growth rates and biomass," and the cultures in the low CO_2 treatment reached a stationary growth phase after only five days, "while both ambient and high CO_2 cultures exhibited exponential growth until day 15 before declining."

The researchers suggest "enhanced N fixation and growth in the high CO_2 cultures occurs due to reallocation of energy and resources from carbon concentrating mechanisms required under low and ambient CO_2." They conclude, "in oceanic regions, where light and nutrients such as P and Fe are not limiting, we expect the projected concentrations of CO_2 to increase N fixation and growth of *Trichodesmium*," and "other diazotrophs may be similarly affected, thereby enhancing inputs of new N and increasing primary productivity in the oceans." They state in the final sentence of their paper, "*Trichodesmium's* dramatic response to elevated CO_2 may consolidate its dominance in subtropical and tropical regions and its role in C and N cycling, fueling subsequent primary production, phytoplankton blooms, and sustaining oceanic food-webs."

Fu *et al.* (2008) examined "the physiological responses of steady-state iron (Fe)-replete and Fe-limited cultures of the biogeochemically critical marine unicellular diazotrophic cyanobacterium *Crocosphaera* [*watsonii*] at glacial (190 ppm), current (380 ppm), and projected year 2100 (750 ppm) CO_2 levels." They employed semi-continuous culturing methods that used filtered, microwave-sterilized surface Sargasso seawater enriched with phosphate and trace nutrients. When the seawater was replete

with iron, daily primary production at 750 ppm CO_2 was 21% greater than it was at 380 ppm, whereas at 190 ppm CO_2 it was 38% lower than at 380 ppm. When the seawater was iron-limited, daily primary production at 750 ppm CO_2 was 150% greater than it was at 380 ppm, and at 190 ppm CO_2 it was 22% lower than at 380 ppm. N_2 fixation rates varied little among the three CO_2 treatments when the seawater was iron-limited; but when the seawater was replete with iron, N_2 fixation at 750 ppm CO_2 was 60% greater than it was at 380 ppm, and at 190 ppm CO_2 it was 33% lower than at 380 ppm.

Fu *et al.* write, "several studies examining the marine diazotrophic cyanobacterium *Trichodesmium* have shown significant increases in N_2 fixation and photosynthesis in response to elevated CO_2 concentration (Hutchins *et al.*, 2007; Levitan *et al.*, 2007; Ramos *et al.*, 2007)," and their data "extend these findings to encompass the marine unicellular N_2-fixing cyanobacterium *Crocosphaera*." This group, they add, "is now recognized as being perhaps equally as important as *Trichodesmium* to the ocean nitrogen cycle (Montoya *et al.*, 2004)." They conclude, "anthropogenic CO_2 enrichment could substantially increase global oceanic N_2 and CO_2 fixation."

Kranz *et al.* (2009) write, "marine phytoplankton contribute up to 50% of global primary production (Falkowski *et al.*, 1998) and influence Earth's climate by altering various biogeochemical cycles (Schlesinger, 2005)." They also note, among diazotrophic cyanobacteria (dinitrogen-fixers), *Trichodesmium* species contribute "about half of all marine N_2 fixation (Mahaffey *et al.*, 2005)," supporting "a large fraction of biological productivity in tropical and subtropical areas and exerting, over long timescales, a significant influence on global carbon cycles by providing a major source of reactive N to the water column (Falkowski and Raven, 1997)."

Kranz *et al.* grew *Trichodesmium erythraeum* IMS101 in semi-continuous batch cultures through which they bubbled air with CO_2 concentrations of either 370 or 1,000 ppm. After the cultures were acclimated to their respective CO_2 concentrations for at least 14 days (covering more than five generations), the scientists measured the rates of particulate organic carbon (POC) and particulate organic nitrogen (PON) fixation, discovering "a strong increase in photosynthesis and N_2 fixation under elevated CO_2 levels," such that POC and PON production rates rose "by almost 40%."

The German scientists note other scientists have worked with the same *Trichodesmium* species:

"Barcelos e Ramos *et al.* (2007) and Levitan *et al.* (2007) observed stimulation in N_2 fixation by approximately 40% and even up to 400%, while Hutchins *et al.* (2007) obtained stimulation by up to 35%." Kranz *et al.* write, "the observed increase in photosynthesis and N_2 fixation could have potential biogeochemical implications, as it may stimulate productivity in N-limited oligotrophic regions and thus provide a negative feedback on rising atmospheric CO_2 levels."

Kranz *et al.* (2011) wrote, "marine phytoplankton are responsible for almost half of all photosynthetic carbon fixation on Earth and play a vital role in altering the CO_2 exchange between ocean and atmosphere," citing Maier-Reimer *et al.* (1996) and Gruber (2004). They point out a lack of nitrates often limits phytoplanktonic growth, and diazotrophic cyanobacteria that fix nitrogen, such as *Trichodesmium* species, thus play "a crucial role in many marine ecosystems by providing a new source of biologically available nitrogen." The scientists describe how atmospheric CO_2 enrichment helps enhance both parts of this important phenomenon.

The three researchers from the Alfred Wegener Institute for Polar and Marine Research in Bremerhaven, Germany report, "four recent studies tested the effect of different CO_2 concentrations on the growth, biomass production and elemental composition of *Trichodesmium* (Barcelos e Ramos *et al.*, 2007; Hutchins *et al.*, 2007; Kranz *et al.*, 2009; Levitan *et al.*, 2007)," and these studies "concordantly demonstrated higher growth and/or production rates under elevated pCO_2, with a magnitude exceeding those CO_2 effects previously seen in other marine phytoplankton."

Focusing on particulate organic nitrogen (PON) production, they note *Trichodesmium* species are particularly effective in this regard: "the stimulation in N_2 fixation and/or PON production between present-day pCO_2 values (370–400 ppm) and those predicted for the year 2100 (750–1000 ppm) ranged between 35 and 240%." They state "data on CO_2 dependency of N_2 fixation rates from recent publications suggest that N_2 fixation by *Trichodesmium* species might increase by more than 20 Tg N per year to about 100 Tg N per year until the end of this century," citing Hutchins *et al.* (2009).

These findings indicate the oceans are primed to do their part in preserving and protecting the biosphere, as they ramp up their productivity to sustain a greater population of aquatic organisms that may be tapped to supply additional food for the planet's burgeoning human population, and remove

from the atmosphere and sequester in their sediments increasing amounts of carbon as anthropogenic CO_2 emissions continue to rise.

Garcia *et al*. (2011) emphasize N_2 fixation by marine diazotrophic cyanobacteria (such as various species of *Trichodesmium*) "contributes substantial new nitrogen to marine environments, including the North Atlantic, Pacific, and Indian Oceans (Carpenter *et al*., 1993; Capone *et al*., 1997, 2005; Karl *et al*., 2002)." They further note phosphorus and iron have been identified as key factors that control N_2 fixation in those environments. They report other studies suggest the current low partial pressure of CO_2 in the atmosphere "may be another possible limiting factor for N_2 fixation and CO_2 fixation by *Trichodesmium*," citing Barcelos e Ramos *et al*. (2007), Hutchins *et al*. (2007), Levitan *et al*. (2007, 2010), and Kranz *et al*. (2009).

In a laboratory study designed to explore the limiting potential of low partial pressure of CO_2, Garcia *et al*. examined the effects of near-present-day (~380 ppm) and elevated (~750 ppm) atmospheric CO_2 concentrations on CO_2 and N_2 fixation by *T. erythraeum* isolates from the Pacific and Atlantic Oceans under a range of irradiance conditions. According to the seven scientists, "the positive effect of elevated CO_2 on gross N_2 fixation was large (~50% increase) under mid and/or low irradiances compared with that at high light (~20% increase)," noting data from Kranz *et al*. (2010) and Levitan *et al*. (2010) corroborated their findings. In the Kranz *et al*. study, they report, "under low light, gross N_2-fixation rates were 200% higher in a high-CO_2 treatment (900 ppm) compared with a low-CO_2 treatment (150 ppm), whereas under high light, gross N_2-fixation rates were only 112% higher under elevated CO_2." In the case of CO_2 fixation, they found CO_2-fixation rates increased significantly "in response to high CO_2 under mid- and high irradiances only."

As the atmosphere's CO_2 concentration continues to rise, therefore, this phenomenon should boost the growth rates of marine diazotrophic cyanobacteria and enable them to make more nitrogen available to themselves and co-occurring species, which should significantly increase both the quantity and quality of the worldwide phytoplanktonic food base that ultimately supports all marine animal life.

Holland *et al*. (2012) studied the potentially toxic cyanobacterium *Cylindrospermopsis raciborskii*, originally described as a tropical-subtropical species but increasingly found in temperate regions. Noting "climate change is hypothesized to be a factor in this expansion," the five researchers state, "identifying

future risk from this, and other nuisance cyano-bacteria, is paramount." Working with a strain of the cyanobacterium that was originally isolated from a lake near Brisbane (Australia), Holland *et al*. "used continuous (turbidostats) and batch cultures grown under two different light regimes, and adjusted the alkalinity of the media (with an associated change in pH, HCO_3^- and CO_2) to assess the effect of these parameters on the specific growth rate, inorganic carbon acquisition and photosynthetic parameters of *C. raciborskii*."

Although there were insufficient data to confirm results obtained from the low-light experiments, the Australian researchers discovered "there was a positive linear relationship in the 'high' light turbidostats between the growth rate and pH," as the potentially toxic *C. raciborskii* grew more profusely when atmospheric CO_2 concentrations were low and water pH was high, leading Holland *et al*. to conclude high-CO_2/low-pH conditions may change the composition of marine communities "to favor species that are better adapted to these new growth conditions, such as Chrysophytes," which are known to produce "more than half of the food consumed by aquatic animals," citing Maberly *et al*. (2009).

Teira *et al*. (2012) "tested the direct effect of an elevated CO_2 concentration (1,000 ppm) on the biomass and metabolic rates (leucine incorporation, CO_2 fixation and respiration) of two isolates belonging to two relevant marine bacterial families, Rhodobacteraceae (strain MED165) and Flavo-bacteriaceae (strain MED217)," referring to the former as simply *Roseobacter* and the latter as *Cytophaga*. "Contrary to some expectations," they found "lowering pH did not negatively affect bacterial growth." Doing so in fact increased the growth efficiency of *Cytophaga*. The scientists note, "in both cases, the bacterial activity under high CO_2 would increase the buffering capacity of seawater," concluding the responses of the two marine bacterial families "would tend to increase the pH of seawater, acting as a negative feedback between elevated atmospheric CO_2 concentrations and ocean acidification."

Lomas *et al*. (2012) note, "marine cyanobacteria, both unicellular *Prochlorococcus* and *Synechococcus* and colonial *Trichodesmium* spp., play important roles in the ocean carbon cycle and the biological carbon pump, particularly in the subtropical and tropical gyres (e.g. Partensky *et al*., 1999; Capone *et al*., 2005)," adding, *Trichodesmium* "is thought to account for about half of the total N_2-fixation in the oceans," citing Barcelos e Ramos *et al*. (2007),

Hutchins *et al*. (2007), Levitan *et al*. (2007), and Kranz *et al*. (2009, 2010).

Working on board the RV Atlantic Explorer between July 2009 and April 2010 at the Bermuda Atlantic Time-series Study (BATS) site in the subtropical North Atlantic Ocean about 86 km southeast of Bermuda, Lomas *et al*. examined the C-fixation responses of natural assemblages of cyanobacteria dominated by *Synechococcus* and *Prochlorococcus* and the N_2- and C-fixation responses of isolated *Trichodesmium* colonies to changes in pH/pCO_2 conditions between the time of the last glacial minimum (8.4/150 ppm) and projected year 2100 values (7.8/800 ppm). They found "whole community assemblages dominated by *Prochloro-coccus* and *Synechococcus*, whether nutrient-replete or P-limited, did not show a clear response of C-fixation rates to changes in pH/pCO_2." They observed "Fe- and P-replete colonies of *Trichodesmium* increased N_2-fixation rates at pH 7.8 by 54% over ambient pH/pCO_2 conditions, while N_2-fixation at pH 8.4 was 21% lower than at ambient pH/pCO_2." They found C-fixation rates of *Trichodesmium* "were on average 13% greater at low pH than at ambient pH and 37% greater than at high pH." They note "these results for natural populations of all three cyanobacteria concur with previous research and suggest that one important response to changes in ocean pH and pCO_2 might be an increase in N_2 and C fixation by *Trichodesmium* under nutrient-replete conditions."

Lomas *et al*. say their results for *Trichodesmium*, along with similar findings by several other marine scientists, suggest "ocean acidification would likely result in a positive feedback on the growth and physiology of natural populations, resulting in a positive change in their role in ocean carbon and nitrogen cycles."

6.3.2.1.3 Diatoms

Diatoms are a type of algae, most of which are unicellular, although they also form colonies that take the shape of filaments or ribbons. A unique feature of diatom cells is that they are encased within a special cell wall made of silica that is called a frustule, which can assume a wide variety of forms but usually consists of two asymmetrical sides with a split between them. Functionally, diatoms serve as primary producers in various marine food chains, and thus it is important to know how they may respond to continued increases in the air's CO_2 content. This section reviews much of what scientists have learned about the subject over the past several years, as summarized in the following bullet points.

- The light-saturated photosynthetic rate of the widely distributed *Skeletonema costatum* diatom is increased by elevated CO_2's stimulating of cell numbers, chlorophyll *a* content, the photosynthetic chemistry of photosystem II, and the efficiency of its light reaction.

- The growth-promoting effect of elevated atmospheric CO_2 on diatoms and coccolithophores

probably has been responsible for limiting the rise in atmospheric CO_2 since the dawn of the Industrial Revolution to approximately 90% of what it otherwise would have been.

- Because diatoms are responsible for about half of the world's primary marine production, their enhanced growth due to atmospheric **CO_2** enrichment should provide a significant brake on the rate of rise of the air's CO_2 content and reduce its ability to cause global warming.

- As diatoms serve as primary producers in numerous marine food chains, the several trophic levels above them should benefit from lower ocean pH levels as the atmosphere's CO_2 content continues to rise.

Chen and Gao (2004) grew a strain (2042) of *Skeletonema costatum*—a unicellular marine diatom, widely distributed in coastal waters throughout the world, that constitutes a major component of natural assemblages of most marine phytoplankton—in filtered nutrient-enriched seawater maintained at 20°C under a 12-hour/12-hour light/dark cycle at a light intensity of 200 μmol m^{-2} s^{-1}, while continuously aerating both cultures with air of either 350 or 1,000 ppm CO_2 as they measured physiological parameters of the diatom's photosynthetic activity.

The scientists report cell numbers of the diatom "increased steadily throughout the light period, and they were 1.6 and 2.1 times higher after the 12-hour light period for the alga grown at 350 and 1000 ppm CO_2, respectively." They also found chlorophyll *a* concentrations in the bulk of the two CO_2 cultures "increased 4.4- and 5.4-fold during the middle 8 hours of the light period for the alga grown at 350 and 1000 ppm CO_2, respectively," and "the contents of cellular chlorophyll *a* were higher for the alga grown at 1000 ppm CO_2 than that at 350 ppm CO_2." The initial slope of the light saturation curve of photosynthesis and the photochemical efficiency of photosystem II "increased with increasing CO_2, indicating that the efficiency of light-harvesting and energy conversion in photosynthesis were increased." The two scientists report "the light-saturated photosynthesis rate based on cell number, the chlorophyll *a* content, the photosynthetic chemistry of photosystem II and the efficiency of the light reaction all increased to various degrees with elevated CO_2."

Three years later, in a study conducted between 15 May and 9 June of 2005 at the Espegrend Marine Biological Station of the University of Bergen, on a

fjord in southern Norway, Riebesell *et al*. (2007) maintained nine cylindrical mesocosms—which extended from the water surface to a depth of 9–10 meters—in equilibrium with air of either ambient CO_2 concentration (350 ppm), doubled CO_2 (700 ppm) or tripled CO_2 (1,050 ppm), while measuring several phytoplanktonic physiological parameters. They found "net community carbon consumption under increased CO_2 exceeded present rates by 27% (2 x CO_2) and 39% (3 x CO_2)," and continuous oxygen measurements in the mesocosms identified "enhanced net photosynthesis to be the source of the observed CO_2 effect."

Noting "the phytoplankton groups dominating in the mesocosm studies—diatoms and coccolithophores—are also the main primary producers in high productivity areas and are the principal drivers of biologically induced carbon export to the deep sea," the 11 scientists say their findings "underscore the importance of biologically driven feedbacks in the ocean to global change." Noting "increased CO_2 has been shown to enhance fixation of free nitrogen, thereby relaxing nutrient limitation by nitrogen availability and increasing CO_2 uptake (Barcelos e Ramos *et al.*, 2007)," Arrigo (2007) states in a *News & Views* discussion of Riebesell *et al*.'s paper "neither these, nor other possible non-steady-state biological feedbacks, are currently accounted for in models of global climate—a potentially serious omission, given that the biological pump is responsible for much of the vertical CO_2 gradient in the ocean." Arrigo reports the diatom and coccolithophore growth-promoting effect of CO_2 measured and described by Riebesell *et al*. probably has been responsible for limiting the rise in atmospheric CO_2 since the dawn of the Industrial Revolution to approximately 90% of what it otherwise would have been.

Sobrino *et al*. (2008) grew cultures of *Thalassiosira pseudonana*, "a widely distributed diatom," exposing them to either photosynthetically active radiation (PAR: 400–700 nm) or PAR plus ultraviolet radiation (UVR: 280–400 nm) in 500-mL Teflon bottles maintained at 20°C, using a semi-continuous approach that employed daily dilutions with fresh growth medium (filtered seawater from the Gulf Stream that was enriched with f/2 nutrients) through which air of one of two atmospheric CO_2 concentrations (380 or 1,000 ppm) was continuously bubbled. They discovered exposure of the seawater medium to CO_2-enriched air increased the photosynthetic rate of the marine diatoms by approximately 45% in the presence of PAR and by about 60% in the

presence of both PAR and UVR, and it increased their growth rate by approximately 20% in both of the radiation environments. They note, "among the phytoplankton species inhabiting the [ocean's] surface layer, diatoms are responsible for almost 40% of the ocean primary productivity (Nelson *et al.*, 1995)."

Tortell *et al.* (2008) measured CO_2 uptake of *in situ* phytoplankton assemblages collected at 35 stations in the Ross Sea polynya during austral spring and summer, together with ^{14}C uptake for a subset of 11 station samples, while they conducted CO_2 manipulation experiments with phytoplankton collected at three Ross Sea locations in the Southern Ocean via shipboard incubations using a semi-continuous batch-culture technique. The researchers report, "for the *Phaeocystis*-dominated springtime phytoplankton assemblages, there was a statistically significant increase in ^{14}C fixation between 100 and 380 ppm CO_2, but no further effects observed at 800 ppm CO_2." In the case of the diatom-dominated summertime phytoplankton assemblages, the CO_2-induced increase in both relative growth rate and primary productivity continued through 800 ppm, and it promoted "a shift towards larger chain-forming species." Noting the larger chain-forming species of diatoms "are prolific bloom formers with a very high capacity for organic carbon export to the sediments (Stickley *et al.*, 2005)," Tortell *et al.* conclude "potential CO_2-dependent productivity increases and algal species shifts could thus act to increase the efficiency of the biological pump, enhancing Southern Ocean CO_2 uptake and contributing to a negative feedback on increased atmospheric CO_2."

Wu *et al.* (2010) suggest increased CO_2 availability may benefit marine phytoplankton, because "the low affinity of their carboxylating enzyme (Rubisco) for CO_2 (Badger *et al.*, 1998) ... could lead to enhanced phytoplankton growth and photosynthetic carbon fixation" in a high-CO_2 world of the future, as had been suggested by the work of Riebesell *et al.* (1993) and Hein and Sand-Jensen (1997).

Wu *et al.* cultured the diatom *Phaeodactylum tricornutum*, which had been isolated from the South China Sea, for at least 20 generations in artificial seawater equilibrated with air of either 388 or 1,000 ppm CO_2, which resulted in water pH values of either 8.15 or 7.80, respectively, while they measured the diatom's photosynthetic carbon fixation, dark respiration, and growth rates. The three researchers found photosynthetic carbon fixation was enhanced by 12% under the high CO_2 and low pH conditions. Since dark respiration also was enhanced, the daily

net photosynthetic production was stimulated by a lesser 5.8%, and this value "closely agreed with the observed increase in growth," which they had independently determined to have been enhanced by 5.2% under the high CO_2 and low pH conditions.

Wu *et al.* write, if "the roughly 5% increase in the growth of diatoms were taken into account based on the values obtained in this study, this would allow diatoms to rapidly accumulate more biomass (by about 34% in 6 days) and draw down available nitrogen and other nutrients, leading to a greater biological carbon flux to the deep sea." And because diatoms contribute "about half of the marine primary production," this phenomenon would provide a significant brake on the rate of rise of the atmosphere's CO_2 concentration and its ability to cause global warming.

Boelen *et al.* (2011) assessed the photophysiology of the Antarctic diatom *Chaetoceros brevis* in seawater equilibrated with ambient CO_2 air (380 ppm) and air of approximately twice-ambient CO_2 (750 ppm) and half-ambient CO_2 (190 ppm), under four irradiance regimes: two simulating deep and shallow vertical mixing, and two that mimicked limiting and saturating stable water column conditions.

The six scientists found no significant differences between the enhanced and reduced CO_2 levels with respect to "growth, pigment content and composition, photosynthesis, photoprotection and Rubisco activity." They conclude, "within the range tested, CO_2 does not significantly affect the photophysiological performance of *C. brevis*." Their results "agree with other studies on marine diatoms showing little or no effect of elevated CO_2 on growth (Burkhardt *et al.*, 1999) or maximum rates of photosynthesis (Rost *et al.*, 2003; Trimborn *et al.*, 2009)," although they note in other studies "elevated CO_2 concentrations enhanced growth rates (e.g., Riebesell *et al.*, 1993; Clark and Flynn, 2000)," and "a recent field study in the Southern Ocean (Tortell *et al.*, 2008) showed an increase in phytoplankton productivity and the promotion of large chain-forming *Chaetoceros* species under elevated CO_2."

Boelen *et al.* state, "under saturating and limiting, as well as under dynamic and constant irradiance conditions, the marine Antarctic diatom *C. brevis* has the ability to adjust its cellular physiology in response to changing CO_2 levels with minimal effects on growth and photosynthesis." Although this maintenance of the status quo could be considered a neutral response to elevated CO_2, it also could be regarded as a positive finding, given that many people

contend atmospheric CO_2 enrichment will be bad for almost all forms of oceanic life.

Crawfurd *et al*. (2011) note diatoms are very important for the productivity of the world's oceans, as they contribute about 45% of global marine primary production, citing Mann (1999); therefore it is essential to understand how diatoms and other marine phytoplankton will respond to the higher aqueous CO_2 and lower pH conditions that will prevail in ocean surface waters in the near future, as a result of the dissolution of anthropogenic CO_2 in them. They grew more than 100 generations of the diatom *Thalassiosira pseudonana* in seawater maintained in equilibrium with air of either current (ambient) CO_2 concentration or expected end-of-the-century (twice-ambient) CO_2 concentration (380 or 760 ppm)—which produced pH values of 8.1 and 7.8, respectively—for three months, after which they evaluated a number of the species' physical and physiological characteristics. The five UK researchers found "very few effects on *T. pseudonana* of long-term culture at different pCO$_2$ and pH." They report, "growth rates were identical in cultures supplied with 780 or 360 ppm CO_2," and "similar results have been reported for other diatom species," citing Tortell *et al*. (1997), Tortell (2000), Kim *et al*. (2006), and Shi *et al*. (2009). Crawfurd *et al*. conclude, "if all diatoms respond in a similar fashion to *T. pseudonana*, acidification of this magnitude in the future ocean may have little effect on diatom productivity."

McCarthy *et al*. (2012) grew two strains of the diatom *Thalassiosira pseudonana* under low light in turbidostat photobioreactors bubbled with air containing either 390 or 750 ppm CO_2. They found the increased concentration of CO_2 led to increased growth rates in both strains of 20%–40%. They also report total cellular protein did not change between the ambient and 750 ppm CO_2 treatments, but cellular rubisco content showed a two- to three-fold increase with elevated CO_2. McCarthy *et al*. state the CO_2 fertilization effect on the growth rate of *T. pseudonana* observed at low light and nutrient repletion imparts this species with increased competitive ability, concluding "there could be a net increase in capacity for primary productivity at 750 ppm CO_2, at least with regard to small diatoms in coastal environments."

Li *et al*. (2012) investigated the diatom *Phaeodactylum tricornutum* as a model organism, culturing its cells in both low CO_2 (390 ppm) and high CO_2 (1,000 ppm), as well as at low nitrogen (10 μmol/L) and high nitrogen (110 μmol/L) concentrations. They report, "no direct effects on growth rate were found between the CO_2 treatments" and "no direct effects on pigmentation were found between the CO_2 treatments." They also note "no significant change in the [quantum] yield was found between the low and high CO_2 levels" and "increased dissolved CO_2 concentration did not affect the mean cell size and cell volume of *Phaeodactylum tricornutum*." Moreover, "under the nitrogen replete treatment the CO_2 concentration did not affect the C:N ratio, even though the cells at the high CO_2 level significantly increased their nitrogen content by 13%."

Real-world data suggest diatoms will continue to operate much as they have over prior millennia as the air's CO_2 content continues to rise, or they will be significantly stimulated to do everything they did before, only much better and on a larger scale. Given that diatoms serve as the primary producers in numerous marine food chains, the several trophic levels above them also should be at worst unharmed, and probably benefited by, lower ocean pH levels.

6.3.2.1.4 Foraminifera

Foraminifera are amoeboid protists with reticulating pseudopods—fine strands of cytoplasm that subdivide into branches that merge to form a dynamic network. They are typically less than one mm in size (but can be much larger), and they produce an elaborate calcium carbonate shell called a test, which may have one or more chambers. According to Schiebel (2002), these widespread calcifying protozoa are responsible for 32–80% of the global deep-ocean flux of calcite. Therefore, it is important to determine how various forams, as they are often called, may be affected by likely future declines in ocean pH levels. This section describes some of what scientists have learned about this subject over the past several years, briefly summarized in the following bullet points.

- Some foraminiferal species will tolerate CO_2 values one to two orders of magnitude higher than those predicted for the next few centuries.

- Other forams will tolerate CO_2 values one to two orders of magnitude greater than those predicted to occur for the extreme case of burning all the fossil fuels in Earth's crust.

- Some forams not only survive but successfully reproduce in seawater maintained in equilibrium with air containing as much as 200,000 ppm of CO_2.

Lombard *et al*. (2010) cultured specimens of *Orbulina universa* collected by scuba divers off the coast of Catalina Island, California (USA) and *Globigerinoides sacculifer* obtained near Puerto Rico (USA) under high and low irradiances (335 and 35 μmol photons m^{-2} s^{-1}, respectively) in filtered seawater that had its pH and carbonate ion concentration (CO_3^{2-}) manipulated by adding NaOH or HCl to it. They measured the forams' initial and final size, survival time (days from collection to gametogenesis), and final shell weight for individuals that underwent gametogenesis and grew at least one chamber. They determined under the IS92a "business as usual" scenario as defined by IPCC and projected for the year 2100, the calcification rates of *G. sacculifer* and *O. universa* "could decline by 6–13% compared to recent rates." That is not a large decline, and the four researchers note, "the future increase in temperature [predicted by IPCC] could increase the production of calcite by foraminifera, counter-acting the negative impact of ocean acidification."

Kuroyanagi *et al*. (2009) cultured asexually produced individuals of *Marginopora kudakajimensis*—a large calcifying microorganism that contributes to organic and inorganic carbon production in coral reefs—under laboratory conditions for 71 days in glass jars containing approximately 110 ml of filtered natural seawater (control pH of about 8.2) and two less-basic pH conditions of about 7.9 and 7.7, with the lower values being created by addition of 0.1 N HCl. In declining from the control pH of 8.2 to a pH of 7.9, the mean maximum shell diameter of the large foraminifer rose by 8.6%; its mean shell weight rose by a much smaller and insignificant 0.7%. As the seawater's pH declined to 7.7, the organism's mean maximum shell diameter fell by 12.1% and its mean shell weight fell by 49.3%. Kuroyanagi *et al*. conclude if oceanic pH remains within the range of 8.2 to 7.9, "large foraminifers should be able to maintain present calcification rates."

Bernhard *et al*. (2009) grew the marine foraminiferal protist *Allogromia laticollaris*—which they described as "a ubiquitous protistan constituent of marine microbial systems" and "an important link in the marine food web"—in a mixture of 32% seawater and Alga-Gro seawater medium in 20-ml glass culture tubes, examining its response to several

super-high atmospheric CO_2 concentrations to which the tubes were exposed: 15,000, 30,000, 60,000, 90,000 and 200,000 ppm, values compared to the study's atmospheric control concentration of 375 ppm CO_2. The protist was "able to survive 10–14-day exposure to elevated CO_2 as high as 200,000 ppm." They write, "both ATP [adenosine triphosphate, an indicator of cellular energy] data and microscopic examination demonstrated that considerable populations of *A. laticollaris* survived exposure to all experimental treatments of elevated CO_2, even both replicates of the 200,000-ppm CO_2 experiments." They also found "at least three specimens reproduced during exposure to either 90,000 ppm or 200,000 ppm CO_2," whereas "such reproduction was observed only once in an atmospheric [375-ppm CO_2] treatment."

The four researchers state "*A. laticollaris* is an appropriate species to predict the response of shallow-water thecate foraminifera to predicted increases in atmospheric CO_2, given its isolation [i.e., acquisition] from a shallow-water semi-tropical setting." They say their results indicate "at least some foraminiferal species will tolerate CO_2 values that are one to two orders of magnitude higher than those predicted for the next few centuries." Indeed, their results indicate *A. laticollaris* will tolerate CO_2 values one to two orders of magnitude greater than those predicted to occur for the "extreme case" of burning all fossil fuels in Earth's crust.

But aren't *all* forams amazingly resilient creatures? In a study broaching this question, Cannariato *et al*. (1999) investigated the character, magnitude, and speed of biotic responses of benthic foraminifera to millennial-scale climatic oscillations, using data from an ocean sediment core in the Northeast Pacific that extended back in time some 60,000 years. A number of rapid climatic switches over the 60,000-year record were noted, representing periods of what the three researchers call "extreme environmental variability." They found no evidence of extinctions, and the benthic ecosystems appeared to be "both resilient and robust in response to rapid and often extreme environmental conditions." The scientists note faunal turnovers occurred within decades throughout the record "without extinction or speciation." They conclude, "broad segments of the biosphere are well adapted to rapid climate change," which suggests broad segments of the biosphere may be equally well adapted to lower ocean pH levels.

Hikami *et al*. (2011) measured foram net calcification rates of two algal symbiont-bearing, reef-dwelling forams (*Amphisorus kudakajimensis* and *Calcarina gaudichaudii*) in seawater maintained

at five $p\mathrm{CO_2}$ concentrations (245, 375, 588, 763, and 907 ppm). They also conducted a second culture experiment in seawater in which bicarbonate ion concentrations were varied, while keeping carbonate ion concentration constant.

In the first experiment, Hikami et al. found "net calcification of *A. kudakajimensis* was reduced under higher $p\mathrm{CO_2}$, whereas calcification of *C. gaudichaudii* generally increased with increased $p\mathrm{CO_2}$." In the second experiment, they found "calcification was not significantly different between treatments in *Amphisorus hemprichii*, a species closely related to *A. kudakajimensis*, or in *C. gaudichaudii*."

Explaining the results of their first experiment, the nine researchers note the upward calcification trend of *Calcarina* with rising $p\mathrm{CO_2}$ "can probably be attributed to the increase in $\mathrm{CO_2}$, possibly through enhancement of symbiont photosynthesis, a phenomenon known as the $\mathrm{CO_2}$-fertilizing effect (e.g., Ries et al., 2009)." They note *Calcarina* harbor diatoms, and "both a single-species culture experiment (Wu et al., 2010) and a mesocosm bloom experiment (Engel et al., 2008) have shown that high-$\mathrm{CO_2}$ seawater is favorable to diatom growth," which in turn stimulates calcification. They also note Rost et al. (2006) report dinoflagellates, which are harbored by *Amphisorus,* "use $\mathrm{HCO_3^-}$ as their carbon source, so their rate of carbon fixation may remain unaffected by fluctuating $\mathrm{CO_2}$ levels."

As for the second experiment, the seawater pH varied but little between the different bicarbonate ion concentration treatments, resulting in little variation in the calcification rates of both species. Hikami et al. conclude the different influences of sea-water chemistry they observed in the two forams may have been attributable to the different types of symbiotic algae they hosted.

Vogel and Uthicke (2012) note, "several studies highlight the importance of large benthic foraminifera (LBF) as biological indicators for water quality and ecosystem health," citing Hallock et al. (2003), Uthicke and Nobes (2008), and Uthicke et al. (2010), but "impacts of ocean acidification on LBF physiology are not well studied." They investigated "the influence of increased $\mathrm{CO_2}$ on calcification and photobiology of LBF hosting different types of photosynthetic endosymbionts." The two researchers collected samples of the foraminifers *Amphistegina radiata*, *Heterostegina depressa*, and *Marginopora vertebralis* from two locations on Australia's Great Barrier Reef on several field trips between October 2010 and April 2011. They exposed the samples in a laboratory over a period of six weeks to four seawater conditions (467, 784, 1,169, and 1,662 ppm $\mathrm{CO_2}$), periodically measuring a number of physiological parameters and processes.

The researchers found no negative effects of elevated $\mathrm{CO_2}$ on the calcification of any of the LBF species investigated compared to control conditions. The growth rate of *M. vertebralis* increased with elevated $\mathrm{CO_2}$, with mean calcification rates at the two highest $\mathrm{CO_2}$ treatments (1,169 and 1,662 ppm) being 63% greater than those at the two lowest treatments (467 and 784 ppm). Increased $\mathrm{CO_2}$ had no effect on chlorophyll *a* content in either *A. radiata* or *H. depressa*, but "chlorophyll *a* content approximately doubled in *M. vertebralis* from initial to final measurements." In addition, "the maximum quantum yield of *A. radiata*, *H. depressa* and *M. vertebralis* did not vary significantly between different $\mathrm{CO_2}$ treatments." Nor did they find significant negative impacts on photosynthetic production and respiration in the three LBF species.

Vogel and Uthicke say their study "illustrated that the species investigated were still able to build up their calcite skeletons in $\mathrm{CO_2}$ conditions predicted for the year 2100 and beyond," and "contrary to expectations, *M. vertebralis* showed significantly increased growth rates in elevated $\mathrm{CO_2}$."

6.3.2.1.5 Other Individual Types

Scientists also have studied phytoplankton other than coccolithophores, cyanobacteria, diatoms, and foraminifera, and this brief section reviews the findings of studies where the responses of these species to lower ocean pH levels have been either experimentally or observationally determined, as described in the bullet points below and in the text that follows them.

- Atmospheric CO_2 enrichment induced "a protective effect against the oxidative damage of UV-B-induced stress" in *Platymonas subcordiformis*, suggesting elevated CO_2 should be able to "enhance the capacity of [UV-B] stress resistance."

- A study of *Stichococcus cylindricus* and *Stichococcus minor* revealed the two marine microalgae "were able to tolerate a broad range of pH from pH 5.0 to 9.5," as well as a broad range of salinities.

- A 2.63-fold increase in the air's CO_2 content led to increases in photosynthetic rates among the 16 ecotypes of a unicellular species of marine green alga (*Ostreococcus tauri*) that ranged from 1.02- to 2.18-fold greater than the current mean, while CO_2-induced size differences among ecotypes were found to range from 1.3- to 1.9-fold greater than the current mean. Differences in plastic responses for C/N ratios, which partly determine the food quality of phytoplankton, were found to range from 1.06- to 1.56-fold greater than the current mean.

Gordillo *et al*. (2003) studied the CO_2-induced growth response of the microalgal chlorophyte *Dunaliella viridis*, which possesses a carbon-concentrating mechanism and has been used as a model species for the study of inorganic carbon uptake. They batch-cultured the chlorophyte, one of the most ubiquitous eukaryotic organisms found in hypersaline environments, in 250-ml Perspex cylinders under laboratory conditions at high (5 mM) and low (0.5 mM) nitrate concentrations, while continuously aerating the cultures with air of either 350 or 10,000 ppm CO_2.

They found atmospheric CO_2 enrichment had little effect on dark respiration in both N treatments, and it had little effect on photosynthesis in the low-N treatment. In the high-N treatment, the extra CO_2 increased photosynthesis by 114%. In the case of biomass production, the results were even more divergent: in the low-N treatment elevated CO_2 had no effect, but in the high-N treatment it nearly tripled the cell density of the culture solution. Gordillo *et al*. note "it has long been debated whether phytoplankton species are growth-limited by current levels of CO_2 in aquatic systems, i.e. whether an increase in atmospheric CO_2 could stimulate growth (Riebesell *et al*., 1993)." Their results clearly indicate it can, if sufficient nitrogen is available.

Gordillo *et al*. also learned that in the high-N treatment, where elevated CO_2 greatly stimulated photosynthesis and biomass production, once the logarithmic growth phase had run its course and

equilibrium growth was attained, approximately 70% of the carbon assimilated by the chlorophyte was released to the water, whereas in the low- CO_2 treatment only 35% was released. Gordillo *et al*. write, "the release of organic carbon to the external medium has been proposed as a mechanism for maintaining the metabolic integrity of the cell (Ormerod, 1983)," and "according to Wood and Van Valen (1990), organic carbon release would be a sink mechanism protecting the photosynthetic apparatus from an overload of products that cannot be invested in growth or stored." They also note stores of photosynthetic products "are reduced to avoid overload and produce a high demand for photosynthates." Under these conditions, they conclude the process would "divert assimilated C to either the production of new biomass, or the release to the external medium once the culture conditions do not allow further exponential growth."

A second consequence of CO_2-enhanced organic carbon release is that the internal C:N balance of the phytoplankton is maintained within a rather tight range. This phenomenon has been observed in the green seaweed *Ulva rigida* (Gordillo *et al*., 2001) and the cyanobacterium *Spirulina platensis* (Gordillo *et al*., 1999). What the study of Gordillo *et al*. (2003) reveals about the response of *Dunaliella viridis* to atmospheric CO_2 enrichment may be applicable to many, if not most, aquatic plants.

Yu *et al*. (2004) grew the marine microalgae *Platymonas subcordiformis* (Wille) Hazen at ambient levels of atmospheric CO_2 concentration and UV-B radiation flux density as well as at elevated levels of 5,000 ppm CO_2 and UV-B radiation characteristic of that anticipated to result from a 25% stratospheric ozone depletion under clear sky conditions in summer. By itself, they report, the elevated UV-B treatment "significantly decreased [microalgal] dry weight, photosynthetic rate, chlorophyll *a* and carotenoid contents," and the elevated CO_2 treatment by itself "enhanced dry weight and photosynthetic rate, but chlorophyll *a* content and carotenoid content had no major difference compared with those of ambient UV-B and ambient CO_2." They also report elevated UV-B by itself significantly increased the production of the toxic superoxide anion and hydrogen peroxide, as well as malonyldialdehyde, which is an end-product of lipid peroxidation, whereas elevated CO_2 by itself did just the opposite. In the treatment consisting of both elevated UV-B and elevated CO_2, the concentrations of these three malevolent substances were lower than those observed in the elevated UV-B and ambient CO_2

treatment. Finally, they note elevated CO_2 decreased the levels of several antioxidant enzymes found in the microalgae, reflecting their reduced need for detoxification of reactive oxygen species in the elevated CO_2 treatment.

Yu *et al*. conclude atmospheric CO_2 enrichment "could reduce the oxidative stress of reactive oxygen species to *P. subcordiformis*, and reduce the lipid peroxidation damage of UV-B to *P. subcordiformis*." They also state, "CO_2 enrichment showed a protective effect against the oxidative damage of UV-B-induced stress," and, therefore, elevated CO_2 should be able to "enhance the capacity of stress resistance." They conclude microalgae grown under high CO_2 "would better overcome the adverse impact of environmental stress factor[s] that act via generation of activated oxygen species."

Moazami-Goudarzi and Colman (2012) measured the growth rates of two marine microalgae (*Stichococcus cylindricus* and *Stichococcus minor*) in artificial seawater, as per Berges *et al*. (2001), within 125-ml Erlenmeyer flasks at pH values of 5.0, 6.0, 7.0, 8.2, 9.0, and 9.5, as well as at a variety of salinity levels (25, 50, 100, 200, and 470 mM). The two Canadian researchers discovered both species had similar growth rates and grew over the range of pH 5.0 to 9.5, with "cells grown at pH 5.0, 6.0 and 7.0 showing no significant difference in growth rates." They also report "both species were found to have similar growth rates and to grow over a range of salinities at sodium chloride concentrations of 25, 50, 100, 200 and 470 mM." Moazami-Goudarzi and Colman found *S. minor* and *S. cylindricus* "were able to tolerate a broad range of pH from pH 5.0 to 9.5," as well as the broad range of salinities they investigated.

Schaum *et al*. (2013) write, "marine phytoplankton are the foundation of ocean ecosystems," noting "these small but mighty microbes are responsible for roughly half of global carbon fixation" and they "form a fundamental part of the biological carbon pump that exports fixed carbon to the deep ocean." They state "empirical studies so far predict changes [in response to rising atmospheric CO_2 concentrations] in phytoplankton communities using single or a few genotypes to represent functional groups," whereas the real-world variation in responses within functional groups "has not been quantified." The four researchers used "16 ecotypes of *Ostreococcus tauri* [a unicellular species of marine green alga] from nine habitat types," which "were obtained from the Roscoff Culture Collection and the Plymouth Marine Laboratory, grown in Keller medium and made clonal by dilution, so that each

culture originated from single cells." Those samples were "acclimated for 5–7 asexual generations to 380 ppm CO_2 or 1,000 ppm CO_2 in a closed-system and grown in semi-continuous batch cultures at low densities," allowing the researchers to "quantify variations in plastic responses to elevated CO_2 for ecologically relevant traits such as photosynthesis" while also characterizing "changes in traits affecting food quality for five of these ecotypes."

Schaum *et al.* note they were able to "link plasticity in photosynthesis rates to changes in the relative fitness of ecotypes during asexual growth," and they were further able to "use this link to predict which ecotypes are likely to rise in frequency in a high-CO_2 environment." They found the 2.63-fold increase in the air's CO_2 content of their experiment led to increases in photosynthetic rates among the 16 ecotypes they studied, ranging from 1.02- to 2.18-fold greater than the current mean, and CO_2-induced size differences among ecotypes were found to range from 1.3- to 1.9-fold greater than the current mean. Differences in plastic responses for C/N ratios, which partly determine the food quality of phytoplankton, were found to range from 1.06- to 1.56-fold greater than the current mean. The four scientists conclude, "as CO_2 levels increase, *O. tauri* will grow and photosynthesize faster, and have larger cells with a higher C/N ratio than contemporary cells," with the result "*Ostreococcus*, along with other green algae and cyanobacteria, are likely to increase in abundance in high-CO_2 conditions" with concomitant benefits for the biosphere.

6.3.2.1.6 Mixtures of All Types

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on mixtures of various types of marine phytoplankton. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Ultra-high CO_2 enrichment (5,000 ppm) promoted the growth of six species of marine microalgae.

- The effects of atmospheric CO_2 enrichment on various marine phytoplankton in a fjord adjacent to the Large-Scale Facilities of the Biological Station of the University of Bergen in Espegrend, Norway revealed no significant species shifts between treatments, and "the ecosystem composition, bacterial and phytoplankton abundances and productivity, grazing rates and total grazer

abundance and reproduction were not significantly affected by CO_2 induced effects."

- "Changes in iron speciation and the resulting potential negative feedback mechanism of phytoplankton productivity on atmospheric CO_2"—i.e., the drawdown of atmospheric CO_2 due to enhanced phytoplanktonic growth and transferral of the carbon thus removed from the atmosphere to the ocean depths—"need to be considered when assessing the ecological effects of ocean acidification."

- The "broad level of pH-tolerance" observed in coastal environments likely results from the adaptation of organisms living there to the large pH fluctuations that routinely occur "as a result of respiratory and photosynthetic processes," as well as "hydrographical events," that alter the "seasonal, and even diurnal, fluctuations in coastal seawater pH" over a large range.

- "Nitrifying organisms in coastal systems tolerate a wide range of pH values," suggesting "the current hypothesis of the negative impacts of ocean acidification on nitrification, at least for the coastal ocean, might need reevaluation."

- Atmospheric CO_2 enrichment is not likely to lead to a degradation of planktonic food quality in Arctic waters.

Wolf-Gladrow *et al*. (1999) examined the direct effects of atmospheric CO_2 enrichment on marine phytoplankton, including the consequences of these phenomena for the world's oceanic carbon pump, finding the ongoing rise in the air's CO_2 content may also benefit the planet's marine biota, producing significant increases in phytoplanktonic growth rates that may "serve as negative feedbacks to anthropogenic CO_2 increase."

More than a decade later, Joint *et al*. (2011) note "the pH of the surface ocean is changing as a result of increases in atmospheric carbon dioxide," and "there are concerns about potential impacts of lower pH and associated alterations in seawater carbonate chemistry on the biogeochemical processes in the ocean." They note "it is important to place these changes within the context of pH in the present-day ocean."

According to the three researchers, "marine and freshwater assemblages have always experienced variable pH conditions." For example, "phytoplankton blooms can rapidly reduce pCO₂, with a concomitant increase in pH," which subsequently declines as the blooms die out, demonstrating "pH is naturally variable and that marine organisms—particularly microbes—must already be capable of adapting to rapid and sometimes large changes in pH." They also note, "oceanic pH can change by up to 0.06 pH unit during the year even in the oligotrophic Central Pacific, which does not experience the dramatic phytoplankton blooms of temperate oceans." Regarding freshwater ecosystems, Joint *et al*. report, "Maberly (1996) showed that diel variations in a lake can be as much as 2–3 pH units," and "Talling (2006) showed that in some English lakes, pH could change by >2.5 pH units over a depth of only 14 m," noting "phytoplankton, bacteria, archaea and metazoans are all present in lakes, and appear to be able to accommodate large daily and seasonal changes in pH."

The three researchers conclude, "perhaps the most appropriate null hypothesis to test is that marine microbes possess the flexibility to accommodate pH change and there will be no catastrophic changes in marine biogeochemical processes that are driven by phytoplankton, bacteria and archaea." Many researchers have done just that.

Yu *et al*. (2006) grew monocultures of six species of marine microalgae (*Chlorella* sp., *Dunaliella salina*, *Isochrysis galbana* Parke 8701, *Nitzschia closterium*, *Platymanas subcordiformis*, and *Platymanas* sp.) in Erlenmeyer flasks under 14:10 dark:light 24-hour cycles through which air of either 360 or 5,000 ppm CO_2 was continuously bubbled for five days. They measured algal cell densities at one-day intervals in order to calculate and compare algal specific growth rates. All six species responded positively to the ultra-high CO_2 enrichment of the air, with the ratios of their specific growth rates in the CO_2-enriched compared to ambient-air treatments being 1.15 for *Chlorella* sp., 1.35 for *Dunaliella salina*, 1.35 for *Isochrysis galbana*, 1.40 for *Nitzschia closterium*, 1.47 for *Platymanas subcordiformis*, and 1.60 for *Platymanas* sp.

Yu *et al*. conclude, a "high concentration of CO_2 promotes the growth of microalgae," citing not only their results but also the findings of other researchers, including Lin (1991), Nobutaka *et al*. (1992), Riebesell *et al*. (1993), Hein and Sand-Jensen (1997), Liang and Yonemoto (1999), Hu and Gao (2001), and Xia and Gao (2001, 2002). They note, "possibly, the CO_2 enrichment made the chloroplast[s] more developed," so "both the photosynthesis and cell division rate were increased," and, therefore, "the algal cell density was enhanced."

Vogt *et al.* (2008) studied the effects of atmospheric CO_2 enrichment on various marine microorganisms in nine marine mesocosms maintained within two-meter-diameter polyethylene bags submerged to a depth of 10 meters in a fjord adjacent to the Large-Scale Facilities of the Biological Station of the University of Bergen in Espegrend, Norway. They maintained three of the mesocosms at ambient levels of CO_2 (~375 ppm), three at levels expected to prevail at the end of the current century (760 ppm or 2x CO_2), and three at levels predicted for the middle of the next century (1,150 ppm or 3x CO_2), taking measurements of numerous ecosystem parameters over a period of 24 days.

Vogt *et al.* detected no significant phytoplankton species shifts between treatments, and "the ecosystem composition, bacterial and phytoplankton abundances and productivity, grazing rates and total grazer abundance and reproduction were not significantly affected by CO_2 induced effects," citing the work of Riebesell *et al.* (2007), Riebesell *et al.* (2008), Egge *et al.* (2007), Paulino *et al.* (2007), Larsen *et al.* (2007), Suffrian *et al.* (2008), and Carotenuto *et al.* (2007). The eight researchers say their observations suggest "the system under study was surprisingly resilient to abrupt and large pH changes."

Three oceanic CO_2-enrichment experiments (I, II, and III) were carried out in 2001, 2003, and 2005 at the Marine Biological Station of the University of Bergen at Espegrend, Norway, where researchers maintained nine marine ecosystems in two-meter-diameter polyethylene bags submerged to a depth of 10 meters in an adjacent fjord, keeping three of the mesocosms at ambient levels of CO_2 (1xCO_2), three others at 2xCO_2 and three more at 3xCO_2 (via aeration of the water column and the overlying atmosphere with CO_2-enriched air). They performed this work in the context of the Pelagic Ecosystem CO_2 Enrichment (PeECE) program, enabling the PeECE I, PeECE II, and PeECE III experiments.

After a one-time addition of nutrients intended to initiate a phytoplankton bloom on the day before the start of their 24-day study, Egge *et al.* (2009) measured primary production in the nine mesocosms at two-day intervals during the PeECE III experiment, along with oxygen production and consumption, the presence of transparent exopolymer particles, and the composition of the phytoplanktonic community. The seven scientists report, "in the second half of the experiment there was a tendency of higher production at elevated CO_2 levels," which was "visible from ca. day 10 in the cumulative production, with a significant difference between 3x and 1x CO_2 from day 20 onward," as shown in Figure 6.3.2.1.6.1.
Figure 6.3.2.1.6.1. Cumulative primary production from the start of the PeECE III experiment of Egge *et al.* (2009), adapted from the authors' paper.

Egge *et al.* state their results "demonstrate a small, but statistically significant effect of elevated CO_2 on daily primary production" that is "consistent with the over-consumption of dissolved inorganic carbon at elevated CO_2 reported by Riebesell *et al.* (2007) and Bellerby *et al.* (2008)." These observations once again suggest the planet's rising atmospheric CO_2 concentration may stimulate oceanic primary production and thereby enable the sustaining of a greater population of higher-trophic-level marine organisms.

855

Breitbarth *et al.* (2010) write, "studies of artificial and natural iron input have demonstrated iron control of phytoplankton productivity and CO_2 drawdown over vast oceanic regions (Boyd *et al.*, 2007; Blain *et al.*, 2007; Pollard *et al.*, 2009) and in coastal upwelling regions (Bruland *et al.*, 2001; Hutchins and Bruland, 1998)," and "temporal control of iron on phytoplankton productivity was also observed in a Norwegian fjord system (Ozturk *et al.*, 2002)." Breitbarth *et al.* measured dissolved iron (dFe) concentrations as well as levels and oxidation rates of Fe(II)—a necessary trace element (the ferrous species of iron) used by almost all living organisms—over the course of natural phytoplanktonic blooms to determine whether lower ocean pH levels may affect iron speciation in seawater. The researchers made measurements in mesocosms consisting of two-meter-diameter polyethylene bags submerged to a depth of 10 meters and maintained in equilibrium with air possessing CO_2 concentrations of either 350, 700, or 1,050 ppm via aeration of the water column and the overlying atmosphere with air of the three CO_2 concentrations (Schulz *et al.*, 2008).

The eight researchers report CO_2 perturbation and phytoplanktonic bloom development resulted in pH value ranges of 8.13–8.26, 7.82–8.08, and 7.67–7.97 at 3570, 700, and 1050ppm CO_2, respectively. They say their measurements revealed significantly higher dFe concentrations in the high CO_2 treatment compared to the mid and low CO_2 treatments, and the high-CO_2 mesocosms showed higher values of FE(II) compared to the lower CO_2 treatments.

Breitbarth *et al.* conclude "ocean acidification may lead to enhanced Fe-bioavailability due to an increased fraction of dFe and elevated Fe(II) concentrations in coastal systems ... due to pH induced changes in organic iron complexation and Fe(II) oxidation rates," noting these phenomena "will result in increased turnover of Fe in surface seawater, potentially maintaining iron bioavailability given a sufficient supply of total Fe, since equilibrium partitioning eventually restores the biolabile Fe pools that have been depleted by biological uptake." They write, "these processes may further fuel increased phytoplankton carbon acquisition and export at future atmospheric CO_2 levels," citing Riebesell *et al.* (2007). They conclude, "changes in iron speciation and the resulting potential negative feedback mechanism of phytoplankton productivity on atmospheric CO_2"—the drawdown of atmospheric CO_2 due to enhanced phytoplanktonic growth and transferral of the carbon thus removed from the atmosphere to the ocean depths—"need to be considered when assessing the ecological effects of ocean acidification."

According to Wyatt *et al.* (2010), "the assimilation of inorganic nutrients fuels phytoplankton growth," and therefore, "any alteration in the bioavailability of these nutrients is likely to impact productivity and, by extension, climate regulation through the uptake of CO_2 by marine algae." The authors note, "the reduction of surface ocean pH anticipated for the next century will alter the equilibrium coefficient between dissolved ammonia ($NH_3(aq)$) and ammonium (NH_4^+) shifting the equilibrium towards NH_4^+ (Zeebe and Wolf-Gladrow, 2001; Bell *et al.*, 2007, 2008)." As a result, the future decease in ocean pH due to the ongoing rise in the air's CO_2 content could result in the transfer of more gaseous NH_3 from the overlying atmosphere to the ocean, as has been noted by Jacobson (2005).

Wyatt *et al.* collected surface seawater samples from a coastal monitoring site in the Western English Channel (WEC) from 17 March to 21 July 2008, a period of time that included two distinct phases of the annual spring phytoplankton bloom (a pre-bloom period of five weeks and the bloom proper of 11 weeks). They measured ambient pH for carbonate system estimates and dissolved inorganic nutrients, and they equilibrated the samples with CO_2-in-air mixtures that resulted in CO_2 concentrations of 380, 500, 760, and 1,000 ppm that led to pH values of 8.05, 8.01, 7.87, and 7.76, respectively, to be compared with the mean ambient value of 8.18.

The six scientists report the phytoplankton community "was predominantly limited by the availability of inorganic nitrogen," and "during early and mid-summer, NH_X became the primary source of inorganic nitrogen." They also found "an overall increase in NH_X concentrations by 20% was observed between the present day CO_2 treatment (380 ppm) and 1000 ppm." Wyatt *et al.* write, "as excess CO_2 dissociates in the oceans, the increased hydrogen ion concentration ionizes $NH_3(aq)$ and decreases the ratio of $NH_3(aq):NH_4^+$," and this reduction in $NH_3(aq)$ "would lead to an imbalance in the equilibrium between $NH_3(aq)$ in the surface water and gaseous NH_3 in the overlying atmosphere resulting in the drawdown of atmospheric NH_3 to the surface ocean." Whereas the surface waters of the WEC "are a net source of 150 µmol/m^2/year of NH_3 to the atmosphere at present (2009)," they say it is likely "the WEC will become a net sink of 300 µmol/m^2/year for atmospheric NH_3 as atmospheric CO_2 rises to 717 ppm and the surface pH decreases to 7.83," due to the increase in phytoplanktonic productivity driven

by the increased transfer of gaseous NH_3 from the air to the surface waters of the WEC. This phenomenon would boost the productivity of higher oceanic trophic levels, help sequester more carbon at the bottom of the sea, and thereby reduce the rate of increase in radiative forcing that is speculated to fuel global warming.

Nielsen *et al*. (2012) set out to test "whether reduced pH would affect plankton communities over an incubation period of 14 days." They conducted their experiment "in a laboratory microcosm setup using a natural plankton community from the Derwent River estuary, Australia," in which "two treatments with reduced pH (8.0 and 7.7) were compared to an unaltered control of pH 8.3," and "measured parameters included community photo-synthesis, nutrient uptake and biomass build-up, as well as enumeration of 25 protist taxa and quantitative HPLC of phytoplankton pigments." They found nutrient uptake and photosynthetic parameters "were all unaffected by pH treatments 8.3–7.7," treatments they say "match the predicted 21st century changes in CO_2 and pH." They note "cellular carbon and total particulate organic carbon were both completely unaffected by pH treatment within this range," and "the same was true for the succession of all 25 enumerated protist species." They report "phytoplankton pigment analysis did not show effects of pH either," and "the investigated plankton community was thus, in all ways, resilient to pH changes between 8.3 and 7.7," noting once again these changes are equivalent to the changes predicted for the next century.

Nielsen *et al*. write, "others have also found no or very limited changes in phytoplankton communities in response to 21st century predicted changes in pH and CO_2," citing Kim *et al*. (2006), Riebesell *et al*. (2007), and Suffrian *et al*. (2008). They also note, "many coastal plankton communities are impervious to such changes," citing Nielson *et al*. (2010). One potential reason for this "broad level of pH-tolerance," as they describe it, is "pH in coastal waters often fluctuates as a result of respiratory and photosynthetic processes" and "hydrographical events," with the result "seasonal, and even diurnal, fluctuations in coastal seawater pH have been shown to encompass 7.5 to 9.6 (Macedo *et al*., 2001; Hansen, 2002)." They conclude "it is unlikely that the investigated plankton community would be sig-nificantly affected by a pH and CO_2 change as predicted for the 21st century."

Regarding the effects of lower ocean pH levels on the marine nitrogen cycle, Fulweiler *et al*. (2011)

write, "the current hypothesis, based on the manipulation of water column pH in laboratory studies, states decreasing pH will impact the nitrogen cycle by decreasing nitrification," and this decrease in the microbial conversion of ammonium to nitrate would likely negatively impact both marine phytoplankton composition and production.

Fulweiler *et al*. "compiled an existing unique data set of concurrent water column nitrification rates and water column pH values from a temperate New England estuary (Narragansett Bay, Rhode Island, USA)," which had been obtained and reported previously by Berounsky (1990) and Berounsky and Nixon (1985a,b, 1990, 1993). Fulweiler *et al*. say they "found the exact opposite trend to the current hypothesis: water column nitrification rates were highest at low pH and decreased significantly as pH increased," and "these results are in direct contradiction to some of the more recently published studies examining the impact of ocean acidification on marine nitrification (Huesemann *et al*., 2002; Beman *et al*., 2011)." They note their findings "are consistent with previous studies from three decades ago," citing Anthonisen *et al*. (1976) and Focht and Verstraete (1977).

Fulweiler *et al*. emphasize their results "highlight that nitrifying organisms in coastal systems tolerate a wide range of pH values," and "the degree of negative correlation with pH may depend on site-specific environmental conditions." They conclude their findings indicate "the current hypothesis of the negative impacts of ocean acidification on nitrification, at least for the coastal ocean, might need reevaluation."

Leu *et al*. (2013) write, "ocean acidification occurs as a consequence of increasing atmospheric CO_2 concentrations, and is thought to represent a major threat for some groups of marine organisms" because polyunsaturated fatty acids or PUFAs—essential metabolites that are synthesized only by algae and therefore have to be acquired via their ingestion by all other organisms—may not be as prominent in Arctic plankton in a high-CO_2 world as they are today, leading to a degradation of planktonic food quality. The five researchers studied the effect of lower ocean pH levels on a natural plankton community in the Arctic in a large-scale mesocosm experiment carried out in Kongsfjorden (Svalbard, Norway at 79°N), where nine mesocosms of ~50 m^3 each were exposed to eight CO_2 levels (from natural background conditions to ~1,420 ppm, yielding pH values ranging from ~8.3 to 7.5).

Leu *et al*. report, "no indications were found for a

generally detrimental effect of ocean acidification on the planktonic food quality in terms of essential fatty acids." They write, "it is remarkable that the overall community response with respect to the relative amount of PUFAs to increased CO_2 concentrations was rather positive." They conclude "findings about detrimental effects of ocean acidification on single species in laboratory studies (as, for instance, Riebesell *et al*. (2000) or Tsuzuki *et al*. (1990)), and even their consequences for grazers (Rossoll *et al*., 2012) are probably less relevant in a natural situation where other, more CO_2-tolerant species take over."

Leu *et al*. write, "the overall availability of essential PUFAs for higher trophic levels seems not to be affected negatively, although the specific fatty acid composition may change." They note "the overall amount of essential PUFAs available to the entire community (or at least within a certain size class) is the important measure for the algal food quality," which "also holds true for the implications for trophic transfer efficiency and consequences for phytoplankton-zooplankton ratios," as discussed by Brett and Muller-Navarra (1997).

Aberle *et al*. (2013) also set out to "test whether Arctic coastal plankton communities will be in any way affected by high pCO_2/low pH and thus susceptible to ocean acidification [(OA)]." They conducted a mesocosm experiment on a natural Arctic plankton community in Kongsfjorden, Svalbard. Over a period of about one month, they deployed and moored nine polyethylene mesocosms and injected CO_2-enriched seawater into them to achieve three degrees of CO_2 equilibrium concentrations—low (175–250 ppm), intermediate (340–600 ppm), and high (675–1,085 ppm). They added nutrients to all three mesocosm treatments 13 days later "to ensure a sufficient nutrient supply for bloom development."

Aberle *et al*. report they "found almost no direct effects of OA on microzooplankton composition and diversity," and "both the relative shares of ciliates and heterotrophic dinoflagellates as well as the taxonomic composition of microzooplankton remained unaffected by changes in pCO_2/pH." Aberle *et al*. conclude they must reject their hypothesis that a high CO_2 concentration would alter microzooplankton community structure, carrying capacity, or phenology, on the basis of their mesocosm experiment, noting the findings of their study point to "a relatively high robustness of microzooplankton towards elevated CO_2 in coastal waters."

Johnson *et al*. (2013) write, "in response to low ambient CO_2 concentrations, most marine microalgae have evolved a carbon concentrating mechanism

(CCM) to elevate concentrations at the site of carbon fixation (Beardall and Giordano, 2002; Raven and Beardall, 2003; Raven *et al*., 2011)." They note, since "increases in dissolved CO_2 are predicted to cause down-regulation of microalgal CCM capacity (Giordano *et al*., 2005; Hopkinson *et al*., 2011)," which should reduce the energetic costs of CCMs (Raven, 1991), this phenomenon "will potentially allow more energy for other growth processes." They write, "as the carbon acquisition mechanisms and efficiencies of CCMs differ between algae, it is thought that rising CO_2 will benefit different species to varying degrees (Hein and Sand-Jensen, 1997; Tortell *et al*., 2000; Rost *et al*., 2003; Beardall and Raven, 2004; Riebesell, 2004; Fu *et al*., 2008) and may result in dramatic community shifts with profound consequences for marine biogeochemistry (Hutchins *et al*., 2009)."

Johnson *et al*. compared periphyton assemblages on artificial substrata installed along a coastal CO_2 gradient, ranging from a median value of 419 to 592 to 1,611 ppm, at a shallow-water cold-vent system off the island of Vulcano, NE Sicily, with the aim of testing the hypothesis that periphyton assemblages respond to CO_2 gradients and characterizing any changes in diatom and cyanobacteria populations to better understand the ecological effects of real-world lower ocean pH levels .

The six scientists report periphyton communities were indeed "altered significantly as CO_2 concentrations increased," and "CO_2 enrichment caused significant increases in chlorophyll *a* concentrations and in diatom abundance." Furthermore, "by using chl *a* as an index of the photosynthetic standing crop (Underwood, 1984)," they say "periphyton biomass was found to increase substantially (fivefold) at the CO_2-enriched stations," indicating "elevations in CO_2 stimulate primary productivity in these benthic assemblages." Johnson *et al*. conclude lower ocean pH levels are "likely to have wide-ranging consequences from local-scale influences on the structure of overlying benthic communities to effects on food web structure and larger-scale biogeochemical cycles."

6.3.2.2 Macroalgae

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on macroalgae. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in

the bullet points are included in the main body of the section.)

- Cultures of two red macroalga grown in seawater treatments of + 650-ppm and +1,250-ppm CO_2 were enhanced by 20% and 60%, respectively, for *Gracilaria chilensis*, and by 130% and 190%, respectively, for *Gracilaria sp*.

- The ongoing rise in the air's CO_2 content likely will not "hasten the transformation of reef community structure from coral to algal dominance."

- "Elevated levels of CO_2 in seawater increase the growth rate of many seaweed species despite the variety of ways in which carbon is utilized in these algae."

- At twice the current ambient CO_2 concentration, daily net carbon gain and total wet biomass production rates of a red seaweed common to the Northeast Atlantic intertidal zone were 52 and 314% greater than under ambient CO_2 conditions.

- Slightly less than a doubling of the air's CO_2 concentration increased the mean relative growth rate of a brown seaweed from along the coast of Nanao Island, Shantou, China by about 50%, as well as its mean rate of nitrate uptake during the study's 12-hour light periods by some 200%, and its nitrate reductase activity by approximately 20% over a wide range of substrate nitrate concentrations.

- Elevated CO_2 experiments on eelgrass "led to significantly higher reproductive output, below-ground biomass and vegetative proliferation of new shoots in light-replete treatments."

- "Ocean acidification will stimulate seagrass biomass and productivity, leading to more favorable habitat and conditions for associated invertebrate and fish species."

- The global increase of CO_2 "may enhance seagrass survival in eutrophic coastal waters, where populations have been devastated by algal proliferation and reduced column light transparency."

- High pH values created by seagrass photosynthesis can help increase calcification rates of nearby marine organisms.

Gao *et al*. (1993) grew cultures of the red alga *Gracilaria sp*. and *G. chilensis* in vessels enriched with nitrogen and phosphorus continuously aerated with normal air of 350 ppm CO_2, air enriched with an extra 650 ppm CO_2, or air enriched with an extra 1,250 ppm CO_2 for 19 days. Compared to the control treatment, the relative growth enhancements in the +650-ppm and +1,250-ppm CO_2 treatments were 20% and 60%, respectively, for *G. chilensis*, and 130% and 190%, respectively, for *Gracilaria sp*. Gao *et al*. say these results suggest, "in their natural habitats or cultivation sites, photosynthesis and growth of *Gracilaria* species are likely to be CO_2-limited, especially when the population density is high and water movement is slow." As the air's CO_2 content continues to rise, these marine marcoalgae should be able to grow increasingly well. That also may be true of many other macroalgae, for Gao *et al*. note "photosynthesis by most macroalgae is probably limited by inorganic carbon sources in natural seawater," citing Surif and Raven (1989), Maberly (1990), Gao *et al*. (1991), and Levavasseur *et al*. (1991).

This finding might be construed to imply corals in a CO_2-enriched world may be out-competed by marine macroalgae, which, to quote Langdon *et al*. (2003), "are not conspicuous on healthy reefs, but due to various anthropogenic pressures … are becoming increasingly abundant." In an experiment they conducted at the Biosphere–2 facility near Oracle, Arizona (USA), where they studied gross primary production and calcification in a macrophyte-dominated ecosystem that had a coral cover of 3%, Langdon *et al*. found the ongoing rise in the air's CO_2 content will not "hasten the transformation of reef community structure from coral to algal dominance."

Xu *et al*. (2010) write, "*Gracilaria lemaneiformis* (Bory) Weber-van Bosse is an economically important red seaweed that is cultivated on a large scale in China due to the quantity and quality of agar in its cell walls." They note, "much attention has been paid to the biofiltration capacity of the species (Yang *et al*., 2005, 2006; Zhou *et al*., 2006)," and some researchers have suggested it to be "an excellent species for alleviating coastal eutrophication in China (Fei, 2004)." Xu *et al*. examined how this seaweed might respond to elevated CO_2. They grew plants from thalli collected at 0.5 m depth from a farm located in Shen'ao Bay, Nanao Island, Shantou (China) for 16 days in 3-L flasks of natural seawater maintained at either natural (0.5 µM) or high (30 µM) dissolved inorganic phosphorus (Pi) concentrations in contact with air of either 370 or 720 ppm CO_2,

measuring their photosynthetic rates, biomass production, and uptake of nitrate and phosphate.

As best as can be determined from Xu *et al*.'s graphical representations of their results, the 95% increase in the air's CO_2 concentration increased algal photosynthetic rates by only 5% in the natural Pi treatment but approximately 41% in the high Pi treatment. With respect to biomass production, the elevated CO_2 elicited a 48% increase in the natural Pi treatment but no increase in biomass in the high Pi treatment. The extra 29.5 µM Pi in the high Pi treatment itself had boosted biomass production of the low-CO_2 natural-Pi treatment by approximately 83%, and additional CO_2 did not increase growth rates beyond that point.

The three Chinese researchers write, "elevated levels of CO_2 in seawater increase the growth rate of many seaweed species despite the variety of ways in which carbon is utilized in these algae." They note "some species, such as *Porphyra yezoensis* Ueda (Gao *et al*., 1991) and *Hizikia fusiforme* (Harv.) Okamura (Zou, 2005) are capable of using HCO_3^-, but are limited by the current ambient carbon concentration in seawater," and "enrichment of CO_2 relieves this limitation and enhances growth." Regarding the results they obtained with *Gracilaria lemaneiformis*—which they say "efficiently uses HCO_3^- and whose photosynthesis is saturated at the current inorganic carbon concentration of natural seawater (Zou *et al*., 2004)"—they write, "the enhancement of growth could be due to the increased nitrogen uptake rates at elevated CO_2 levels," which in their experiment were 40% in the natural Pi treatment, because "high CO_2 may enhance the activity of nitrate reductase (Mercado *et al*., 1999; Gordillo *et al*., 2001; Zou, 2005) and stimulate the accumulation of nitrogen, which could contribute to growth."

Kubler *et al*. (1999) grew a red seaweed common to the Northeast Atlantic intertidal zone, *Lomentaria articulata*, for three weeks in hydroponic cultures subjected to various atmospheric CO_2 and O_2 concentrations to determine the effects of these gases on growth. They report oxygen concentrations ranging between 10 and 200% of ambient had no significant effects on daily net carbon gain or total wet biomass production rates in this seaweed. In contrast, CO_2 concentrations ranging between 67 and 500% of ambient had highly significant effects. At twice the current ambient CO_2 concentration, for example, daily net carbon gain and total wet biomass production rates were 52 and 314% greater than under ambient CO_2 conditions. Although this seaweed was likely carbon-saturated, when grown at five times the ambient CO_2 concentration it still exhibited daily net carbon gain and wet biomass production rates 23 and 50%, respectively, greater than those of control plants.

Zou (2005) collected specimens of a brown seaweed (*Hizikia fusiforme* (Harv.) Okamura) from intertidal rocks along the coast of Nanao Island, Shantou, China, and maintained them in glass aquariums in filtered natural seawater enriched with 60 µM $NaNO_3$ and 6.0 µM NaH_2PO_4, where they were continuously aerated with ambient air of 360 ppm CO_2 or enriched air of 700 ppm CO_2. He measured the specimens' relative growth and nitrogen assimilation rates and their nitrate reductase activities. The CO_2 enrichment increased the seaweed's mean relative growth rate by about 50%, its mean rate of nitrate uptake during the study's 12-hour light periods by 200%, and its nitrate reductase activity by approximately 20% over a wide range of substrate nitrate concentrations.

Zou notes "the extract of *H. fusiforme* has an immunomodulating activity on humans and this ability might be used for clinical application to treat several diseases such as tumors (Suetsuna, 1998; Shan *et al*., 1999)." He also reports the alga "has been used as a food delicacy and an herbal ingredient in China, Japan and Korea." He says it "is now becoming one of the most important species for seaweed mariculture in China, owing to its high commercial value and increasing market demand." In addition, Zou notes "the intensive cultivation of *H. fusiforme* would remove nutrients more efficiently with the future elevation of CO_2 levels in seawater, which could be a possible solution to the problem of ongoing coastal eutrophication."

Palacios and Zimmerman (2007) conducted an experiment on eelgrass (*Zostera marina*) at the Duke Energy-North America Power Plant at Moss Landing, California (USA), where flue gas generated by the power plant furnace was piped approximately 1 km to a site where it was bubbled through outdoor flow-through seawater aquaria at rates that produced four aqueous CO_2 treatments characteristic of: "(1) the present day atmosphere, with approximately 16 µM CO_2(aq), (2) CO_2 projected for 2100 that increases the CO_2(aq) concentration of seawater to approximately 36 µM CO_2(aq), (3) CO_2 projected for 2200 that increases the CO_2(aq) concentration of seawater to 85 µM CO_2(aq), and (4) a dissolved aqueous CO_2 concentration of 1123 µM CO_2(aq), which triples the light-saturated photosynthesis rate of eelgrass (Zimmerman *et al*., 1997)."

The researchers found elevated CO_2 "led to significantly higher reproductive output, below-ground biomass and vegetative proliferation of new shoots in light-replete treatments," those receiving light at 33% of the surface irradiance level. They write, "shoots growing at 36 µM $CO_2(aq)$ were 25% larger than those in the unenriched treatment [16 µM $CO_2(aq)$]," and "at 85 µM $CO_2(aq)$ shoots were 50% larger than those in the unenriched treatment and at 1123 µM $CO_2(aq)$ shoots were almost twice as large as those in the unenriched treatment." They found at 1123 µM $CO_2(aq)$ "22% of the shoots differentiated into flowers, more than twice the flowering output of the other treatments at this light level."

Noting "increased $CO_2(aq)$ is capable of increasing eelgrass reproductive output via flowering, and area-specific productivity via vegetative shoot proliferation under naturally replete light regimes," Palacios and Zimmerman state "the resulting increases in eelgrass meadow density may initiate a positive feedback loop that facilitates the trapping of sediments and prevents their resuspension, thereby reducing turbidity and increasing light penetration in coastal habitats," such that the resulting increased light penetration "may allow seagrass colonization depths to increase even further."

The two researchers also suggest the CO_2-induced increase in the productivity of eelgrass may "enhance fish and invertebrate stocks as well." They suggest the "deliberate injection of CO_2 to seawater may facilitate restoration efforts by improving the survival rates of recently transplanted eelgrass shoots," noting "it can buffer the negative effects of transplant shock by increasing rhizome reserve capacity and promoting shoot proliferation in light-replete environments." In addition, they say it "may also facilitate eelgrass survival in environments where conditions are periodically limiting, such as long dark winters or unusually warm summers that produce unfavorable productivity to respiration ratios," and "CO_2 injection may also promote flowering and seed production necessary for expansion and maintenance of healthy eelgrass meadows." Finally, they suggest "rising concentrations of $CO_2(aq)$ may increase vegetative propagation and seed production of other seagrass populations besides eelgrass."

According to Suarez-Alvarez et al. (2012), "the increase of coastal activities which produce important amounts of wastes, including inorganic nutrients (Troell et al., 2003), makes micro- and macroalgae interesting organisms to predict possible impacts, responses, and remediation processes by considering biomass production through cultivation techniques,"

citing Gao et al. (1991, 1993), Gao and McKinley (1994), Keffer and Kleinheinz (2002), Doucha et al. (2005), and Israel et al. (2005). They note, "macroalgae, in particular, have been the object of additional interest for CO_2 remediation (Gao and McKinley, 1994) because of their solar energy conversion capacity, high productivity values (higher than most productive terrestrial crops) and the possibility of being, in many cases, intensively cultivated."

Suarez-Alvarez et al. cultivated 8-gram fragments of the macroalga *Hypnea spinella* in 1-L flasks containing filtered seawater enriched with 140 µM NH_4Cl and 14 µM KH_2PO_4 for seven days of acclimation. They then culled the plants to their initial density and grew them for nine more days at ambient (360 ppm), 750, or 1,600 ppm atmospheric CO_2, measuring various plant physiological properties and processes. The authors report light-saturated net photosynthesis rates in the 750 ppm and 1,600 ppm CO_2 treatments were 41.5% and 50.5% greater, respectively, than in the 360 ppm treatment. Relative growth enhancements were 85.6% and 63.2% greater, respectively, and maximum ammonium uptake rates were enhanced by 24.2% and 19.9%, respectively. "From a practical point of view," Suarez-Alvarez et al. write, "these results suggest that intensive culture of *H. spinella* operated in biofilters might be enhanced by CO_2 supply to generate higher biomass productivities and better nitrogen biofiltration efficiencies," and "the use of flue gases for this purpose would also improve the ability of bioremediation of these biofilters, as has already been tested for *Gracilaria cornea*," citing Israel et al. (2005).

Jiang et al. (2010) note "seagrasses are flowering plants that thrive in shallow oceanic and estuarine waters around the world, and are ranked as one of the most ecologically and economically valuable biological systems on Earth," citing Beer et al. (2006). They also observe *Thalassia hemprichii* "is among the most widely-distributed seagrass species in an Indo-Pacific flora, dominating in many mixed meadows," citing Short et al. (2007). They collected intact vegetative plants of *T. hemprichii* from Xincun Bay of Hainan Island, Southern China, which they transported to the laboratory and cultured in flow-through seawater aquaria bubbled with four concentrations of CO_2 representative of the present global ocean, with a pH of 8.10; the projected ocean for 2100, with a pH of 7.75; the projected ocean for 2200, with a pH of 7.50; and the ocean characteristic of "an extreme beyond the current predictions" (a 100-fold

increase in free CO_2, with a pH of 6.2).

The three researchers found the "leaf growth rate of CO_2-enriched plants was significantly higher than that in the unenriched treatment," "nonstructural carbohydrates (NSC) of *T. hemprichii*, especially in belowground tissues, increased strongly with elevated CO_2," and "belowground tissues showed a similar response with NSC." The Chinese scientists list several implications of their finding that "CO_2 enrichment enhances photosynthetic rate, growth rate and NSC concentrations of *T. hemprichii*." With higher atmospheric CO_2 concentrations, they write, "colonization beyond current seagrass depth limits is possible," the extra stored NSC "can be used to meet the carbon demands of plants during periods of low photosynthetic carbon fixation caused by severe environmental disturbance such as underwater light reduction," it can enhance "rhizome growth, flowering shoot production and vegetative proliferation," and it "may buffer the negative effects of transplant shock by increasing rhizome reserve capacity." They also write, "the globally increasing CO_2 may enhance seagrass survival in eutrophic coastal waters, where populations have been devastated by algal proliferation and reduced column light transparency." They conclude "ocean acidification will stimulate seagrass biomass and productivity, leading to more favorable habitat and conditions for associated invertebrate and fish species."

Wu *et al.* (2008) listed several known effects of a CO_2-enriched atmosphere on micro- and macro-algae living in the world's oceans. According to the authors, "enriched CO_2 up to several times the present atmospheric level has been shown to enhance photosynthesis and growth of both phytoplanktonic and macro-species that have less capacity of CCMs [CO_2-concentrating mechanisms]," and "even for species that operate active CCMs and those whose photosynthesis is not limited by CO_2 in seawater, increased CO_2 levels can down-regulate their CCMs and therefore enhance their growth under light-limiting conditions," because "at higher CO_2 levels, less light energy is required to drive CCM." They report enhanced CO_2 levels have been found to enhance the activity of nitrogen reductase in several marine plants, and this phenomenon "would support enhanced growth rate by providing adequate nitrogen required for the metabolism under the high CO_2 level." They write, "altered physiological performances under high-CO_2 conditions may cause genetic alteration in view of adaptation over long time scales," and "marine algae may adapt to a high CO_2 oceanic environment so that evolved communities in

[the] future are likely to be genetically different from contemporary communities."

Semesi *et al.* (2009) investigated whether diel variations in seawater pH caused by the photosynthetic activity of seagrass meadows within Chwaka Bay (Zanzibar, Tanzania) could affect the calcification and photosynthesis rates of calcareous red algae (*Hydrolithon* sp. and *Mesophyllum* sp.) and green algae (*Halimeda renschii*) growing within the marine meadows. They measured rates of calcification and relative photosynthetic electron transport (rETR) of the algae *in situ* in open-bottom incubation cylinders either in the natural presence of the rooted seagrasses or after their leaves had been removed.

Semesi *et al.* report "seagrass photosynthesis increased the seawater pH within the cylinders from 8.3–8.4 to 8.6–8.9 after 2.5 hours (largely in conformity with that of the surrounding seawater), which, in turn, enhanced the rates of calcification 5.8-fold for *Hydrolithon* sp. and 1.6-fold for the other 2 species." They also found "the rETRs of all algae largely followed the irradiance throughout the day and were (in *Mesophyllum* sp.) significantly higher in the presence of seagrasses." The three researchers conclude "algal calcification within seagrass meadows such as those of Chwaka Bay is considerably enhanced by the photosynthetic activity of the seagrasses, which in turn increases the seawater pH."

They state the high pH values created by seagrass photosynthesis are what caused the elevated calcification rates of the macroalgae, and this observation has further implications. It suggests, for example, the lowering of seawater pH caused by higher atmospheric CO_2 concentrations—which results in a lowering of the calcium carbonate saturation state of seawater, and which has been predicted to lead to reductions in coral calcification rates—may be counteracted by CO_2-induced increases in the photosynthetic activity of the symbiotic zooxanthellae of Earth's corals, which may boost the pH of seawater in intimate contact with the coral host, allowing the host to *increase* its calcification rate in CO_2-enriched seawater, or at least not suffer a major reduction in calcification.

Smith *et al.* (2013) provide additional support for this thesis. They state, "benthic marine primary producers affect the chemistry of their surrounding environment through metabolic processes." They note, "photosynthesis and respiration will elevate or depress the concentration of oxygen in the diffusive boundary layer," and "acid-base regulation and

biomineralization/dissolution for calcifying species can alter the relative concentration of inorganic carbon species and thus pH."

To compare species-specific rates of change in pH and oxygen concentrations over a diel cycle for several species of common benthic coral reef organisms—including corals, turf algae, and fleshy and calcifying macroalgae—Smith *et al*. assessed the generality of results across divergent types of reefs in the Caribbean and Pacific. They found "more productive fleshy taxa have the potential to raise both oxygen and pH during the day to a greater extent than calcified species." This discovery, as well as similar observations reported by Anthony *et al*. (2011) and Kleypas *et al*. (2011), suggest "non-calcifying primary producers, especially those driving large amplitudes in diurnal pH fluctuations, may be important 'buffer organisms' against potential ocean acidification on coral reefs." They write, "while particular species of macroalgae can negatively affect corals in a variety of ways," some fleshy algae "may provide a buffering capacity to future ocean acidification scenarios."

Johnson *et al*. (2012) note, "CO_2 gradients in natural settings, where whole ecosystems have been exposed to elevated levels of CO_2, allow us to investigate changes in the interactions, competition, predation and/or herbivory that involve long-lived metazoan species in benthic marine ecosystems." They observe, "volcanic CO_2 gradients are beginning to reveal the ecological shifts that can be expected to occur with globally increasing atmospheric CO_2 in both temperate (Hall-Spencer *et al*., 2008) and tropical ecosystems (Fabricius *et al*., 2011)." Johnson *et al*. assessed the abundance of herbivores (sea urchins) and the response of brown macroalgae (*Padina* spp.) to increasing levels of CO_2 in two natural settings. One of the sites was a set of shallow, volcanic CO_2 seeps on the island of Vulcano, NE Sicily, where *P. pavonica* was studied. The other site, where they studied *P. australis*, was a comparable set of seeps in the D'Entrecasteaux Island group, Papua New Guinea.

The five scientists found "a reduction in sea urchin abundances alongside a proliferation of *Padina* spp., as CO_2 levels increased" along both temperate and tropical rocky shores. The predator sea urchins were absent from locations that had the highest CO_2 levels (lowest pH), while "even in the lowest pH conditions, *P. pavonica* and *P. australis* were still able to calcify, seemingly from the enhancement of photosynthesis under high levels of CO_2."

Johnson *et al*. suggest the absence of sea urchins

in the CO_2-enriched areas "may be one explanation for the proliferation of *Padina* spp., as it becomes released from the top-down control by these keystone grazers," noting "this effect of sea urchin removal has been observed in other *Padina* sp. populations (Sammarco *et al*., 1974) and across other Phaeophyte assemblages (Leinaas and Christie, 1996; Ling *et al*., 2010)." They note "increased photosynthetic activity at high CO_2 has also been observed in other calcified macroalgae (Reiskind *et al*., 1988; Semesi *et al*., 2009)," and in "non-calcified macroalgae (Kubler *et al*., 1999; Connell and Russell, 2010; Russell *et al*., 2011)."

6.3.3 Effects on Marine Animals

6.3.3.1 Bivalves

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on marine bivalves. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Juvenile king scallops display a tolerance to lower ocean pH levels at pCO_2 levels below 1,600 ppm.

- Mussel larvae (*Mytilus edulis*) reared in a laboratory setting mimicking a cold-water environment revealed "no marked effect on fertilization success, development time, or abnormality to the D-shell stage, or on feeding of mussel larvae" from lower ocean pH levels , and under such conditions (pH 7.6) the larvae "were still able to develop a shell in seawater under-saturated with respect to aragonite."

- A laboratory experiment examining "the combined effects of elevated pCO_2 and food availability on juvenile *M. edulis* growth and calcification" showed "only minor impacts of pCO_2 up to 3350 µatm."

- At a naturally CO_2-enriched ocean site, growth and calcification rates of *M. edulis* were "seven times higher" at an "inner fjord field station (mean pCO_2 ca. 1000 µatm) in comparison to a low pCO_2 outer fjord station (ca. 600 µatm)," demonstrating "a high inherent resilience of calcifying benthic communities in an estuarine, eutrophic habitat to elevated seawater pCO_2," where "food supply, and not pCO_2, appears to be the primary factor driving biomass and biogenic $CaCO_3$ production, as well as community structure."

- "Selective breeding may be a solution to 'climate-proof' [the Sydney rock oyster] from the impacts of ocean acidification."

- Larvae spawned from adult Sydney rock oysters (*Saccostrea glomerata*) growing in elevated CO_2 (reduced pH) seawater "were larger and developed faster" than those spawned from adults growing under ambient conditions, suggesting "previous studies that have investigated the effects of elevated CO_2 on the larvae of molluscs and other marine organisms [whose predecessors had not been exposed to elevated CO_2] may overestimate the severity of their responses" to lower ocean pH levels.

- Sperm swimming speeds and fertilization success of the Pacific oyster (*Crassostrea gigas*) are slightly increased under lower ocean pH levels.

- Effects of lower ocean pH levels on *Crassostrea gigas* larvae "during the first three days of development are not significant as long as CO_3^{2-} concentrations remain above aragonite saturated conditions."

- The "pre-adapted ability to resist a wide range of decreased pH may provide *C. gigas* with the necessary tolerance to withstand rapid pH changes over the coming century."

- The discovery of four-decades-old mussels living "in natural conditions of pH values between 5.36 and 7.29" attest to "the extent to which long-term adaptation can develop tolerance to extreme conditions."

Sanders *et al*. (2013) "investigated the effects on oxygen consumption, clearance rates and cellular turnover in juvenile [king scallop] *Pecten maximus* following three months' laboratory exposure to four *p*CO_2 treatments (290, 380, 750, and 1140 ppm)." The four researchers state "none of the exposure levels were found to have significant effects on the clearance rates, respiration rates, condition index or cellular turnover (RNA:DNA) of individuals." These findings are compatible with those of Anderson *et al*. (2013), who also studied the growth, development, and survival of the initial larval stages of *P. maximus* and found them to be susceptible to the deleterious effects of lower ocean pH levels only at *p*CO_2 levels of 1,600 ppm and above. Sanders *et al*. conclude their results suggest "where food is in abundance, bivalves like juvenile *P. maximus* may display a tolerance to limited changes in seawater chemistry."

Berge *et al*. (2006) collected blue mussels (*Mytilus edulis* L.) from the outer part of the Oslofjord outside the Marine Research Station Solbergstrand in Norway and placed them in five 5-L aquariums continuously supplied with low-food-supply seawater extracted from the top meter of the Oslofjord outside the Marine Research Station Solbergstrand in Norway, continuously adding CO_2 to the waters of the aquaria so as to maintain them at five pH values (means of 8.1, 7.6, 7.4, 7.1, and 6.7) for 44 days. Shell lengths at either the time of death or at the end of the study were determined and compared to lengths measured at the start of the study.

According to the authors, "the increased concentration of CO_2 in the water and the correspondingly reduced pH had no acute effects on the mussels." The Norwegian researchers report, "mean increments of shell length were much lower for the two largest CO_2 additions compared to the values in the controls, while for the two smallest doses the growth [was] about the same as in the control, or in one case even higher," such that there were "no significant differences between the three aquaria within the pH range 7.4–8.1."

Berge *et al*. conclude their results "indicate that future reductions in pH caused by increased concentrations of anthropogenic CO_2 in the sea may have an impact on blue mussels," but "comparison of estimates of future pH reduction in the sea (Caldeira and Wickett, 2003) and the observed threshold for negative effects on growth of blue mussels [which they determined to lie somewhere between a pH of 7.4 and 7.1] do however indicate that this will probably not happen in this century." Caldeira and Wickett's calculation of the maximum level to which the air's CO_2 concentration might rise yields a value that approaches 2,000 ppm around the year 2300, representing a surface oceanic pH reduction of 0.7 units, which drops the pH only to 7.4, the upper limit of the "threshold for negative effects on growth of blue mussels" found by Berge *et al*.

Noting "there is a particular need to study effects of OA [lower ocean pH levels] on organisms living in cold-water environments due to the higher solubility of CO_2 at lower temperatures," Bechmann *et al*. (2011) maintained mussel (*Mytilus edulis*) larvae in a laboratory setting under the OA scenario predicted for the year 2100 (pH 7.6) and compared them against batches of larvae held under the current oceanic pH of 8.1 (the control treatment), keeping water temperature at a constant 10°C. They found "no marked effect on fertilization success, development time, or abnormality to the D-shell stage, or on feeding of mussel larvae in the low-pH treatment,"

and the *M. edulis* larvae "were still able to develop a shell in seawater under-saturated with respect to aragonite (a mineral form of $CaCO_3$)." They also found after two months of exposure the mussels were 28% smaller in the pH 7.6 treatment than in the control treatment. They write, "if only the larger larvae settle and survive in the field, the effects of OA on the mussel population may not be dramatic."

Thomsen *et al.* (2010) note, "as most laboratory experiments cannot account for species genetic adaptation potential, they are limited in their predictive power." Thus studies investigating "naturally CO_2-enriched habitats" have "recently gained attention, as they could more accurately serve as analogues for future, more acidic ecosystems." Thomsen *et al.* studied the macrobenthic community in Kiel Fjord, a naturally CO_2-enriched site in the Western Baltic Sea dominated by calcifying marine invertebrates. They determined in 34%, 23%, and 9% of the 42 weeks they were there, the partial pressure (*p*) of CO_2 in the water exceeded preindustrial pCO_2 (280 ppm) by a factor of three (>840 ppm), four (>1,120 ppm), and five (>1,400 ppm), respectively.

The German scientists report juvenile blue mussel (*Mytilus edulis*) recruitment "peaks during the summer months, when high water pCO_2 values of ~1000 ppm prevail." Their short-term laboratory research indicates "blue mussels from Kiel Fjord can maintain control rates of somatic and shell growth at a pCO_2 of 1400 ppm." At 4,000 ppm pCO_2, however, both shell mass and extension rates were significantly reduced; but "regardless of the decreased rates of shell growth at higher [1,400] pCO_2, all mussels increased their shell mass at least by 150% during the 8-week trial, even at Ωarg (Ωcalc) as low as 0.17 (0.28)," where Ω is the calcium carbonate saturate state of either aragonite (arg) or calcite (calc).

Thomsen *et al.* conclude it is likely "long-term acclimation to elevated pCO_2 increases the ability to calcify in *Mytilus* spp.," citing Michaelidis *et al.* (2005) and Ries *et al.* (2009) in addition to their own study. They say they could find "no causal relationship between the acid-base status and metabolic depression in this species at levels of ocean acidification that can be expected in the next few hundred years (IPCC, 2007)," after discovering in the waters of Kiel Fjord (and demonstrating in the laboratory) "communities dominated by calcifying invertebrates can thrive in CO_2-enriched coastal areas."

Working at the same location three years later with a different set of coauthors in a similarly coupled laboratory and field study, Thomsen *et al.* (2013)

examined "the annual pCO_2 variability in [the Kiel Fjord] habitat and the combined effects of elevated pCO_2 and food availability on juvenile *M. edulis* growth and calcification." In the laboratory experiment, "mussel growth and calcification were found to chiefly depend on food supply, with only minor impacts of pCO_2 up to 3,350 µatm." In the field location (Kiel Fjord), where maximum pCO_2 values experienced during the summer were about 2,500 µatm at the surface of the fjord and more than 3,000 µatm at its bottom, they observed "seven times higher growth and calcification rates of *M. edulis* at a high pCO_2 inner fjord field station (mean pCO_2 ca. 1,000 µatm) in comparison to a low pCO_2 outer fjord station (ca. 600 µatm)." They note this high inner fjord productivity "was enabled by higher particulate organic carbon concentrations," as a result of the fjord's "being "highly impacted by eutrophication, which causes bottom water hypoxia and consequently high seawater pCO_2." Thomsen *et al.* conclude their study demonstrates "a high inherent resilience of calcifying benthic communities in an estuarine, eutrophic habitat to elevated seawater pCO_2," where "food supply, and not pCO_2, appears to be the primary factor driving biomass and biogenic $CaCO_3$ production, as well as community structure."

Range *et al.* (2011) conducted a 75-day controlled CO_2 perturbation experiment designed to test the effects of increased pCO_2 and reduced pH of seawater on the calcification, growth, and mortality of juvenile *Ruditapes decussatus* clams. They manipulated the carbonate chemistry of seawater by diffusing pure CO_2 into natural seawater to attain two reduced pH levels (by -0.4 and -0.7 pH unit compared to unmanipulated seawater). The authors hypothesized the juvenile clams would exhibit reduced net calcification, reduced growth of the shell and soft tissue, and increased mortality in the lower-pH conditions. At the conclusion of their experiment, however, the eight researchers found "no differences among pH treatments in terms of net calcification, size or weight of the clams," disproving the first two of their three hypotheses. Their third hypothesis also proved to be wrong—doubly wrong, in fact—for not only was juvenile clam mortality not increased in the low-pH seawater, mortality was significantly reduced in the acidified treatments, which they describe as an "unexpected result."

The Portuguese scientists conclude by noting life is intriguingly complex and "the generalized and intuitively attractive perception that calcification will be the critical process impacted by ocean acidification is being increasingly challenged," citing Widdicombe

and Spicer (2008) and Findlay *et al*. (2009).

To provide a better understanding of the potential for the Sydney rock oyster (*Saccostrea glomerata*) to adapt to the threat of lower ocean pH levels , Parker *et al*. (2011) measured the within- and between-population variability in the species' growth response to elevated pCO_2, working with oysters (denoted as *wild*) they collected from intertidal and shallow subtidal habitats along the southeast coast of Australia, as well as two lines (QB and LKB) of the same species that had been selectively bred to support the country's oyster aquaculture industry. The authors report the wild oysters experienced a 64% reduction in growth after four days in an elevated pCO_2 environment of 1,000 ppm (with a water pH of 7.84) compared to wild oysters reared in the ambient pCO_2 environment of 375 ppm (with a water pH of 8.20). The growth reduction experienced by QB oysters growing in the same two environments was 45%, and that experienced by LKB oysters was 25%. They report the LKB oysters reared at elevated pCO_2 "grew slightly better than the wild oysters reared at ambient pCO_2." Such observations, Parker *et al*. write, provide "preliminary evidence that selective breeding may be a solution to 'climate-proof' important aquaculture industries from the impacts of ocean acidification."

Parker *et al*. (2012) introduce their follow-up study by noting analyses of the impact of lower ocean pH levels on marine organisms conducted to date "have only considered the impacts on 'adults' or 'larvae,' ignoring the potential link between the two life-history stages and the possible carry-over effects that may be passed from adult to offspring," citing Dupont *et al*. (2010), Hendriks *et al*. (2010), and Kroeker *et al*. (2010). Parker *et al*. placed adults of wild-collected and selectively bred populations of the Sydney rock oyster (*Saccostrea glomerata*), obtained at the beginning of reproductive conditioning, in seawater equilibrated with air of either 380 ppm CO_2 or 856 ppm CO_2 which produced seawater pH values of 8.2 and 7.9, respectively, after which they measured the development, growth, and survival responses of the two sets of larvae.

The six scientists found "larvae spawned from adults exposed to elevated PCO_2 were larger and developed faster." In addition, "selectively bred larvae of *S. glomerata* were more resilient to elevated CO_2 than wild larvae," as "measurement of the standard metabolic rate (SMR) of adult *S. glomerata* showed that at ambient CO_2, SMR is increased in selectively bred compared with wild oysters," and it is further increased "during exposure to elevated CO_2." These findings suggest "previous studies that have

investigated the effects of elevated CO_2 on the larvae of molluscs and other marine organisms [whose predecessors had not been exposed to elevated CO_2] may overestimate the severity of their responses." They conclude "marine organisms may have the capacity to acclimate or adapt to elevated CO_2 over the next century."

Miller *et al*. (2009) grew larvae of two oyster species—the Eastern oyster (*Crassostrea virginica*) and the Suminoe oyster (*Crassostrea ariakensis*)—for up to 28 days in estuarine water in equilibrium with air of four CO_2 concentrations (280, 380, 560, and 800 ppm) chosen to represent atmospheric conditions in the preindustrial era, the present day, and the years 2050 and 2100, respectively, as projected by the IS92a business-as-usual scenario of IPCC. They maintained these levels by periodically aerating the aquaria with air containing 1% CO_2, assessing larval growth via image analysis and determining calcification by means of chemical analyses of calcium in the shells of the oyster larvae.

When the larvae of both species were cultured continuously from 96 hours post fertilization for 26 to 28 days while exposed to elevated CO_2 concentrations, they "appeared to grow, calcify and develop normally with no obvious morphological deformities, despite conditions of significant aragonite undersaturation." The scientists state these findings "run counter to expectations that aragonite shelled larvae should be especially prone to dissolution at high pCO_2." They note, "both oyster species generated larval shells that were of similar mean thickness, regardless of pCO_2, Ωarag [aragonite compensation point] or shell area," remarking they "interpret the pattern of similar shell thickness as further evidence of normal larval shell development."

Working with another oyster species (*Crassostrea gigas*), Havenhand and Schlegel (2009) observed and measured sperm swimming behavior and fertilization kinetics in response to lower ocean pH levels . The oysters, collected from a mixed mussel/oyster bed on the coast of western Sweden, were kept in flow-through tanks of filtered sea water the scientists maintained at either the normal ambient pH level or a level reduced by about 0.35 units they created by bubbling CO_2 through the water. In water of pH 8.15, mean sperm swimming speeds were $92.1 \pm 4.8 \mu m/s$, whereas in water of pH 7.8 they were slightly higher, at $94.3 \pm 5.5 \mu m/s$, although the difference was not statistically significant. Mean fertilization success in water of pH 8.15 was 63.4%, whereas in water of pH 7.8 it was also slightly higher, at 64.1%; this difference, too, was not statistically significant.

The Swedish scientists state "the absence of significant overall effects of pH on sperm swimming behavior and fertilization success is remarkable," emphasizing power analyses they conducted "showed clearly that these results were not due to inadequate statistical power," and "the absence of significant effect is likely a true reflection of the responses of *Crassostrea gigas* gametes and zygotes from the Swedish west coast to levels of CO_2-induced acidification expected by the end of this century."

Gazeau *et al*. (2011) assessed "the impact of several carbonate-system perturbations on the growth of Pacific oyster (*Crassostrea gigas*) larvae during the first three days of development (until shelled D-veliger larvae)." They used filtered seawater obtained from the Oosterschelde (a nearby tidal inlet) with five chemistries obtained "by separately manipulating pH, total alkalinity and aragonite saturation state." The seven scientists report "developmental success and growth rates were not directly affected by changes in pH or aragonite saturation state but were highly correlated with the availability of carbonate ions ... as long as carbonate ion concentrations were above aragonite saturation levels." When carbonate ion concentrations dropped below aragonite saturation levels, they found growth and development "strongly decreased."

Gazeau *et al*. conclude, "the effects of ocean acidification on larvae of *Crassostrea gigas* from the Oosterschelde estuary during the first three days of development are not significant as long as CO_3^{2-} concentrations remain above aragonite saturated conditions." They add, "due to relatively high levels of total alkalinity in this area, it is not expected that seawater will become corrosive for aragonite following a decrease of 0.3 to 0.4 pH unit."

The French, English, and Dutch researchers also write, "most calcifying species, including mollusks, are able to concentrate Ca^{2+} and CO_3^{2-} ions at the site of calcification (McConnaughey and Gillikin, 2008)," and the bivalves they studied "should therefore be able to regulate calcification rates under suboptimal concentrations of Ca^{2+} and CO_3^{2-}." They note, "Thomsen *et al*. (2010) have shown that blue mussels are actively growing in a bay of the Western Baltic Sea naturally enriched with high CO_2 water," and "juvenile recruitment occurs in summer time coinciding with low pH levels and aragonite under-saturated conditions." Thus the evidence indicates lower ocean pH levels will not seriously affect mollusks.

Ginger *et al*. (2013) note, "our knowledge of the effect of reduced pH on *C. gigas* larvae presently relies presumptively on four short-term (< 4 days) survival and growth studies." They studied "the effects of long-term (40 days) exposure to pH 8.1, 7.7 and 7.4 on larval shell growth, metamorphosis, respiration and filtration rates at the time of metamorphosis," as well as the juvenile shell growth and structure of *C. gigas*. The seven scientists discovered "mean survival and growth rates were not affected by pH"; "the metabolic, feeding and metamorphosis rates of pediveliger larvae were similar, between pH 8.1 and 7.7"; "the pediveligers at pH 7.4 showed reduced weight-specific metabolic and filtration rates, yet were able to sustain a more rapid post-settlement growth rate"; and "no evidence suggested that low pH treatments resulted in alterations to the shell ultra-structures or elemental compositions (i.e., Mg/Ca and Sr/Ca ratios)." Ginger *et al*. conclude "larval and post-larval forms of the *C. gigas* in the Yellow Sea are probably resistant to elevated CO_2 and decreased near-future pH scenarios." They note "the pre-adapted ability to resist a wide range of decreased pH may provide *C. gigas* with the necessary tolerance to withstand rapid pH changes over the coming century."

Working with juvenile *Mytilus galloprovincialis* specimens obtained from a mussel raft in the Ria de Ares-Betanzos of Northwest Spain and reared in an experimental bivalve hatchery in Tavira, Portugal, Fernandez-Reiriz *et al*. (2012) tested the effects of three levels of seawater acidification caused by increasing concentrations of atmospheric CO_2: a natural control level plus two lesser levels of pH, one reduced by 0.3 pH unit and another reduced by 0.6 pH unit. They measured several responses of the mussels after 78 days of exposure to the three sets of pH conditions, focusing on clearance and ingestion rate, absorption efficiency, oxygen consumption, ammonia excretion, oxygen to nitrogen ratio, and scope for growth. The five researchers found no significant differences for clearance, ingestion, and respiration rates. The absorption efficiency and ammonium excretion rate of the juvenile mussels were inversely related to the 0.6 pH reduction, while the maximal scope for growth and tissue dry weight also were observed in the mussels exposed to the pH reduction of 0.6 unit. Fernandez-Reiriz *et al*. conclude their results suggest *M. galloprovincialis* "could be a tolerant ecophysiotype to CO_2 acidification, at least in highly alkaline coastal waters," noting, "mytilids are also able to dominate habitats with low alkalinity and high pCO_2," citing Thomsen *et al*. (2010).

Working with the same species of mussels obtained from the same location off the coast of

Northwest Spain under an identical pH regime, Range *et al.* (2012) tested the effects of seawater acidification on growth, calcification, and mortality of six-month-old juveniles. The eight researchers found the growth of the mussels, measured as relative increases in shell size and body weight during the 84 days of the experiment, "did not differ among treatments." A tendency for faster shell growth under elevated CO_2 was apparent, "at least during the first 60 days of exposure." They note calcification was reduced under elevated CO_2, but by only up to 9%. They state, "given that growth was unaffected, the mussels clearly maintained the ability to lay down $CaCO_3$, which suggests post-deposition dissolution as the main cause for the observed loss of shell mass." They also write, "mortality of the juvenile mussels during the 84 days was small (less than 10%) and was unaffected by the experimental treatments." The Portuguese scientists conclude "there is no evidence of CO_2-related mortalities of juvenile or adult bivalves in natural habitats, even under conditions that far exceed the worst-case scenarios for future ocean acidification (Tunnicliffe *et al.*, 2009)."

Tunnicliffe *et al.* (2009) studied *Bathymodiolus brevior*, "a vent-obligate species that relies partly on symbiotic sulphide-oxidizing bacteria for nutrition (von Cosel and Metivier, 1994)" and is found "at many sites in the western Pacific Ocean, where it occupies habitats of low hydrothermal fluid flux." Using remotely operated vehicles to collect mussel specimens, water samples, and imagery, Tunnicliffe *et al.* examined dense clusters of the vent mussel "in natural conditions of pH values between 5.36 and 7.29 on the northwest Eifuku volcano, Mariana arc, where liquid carbon dioxide and hydrogen sulfide emerge in a hydrothermal setting." They studied the vent mussels clusters along with mussels from "two sites in the southwestern Pacific: Hine Hina in the Lau backarc basin and Monowai volcano on the Kermadec arc," where "the same mussel species nestles in cracks and rubble where weak fluid flow emerges."

Based on the pH values they observed, the authors calculated saturation ratios for calcite (Ω_{calc}) ranging from 0.01 to 0.61, with an average value of only 0.18. They discovered "a dense mussel population, along with many other associated species (Limen and Juniper, 2006), on NW Eifuku, where chemosynthetic symbiosis provides an energetic benefit to living in a corrosive, low-pH environment." Tunnicliffe *et al.* say these findings attest to "the extent to which long-term adaptation can develop tolerance to extreme conditions." They report

discovering four-decades-old mussels living at the sites they visited, stating "the mussels' ability to precipitate shells in such low-pH conditions is remarkable."

In another study using extreme environmental conditions, Hammer *et al.* (2011) exposed specimens of the deep-sea bivalve *Acesta excavata* collected from cold-water reefs to water maintained in equilibrium with an atmospheric CO_2 concentration of approximately 33,000 ppm, which resulted in a pH value of 6.35—corresponding to conditions reported for water in close proximity to natural CO_2 seeps on the ocean floor—for periods of 0.5, 1, 4, 12, 24, or 96 hours, after which they retuned the bivalves to normal CO_2/pH conditions for 1, 4, 12, 24, or 96 hours. The three researchers report the exposure of *A. excavata* to water in equilibrium with the super-high CO_2 concentration "induced extra- and intra-cellular acidosis that remained uncompensated during exposure," and "oxygen consumption dropped significantly during the initial phase." They found it "approached control values at the end of exposure" and "no mortality was observed in exposed animals."

These observations, the researchers write, show "*A. excavata* displays higher tolerance to severe environmental hypercapnia [a condition where there is too much CO_2 in the blood] than what may be expected for deep-sea animals." They note Tunnicliffe *et al.* (2009) "found evidence that permanent exposure to similar conditions causes reduced growth rates and shell thickness in mussels adapted to live at deep-sea vents," and they speculate "such long-term effects may also develop in *A. excavata*." They note previous studies on other species that mostly involved exposure of fish to moderate hypercapnia (P_{CO2} = 10,000 ppm or less) frequently observed complete compensation of extracellular acidosis, citing Heisler (1984, 1986), and "marine invertebrates are often able to partially counteract acidosis through accumulation of bicarbonate ions," citing Lindinger *et al.* (1984), Portner *et al.* (1988), Michaelidis *et al.* (2005), Miles *et al.* (2007), Pane and Barry (2007), and Gutowska *et al.* (2010).

6.3.3.2 Corals

Some scientists predict the ongoing rise in the air's CO$_2$ content will play havoc with Earth's coral reefs in two ways: by stimulating global warming, which has been predicted to dramatically enhance coral bleaching, and by lower ocean pH levels , which is projected to lower the calcium carbonate saturation state of seawater and thereby reduce coral calcification rates. The first of these predictions was examined in Section 6.1.2 of this chapter. The topic of lower ocean pH levels is addressed here.

Several researchers have postulated many of Earth's corals are destined to die, with some species even facing extinction, because of the hypothesized connection between the ongoing rise in the air's CO$_2$ content and reduced rates of coral calcification (Buddemeier, 1994; Buddemeier and Fautin, 1996a,b; Gattuso *et al.*, 1998; Buddemeier, 2001). Kleypas *et al.* (1999), for example, calculated calcification rates of tropical corals already should have declined by 6 to 11% or more since 1880, as a result of the increase in atmospheric CO$_2$ concentration, and they predict the reductions could reach 17 to 35% by 2100 as a result of expected increases in the air's CO$_2$ content in the coming decades. Langdon *et al.* (2000) calculated a decrease in coral calcification rate of up to 40% between 1880 and 2065.

IPCC claimed in its most recent assessment report:

> Elevated temperature along with ocean acidification reduces the calcification rate of corals (*high confidence*), and may tip the calcium carbonate balance of reef frameworks towards dissolution (*medium evidence and agreement*).
>
> — p. 67 of the *Technical Summary*, Working Group II, IPCC Fifth Assessment Report, dated March 28, 2013

> Ocean acidification will cause a decrease of calcification of corals, which will cause not only a reduction in the coral's ability to grow its skeleton, but also in its contribution to reef building (*high confidence*).
>
> — p. 73 of the *Technical Summary*, Working Group II, IPCC Fifth Assessment Report, dated March 28, 2013)

> Ocean warming and acidification expected under RCP 8.5 will reduce calcification, elevate coral mortality and enhance sediment dissolution (*high confidence*; Manzello *et al.*, 2008). Coral reefs may stop growing and start dissolving when

atmospheric CO_2 reaches 560 ppm due to the combined effects of both drivers (*medium evidence*).

— p. 19 of *Chapter 5. Coastal Systems and Low-Lying Areas*, Working Group II, IPCC Fifth Assessment Report, dated March 28, 2013

The research summarized below reveals the dire assessment of IPCC is tenuous at best and more likely wholly incorrect. As Idso *et al*. (2000) have noted, coral calcification is more than a physical-chemical process described by a set of well-defined equations. It is a biologically driven physical-chemical process that may not be amenable to explicit mathematical description. They state, for example, "photosynthetic activity of zooxanthellae is the chief source of energy for the energetically-expensive process of calcification," and much evidence suggests "long-term reef calcification rates generally rise in direct proportion to increases in rates of reef primary production." They also note "the calcium carbonate saturation state of seawater actually rises with an increase in temperature, significantly countering the direct adverse oceanic chemistry consequences of an increase in atmospheric and/or hydrospheric CO_2 concentration." They conclude "the negative predictions of today could well be replaced by positive predictions tomorrow."

As revealed below, numerous scientific studies point toward a much more optimistic view of the future for the planet's corals.

6.3.3.2.1 Laboratory Studies

Researchers have predicted rates of coral calcification, and the photosynthetic rates of their symbiotic algae, will dramatically decline in response to what is typically referred to as an "acidification" of the world's oceans, as the atmosphere's CO_2 concentration continues to rise. This section examines evidence to the contrary obtained from laboratory-based studies. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Larvae from *Acropora* coral species (A. *digitifera* and A. *tenuis*) "may be able to tolerate ambient pH decreases of at least 0.7 pH units."

- "Scleractinian coral species will be able to acclimate to a high CO_2 ocean even if changes in seawater pH are faster and more dramatic than predicted."

- Though short-term exposure to lower ocean pH levels resulted in a decline of calcification and net dissolution of calcium carbonate in *Lophelia pertusa*, longer-term (six months) exposure revealed *L. pertusa* was able to acclimate and experience slightly enhanced rates of calcification, maintaining net growth in waters sub-saturated with aragonite.

- Using "carbonate concentration or aragonite saturation state as the sole predictor of the effects of ocean acidification on coral calcification" is unreliable.

- "Other physiological mechanisms, such as a direct effect of reduced pH on calcium or bicarbonate ion transport and/or variable ability to regulate internal pH, are responsible for the variability in reported experimental effects of acidification on calcification."

- A "firmer grasp of the biological component of biomineralization is paramount" in determining the response of corals to lower ocean pH levels .

- The future increase in oceanic bicarbonate ions may "stimulate photosynthesis and calcification in a wide variety of hermatypic corals," reducing and potentially overcoming theoretical effects of lower ocean pH levels .

- Reef corals may mitigate the effects of seawater acidification by regulating pH in the fluid at the tissue-skeleton interface, and this mechanism "may explain how several coral species continue to calcify even in low pH seawater, which is undersaturated with respect to aragonite."

- The fleshy tissues in octocorals may act as a protective barrier against rising levels of pCO_2, helping to maintain a stable internal environment that avoids the adverse effects of lower ocean pH levels .

- Based "purely on thermodynamic grounds, the predicted change in surface ocean pH in the next decades would appear to have minimal effect on the capacity of [important] acid-rich proteins to precipitate carbonates," which suggests "these proteins will continue to catalyze calcification reactions at ocean pH values projected in the coming century."

Suwa *et al*. (2010) employed controlled infusions of pure CO_2 to create mean pH values of 8.03, 7.64, and 7.31 in filtered seawater that flowed continuously through three sets of multiple tanks into which they had introduced the gametes of two *Acropora* coral species (A. *digitifera* and A. *tenuis*) collected during a natural spawning event. Seven days later they determined their survival percentage, and after 10 more days they documented the size of the developing polyps. After 14 days they documented the percentage of polyps that had acquired zooxanthellae the researchers had collected from the giant clam *T. crocea* and released into the several treatment tanks.

They found "*A. digitifera* larval survival rate did not differ significantly among pH treatments," and the graphs of their data reveal survivorship in *A. tenuis* was about 18.5% greater in the lowest pH (highest CO_2) treatment than in the ambient seawater treatment. At the end of the subsequent 10-day study, polyp size was reduced in the lowest pH treatment, by about 14%, which is not too bad for an atmospheric CO_2 concentration reported by the authors to be in the range of 2,115–3,585 ppm. In the *A. tenuis* coral, this reduction in individual size was more than compensated by the greater percentage increase in survivorship. In addition, after only four days of exposure to the zooxanthellae derived from giant clams, all polyps in all treatments had acquired a full complement of the symbiotic zooxanthella.

The seven scientists say "the survival of coral larvae may not be strongly affected by pH change," or "in other words," as they continue, "coral larvae may be able to tolerate ambient pH decreases of at least 0.7 pH units." A pH decrease of that magnitude is likely never to occur, as it implies atmospheric CO_2 concentrations in the range of 2,115 to 3,585 ppm. If such high concentrations ever were to occur, they would be a long, long time in coming, giving corals far more than sufficient time to acclimate—and even evolve (Idso and Idso, 2009)—to cope with the slowly developing situation.

Takahashi and Kurihara (2013) measured the rates of calcification, respiration, and photosynthesis of the tropical coral *Acropora digitifera*, along with the coral's zooxanthellae density, under near-natural summertime temperature and sunlight conditions for five weeks. Their analysis revealed these "key physiological parameters" were not affected by either predicted mid-range CO_2 concentrations (pCO_2 = 744 ppm, pH = 7.97, Ω_{arag} = 2.6) or by high CO_2 concentrations (pCO_2 = 2,142 ppm, pH = 7.56, Ω_{arag} = 1.1) over the 35-day period of their experiment. They found "no significant correlation between calcification rate and seawater aragonite saturation (Ω_{arag})" and "no evidence of CO_2 impact on bleaching."

Kreif *et al*. (2010) collected two colonies of massive *Porites* corals (which form large multi-century-old colonies and calcify relatively slowly) and four colonies of the branching *Stylophora pistillata* coral (which is short-lived and deposits its skeleton rather rapidly) from a reef adjacent to the Interuniversity Institute for Marine Science in Eilat (Israel) at the northern tip of the Red Sea. They grew fragments of these corals in 1,000-liter tanks through which they pumped Gulf of Eilat seawater adjusted to be in equilibrium with air of three CO_2 concentrations

(385, 1,904, and 3,970 ppm), which led to corresponding pH values of 8.09, 7.49, and 7.19 and corresponding aragonite saturation state (Ω_{arag}) values of 3.99, 1.25, and 0.65. After an incubation period of six months for *S. pistillata* and seven months for the *Porites* corals, the researchers sampled several fragments and analyzed them for a number of properties. Fourteen months from the start of the experiment, they analyzed fragments of each coral species from each CO_2 treatment for zooxanthellae cell density, chlorophyll *a* concentration, and host protein concentration.

They report, "following 14 months incubation under reduced pH conditions, all coral fragments survived and added new skeletal calcium carbonate, despite Ω_{arag} values as low as 1.25 and 0.65." This occurred at a reduced rate of calcification compared to fragments growing in the normal pH treatment with a Ω_{arag} value of 3.99. Yet in spite of this reduction in skeletal growth, the scientists report, "tissue biomass (measured by protein concentration) was found to be higher in both species after 14 months of growth under increased CO_2." They further note Fine and Tchernov (2007) observed the same phenomenon, having "reported a dramatic increase (orders of magnitude larger than the present study) in protein concentration following incubation of scleractinian Mediterranean corals (*Oculina patagonica* and *Madracis pharencis*) under reduced pH," stating "these findings imply tissue thickening in response to exposure to high CO_2." Krief *et al*. also report "a decrease in zooxanthellae cell density with decreasing pH was recorded in both species," but "this trend was accompanied by an increase in chlorophyll concentration per cell at the highest CO_2 level."

The Israeli, French, and UK researchers say "the inverse response of skeleton deposition and tissue biomass to changing CO_2 conditions is consistent with the hypothesis that calcification stimulates zooxanthellae photosynthesis by enhancing CO_2 concentration within the coelenteron (McConnaughey and Whelan, 1997)," and "since calcification is an energy-consuming process ... a coral polyp that spends less energy on skeletal growth can instead allocate the energy to tissue biomass," citing Anthony *et al*. (2002) and Houlbreque *et al*. (2004). They suggest, "while reduced calcification rates have traditionally been investigated as a proxy of coral response to environmental stresses, tissue thickness and protein concentrations are a more sensitive indicator of the health of a colony," citing Houlbreque *et al*. (2004).

Krief *et al*. conclude "the long acclimation time of this study allowed the coral colonies to reach a steady state in terms of their physiological responses to elevated CO_2," and "the deposition of skeleton in seawater with Ω_{arag} < 1 demonstrates the ability of both species to calcify by modifying internal pH toward more alkaline conditions." They further state "the physiological response to higher CO_2/lower pH conditions was significant, but less extreme than reported in previous experiments," suggesting "scleractinian coral species will be able to acclimate to a high CO_2 ocean even if changes in seawater pH are faster and more dramatic than predicted."

Form and Riebesell (2012) studied branches of *Lophelia pertusa*, collected from reefs off the coast of Norway, which they describe as "the most common reef framework-forming and ecosystem engineering cold-water coral with a cosmopolitan distribution (Zibrowius, 1980; Cairns, 1994; Freiwald *et al*., 2004)." They conducted a short-term (eight-day) experiment and a long-term (178-day) experiment, in which they employed different atmospheric CO_2 treatments to create a range of water pH treatments from 8.029 to 7.768 in the eight-day study and from 7.944 to 7.755 in the 178-day study, measuring the corals' growth rates over these intervals. They report "short-term (1-week) high CO_2 exposure resulted in a decline of calcification by 26–29% for a pH decrease of 0.1 unit and net dissolution of calcium carbonate." In contrast, "*L. pertusa* was capable to acclimate to acidified conditions in long-term (6 months) incubations, leading to even slightly enhanced rates of calcification." In the long-term low-pH treatment, "net growth is sustained even in waters sub-saturated with respect to aragonite."

Crook *et al*. (2013) note "almost all tropical corals have algal symbionts (zooxanthellae)," while "most deep and cold-water corals lack zooxanthellae." Because the latter corals have no symbionts and rely solely on heterotrophy for energy, they "provide a simplified system for exploring the roles of nutrition (and energy) in coral calcification." Studying *Balanophyllia elegans*, a solitary azooxanthellate scleractinian coral common in shallow coastal waters around Monterey Bay, California (USA), where it is exposed seasonally to low-pH, high-pCO$_2$ upwelling waters, the five researchers conducted an eight-month factorial laboratory experiment in which they "measured the effects of three pCO$_2$ treatments (410, 770, and 1,220 µatm) and two feeding frequencies (3-day and 21-day intervals) on 'planulation' (larval release) by adult *B. elegans*, and on the survival, skeletal growth and calcification of newly settled juveniles."

Crook *et al.* report "pCO_2 had no effect on the numbers of brooded planulae larvae released," "higher food levels increased the number of larvae released by 50–200%," and "excess food enables corals to counteract partially some of the negative impacts of lower [aragonite] saturation states under higher pCO_2 conditions." They found "after 8 months of growth, high-food skeletons were up to 7 times larger (by volume) than low-food skeletons at every pCO_2 level," and "in every pCO_2 treatment, higher food led to both greater linear extension and greater calcification (skeletal weight) over the 8-month experiment." They also found "calcification by high-pCO_2, high-food corals was 4 times greater than in low-food corals at ambient pCO_2," and "even feeding on planktonic crustaceans only once every 21 days was still sufficient to maintain positive growth at high pCO_2, albeit very slowly." The five U.S. researchers conclude, "as long as food availability remains high, *B. elegans* may be able to largely compensate for the extra energy required for calcification at low saturations, even if calcification occurs at slightly lower rates than at modern pCO_2." They reinforce this conclusion in the last sentence of their paper's abstract, writing, "we conclude that food abundance is critical for azooxanthellate coral calcification, and that *B. elegans* may be partially protected from adverse consequences of ocean acidification in habitats with abundant heterotrophic food."

Nash *et al.* (2012) write, "coral reef ecosystems develop best in high-flow environments," but "their fragile frameworks are also vulnerable to high wave energy." They say the wave-resistant algal rims, which surround many shallow coral reefs and are predominantly made of crustose coralline algae (CCA), are critical structural elements for the survival of such coral reefs. The scientists note "concerns have been growing about the susceptibility of CCA to ocean acidification, because CCA Mg-calcite skeletons are more susceptible to dissolution under low pH conditions than are coral aragonite skeletons." They further note the recent discovery by Nash *et al.* (2011) of the stable carbonate known as dolomite in the CCA *Porolithon onkodes* necessitates a re-appraisal of the impacts of lower ocean pH levels on it and other CCAs, such as *P. pachydermum*.

The 11 researchers "carried out dissolution experiments on fragments of CCA collected fresh, but then dried, from the Heron Island reef front (Great Barrier Reef, Australia)," after which the fragments were exposed to ambient sea water as a control and an enriched CO_2 treatment, where "pH ranged from 7.85 to 8.55 (control) and 7.69–8.44 (treatment), tracking natural diurnal changes measured in the lagoon water." Nash *et al.* (2012) determined "dried dolomite-rich CCA have 6–10 times lower rates of dissolution than predominantly Mg-calcite CCA in both high-CO_2 (~700 ppm) and control (~380 ppm) environments." They found this stabilizing mechanism resulted from "a combination of reduced porosity due to dolomite infilling and selective dissolution of other carbonate minerals." Noting "the prevailing theories that Mg-calcites with higher Mg content will undergo greatest dissolution," they write, "we were surprised to find a trend in the opposite direction." As dolomite-rich CCA frameworks are common in shallow coral reefs globally, Nash *et al.* conclude "it is likely that they will continue to provide protection and stability for coral reef frameworks as CO_2 rises."

Egilsdottir *et al.* (2013) note "it has been suggested that organisms presently surviving in highly variable environments are likely to be more robust to ocean acidification," citing Moulin *et al.* (2011) and Raven (2011), and they hypothesize "the ability of organisms to tolerate significant pH/pCO_2 fluctuations may be a result of adaptation (a genetic trait shared by the population) and/or acclimation (owing to phenotypic plasticity of the individual)." The authors investigated the effect of elevated pCO_2 "in the articulated coralline red alga *Corallina elongata* from an intertidal rock pool on the north coast of Brittany (France), where pCO_2 naturally varied daily between 70 and 1,000 µatm." They grew the algae at four pCO_2 values (380, 550, 750, and 1,000 µatm) in laboratory mesocosms and measured several physiological responses of the coral.

The French and Icelandic researchers report "algae grown under elevated pCO_2 formed fewer new structures and produced calcite with a lower mMg/Ca ratio relative to those grown under 380 µatm." They also observe "respiration, gross primary production and calcification in light and dark were not significantly affected by increased pCO_2." Egilsdottir *et al.* conclude their study "supports the assumption that *C. elongata* from a tidal pool, where pCO_2 fluctuates over diel and seasonal cycles, [are] relatively robust to elevated pCO_2." They also state these observations portend "a greater resilience" of such organisms to the projected "highly variable pH/pCO_2 environments of future ocean acidification."

Ragazzola *et al.* (2013) note coralline algae have been shown to be a major contributor to the formation and stabilization of coral reefs and in enhancing coral larvae settlement, citing Chisholm (2000). Given "their crucial role in shallow water ecosystems and

their worldwide distribution," the scientists write, "understanding the impact of ocean acidification on calcifying algae is fundamental," especially because "their high-Mg calcite skeleton is the most soluble polymorph of $CaCO_3$ (50% more soluble than calcite and 20% more soluble than aragonite)." Coralline algae are, therefore, "likely to be particularly sensitive to a reduction in Ω," which is the calcium carbonate saturation state of seawater, citing Ries (2011), Burdett *et al.* (2012), and Martin *et al.* (2013).

Because "species with wide geographic ranges, such as coralline algae, are in general very plastic and able to acclimatize to a variety of habitats through morphological and functional responses (Brody, 2004)," Ragazzola *et al.* cultured *Lithothamnion glaciale*, one of the main maerl-forming species in the northern latitudes, under different elevated CO_2 levels (410, 560, 840, and 1,120 ppm = 8.02, 7.92, 7.80, and 7.72 pH, respectively) for 10 months, with initial analyses of the various parameters they measured conducted at the three-month point of the study, as reported by Ragazzola *et al.* (2012). The six scientists report the growth rates of the plants in the three CO_2-enriched treatments after the first three months of their study were not significantly different from either each other or those of the ambient-treatment plants. At the end of the 10-month experiment, however, the CO_2-enriched plants' growth rates were approximately 60% lower than that of the ambient-treatment plants. However, the individual cell wall thicknesses of both inter and intra filaments at the three-month point of the study were significantly thinner than those of the control plants, while at the end of the 10-month study they were equivalent to those of the control plants.

Ragazzola *et al.* (2013) note a possible explanation of their findings is "a shift from what could be termed a 'passive' phase during the first three months to an 'active' phase by the end of ten months," whereby "during the 'passive' phase, the increased energy requirement for calcification due to higher CO_2 results in a reduction in the amount of calcite deposited in each cell well," but during the "active phase," *L. glaciale* reduces its growth rate so the cell wall structure can be better maintained. Because maintaining skeletal integrity is one of the main priorities of marine organisms living in high CO_2 environments, the German and UK researchers say "the results of this study indicate that seawater chemistry can drive phenotypic plasticity in coralline algae," and "the ability to change the energy allocation between cell growth and structural support is a clear adaptive response of the organism," which

"is likely to increase its ability to survive in a high CO_2 world."

Ries *et al.* (2010) "investigated the impact of CO_2-induced ocean acidification on the temperate scleractinian coral *Oculina arbuscula* by rearing colonies for 60 days in experimental seawaters bubbled with air-CO_2 gas mixtures of 409, 606, 903, and 2,856 ppm CO_2, yielding average aragonite saturation states (Ω_A) of 2.6, 2.3, 1.6 and 0.8." The authors observed "following the initial acclimation phase, survivorship in each experimental treatment was 100%," and in regard to the corals' rates of calcification and linear extension, "no significant difference was detected relative to the control treatment ($\Omega_A = 2.6$) for corals reared under Ω_A of 2.3 and 1.6," with the latter values corresponding to pH reductions from current conditions of 0.08 and 0.26, respectively. Ries *et al.* "propose that the apparent insensitivity of calcification and linear extension within *O. arbuscula* to reductions in Ω_A from 2.6 to 1.6 reflects the corals' ability to manipulate the carbonate chemistry at their site of calcification."

Herfort *et al.* (2008) note an increase in atmospheric CO_2 will cause an increase in the abundance of HCO_3^- (bicarbonate) ions and dissolved CO_2, and they also report several studies on marine plants have observed "increased photosynthesis with higher than ambient DIC [dissolved inorganic carbon] concentrations," citing Gao *et al.* (1993), Weis (1993), Beer and Rehnberg (1997), Marubini and Thake (1998), Mercado *et al.* (2001, 2003), Herfort *et al.* (2002), and Zou *et al.* (2003). The three researchers employed a wide range of bicarbonate concentrations "to monitor the kinetics of bicarbonate use in both photosynthesis and calcification in two reef-building corals, *Porites porites* and *Acropora* sp." Additions of HCO_3^- to synthetic seawater continued to increase the calcification rate of *Porites porites* until the bicarbonate concentration exceeded three times that of seawater, and photosynthetic rates of the coral's symbiotic algae were stimulated by HCO_3^- addition until they became saturated at twice the normal HCO_3^- concentration of seawater.

Similar experiments conducted on Indo-Pacific *Acropora* sp. showed calcification and photosynthetic rates in these corals were enhanced to an even greater extent, with calcification continuing to increase above a quadrupling of the HCO_3^- concentration and photosynthesis saturating at triple the concentration of seawater. The scientists monitored calcification rates of the *Acropora* sp. in the dark, writing, "although these were lower than in the light for a given HCO_3^- concentration, they still increased dramatically with

HCO_3^- addition, showing that calcification in this coral is light stimulated but not light dependent."

Herfort *et al*. suggest "hermatypic corals incubated in the light achieve high rates of calcification by the synergistic action of photosynthesis," which, as they have shown, is enhanced by elevated concentrations of HCO_3^- ions caused by the rise in the air's CO_2 content. The three researchers note over the next century the predicted increase in atmospheric CO_2 concentration "will result in about a 15% increase in oceanic HCO_3^-," and this development "could stimulate photosynthesis and calcification in a wide variety of hermatypic corals."

Jury *et al*. (2010) explain why some corals show positive responses to lower ocean pH levels in laboratory studies whereas others do not. They note, "physiological data and models of coral calcification indicate that corals utilize a combination of seawater bicarbonate and (mainly) respiratory CO_2 for calcification, not seawater carbonate," but "a number of investigators are attributing observed negative effects of experimental seawater acidification by CO_2 or hydrochloric acid additions to a reduction in seawater carbonate ion concentration and thus aragonite saturation state." They identify "a discrepancy between the physiological and geochemical views of coral biomineralization" and report, "not all calcifying organisms respond negatively to decreased pH or saturation state." They note, "together, these discrepancies suggest that other physiological mechanisms, such as a direct effect of reduced pH on calcium or bicarbonate ion transport and/or variable ability to regulate internal pH, are responsible for the variability in reported experimental effects of acidification on calcification."

Jury *et al*. performed incubations with the coral *Madracis auretenra* (= *Madracis mirabilis sensu* Wells, 1973) in modified seawater chemistries, where, as they describe it, "carbonate parameters were manipulated to isolate the effects of each parameter more effectively than in previous studies, with a total of six different chemistries." Among-treatment differences "were highly significant," and "the corals responded strongly to variation in bicarbonate concentration, but not consistently to carbonate concentration, aragonite saturation state or pH." They found, for example, "corals calcified at normal or elevated rates under low pH (7.6–7.8) when the sea water bicarbonate concentrations were above 1800 μM," and, conversely, "corals incubated at normal pH had low calcification rates if the bicarbonate concentration was lowered."

Jury *et al*. conclude "coral responses to ocean acidification are more diverse than currently thought," and they question "the reliability of using carbonate concentration or aragonite saturation state as the sole predictor of the effects of ocean acidification on coral calcification," stating "if we truly wish to decipher the response of coral calcification to ocean acidification, a firmer grasp of the biological component of biomineralization is paramount."

Venn *et al*. (2013) also focused on how lower ocean pH levels impact the physiological mechanisms that drive calcification, to provide knowledge helpful in predicting how corals and other marine calcifiers will respond and potentially acclimate to lower ocean pH levels . In corals, the authors note, the capacity to regulate pH in the fluid at the tissue-skeleton interface [subcalicoblastic medium (SCM)] and in the calcifying cells [calicoblastic epithelium (CE)] "has been widely proposed to be important in shaping calcification responses to ocean acidification." They studied the impact of seawater acidification on pH_{SCM} and pH_{CE} in the coral *Stylophora pistillata*, "using *in vivo* imaging of pH in corals exposed to reduced seawater pH and elevated pCO_2 in the laboratory for [both] long and short durations." This work included "exposures to levels of acidification and elevated pCO_2 many times greater than those predicted to occur at the end of this century."

Venn *et al*. say they "observed calcification (measured by growth of skeletal crystals and whole colonies) in all our treatments, including treatment pH 7.2, where aragonite was undersaturated." They continue, "this finding agrees with previous work with *S. pistillata* conducted elsewhere, where net calcification was also observed over a similar range of pH and pCO_2 (Krief *et al*., 2010)." Such findings suggest, they write, "*S. pistillata* may have a high tolerance to decreases in seawater pH and changes in seawater chemistry," leading them to conclude "maintenance of elevated pH_{SCM} relative to the surrounding seawater may explain how several coral species continue to calcify even in low pH seawater, which is undersaturated with respect to aragonite (this study and Rodolfo-Metalpa *et al*. (2011) and Cohen *et al*., (2009))." Venn *et al*. report, "reductions in calcification rate, both at the level of crystals and whole colonies, were only observed in our lowest pH treatment [pH 7.2] when pH was significantly depressed in the calcifying cells in addition to the SCM." "Overall," they say their findings suggest "reef corals may mitigate the effects of seawater acidification by regulating pH in the SCM."

Gabay *et al*. (2013) note octocorals possess "an internal calcium carbonate skeleton comprised of

microscopic sclerites embedded in their tissue," citing Fabricius and Alderslade (2001), Jeng *et al.* (2011), and Tentori and Ofwegen (2011). They also note octocorals are "the second most important faunistic component in many reefs, often occupying 50% or more of the available substrate." They say "it is important to predict their response to a scenario of increased pCO_2."

Gabay *et al.* studied three species of octocorals from two families found in the Gulf of Aqaba at Eilat—the zooxanthellate *Ovabunda macrospiculata* and *Heteroxenia fuscens* (family Xeniidae) and *Sarcophyton* sp. (family Alcyoniidae)—which they maintained for five months under normal (8.2) and reduced (7.6 and 7.3) pH conditions, assessing their pulsation rate, protein concentration, polyp weight, density of zooxanthellae, and chlorophyll concentration per cell.

The three Israeli scientists found "no statistically significant difference between the octocorals exposed to reduced pH values compared to the control." They say "these findings indicate that octocorals may possess certain protective mechanisms against rising levels of pCO_2," and they suggest "their fleshy tissues act as a barrier, maintaining a stable internal environment and avoiding the adverse effects of the ambient elevated pCO_2." That notion accords with the observations of Rodolfo-Metalpa *et al.* (2011), and Gabay *et al.* note "this suggestion is further supported by our finding that the ultrastructural features of *O. macroscipulata* sclerites are not affected by increased ambient seawater acidity." They conclude, "octocorals might be able to acclimate and withstand rising levels of ocean acidification, even under conditions that are far beyond what is expected to occur by the end of the present century (pH 7.9)."

Mass *et al.* (2013) write, "despite the broad interest in coral calcification and the potential for climate-driven adverse effects, the molecules and biophysical mechanism responsible for the precipitation of carbonates are poorly understood." They note, "to date, we lack both a characterization of molecules involved in calcification and a mechanistic understanding of processes that lead to and control calcification," and this "lack of knowledge limits our ability to predict the response of corals to increasing atmospheric CO_2." The seven scientists "for the first time," identified, cloned, determined the amino acid sequence of, and characterized four highly acidic proteins they derived from the expression of genes obtained from the common stony coral *Stylophora pistillata*. Each of these proteins can spontaneously catalyze the precipitation of calcium carbonate in vitro.

They found "coral acid-rich proteins (CARPs) not only bind Ca^{2+} stoichiometrically but also precipitate aragonite in vitro in seawater at pH 8.2 and 7.6 via an electrostatic interaction with protons on bicarbonate anions." The seven U.S. researchers conclude, "based purely on thermodynamic grounds, the predicted change in surface ocean pH in the next decades would appear to have minimal effect on the capacity of these acid-rich proteins to precipitate carbonates." They note their findings "strongly suggest that these proteins will continue to catalyze calcification reactions at ocean pH values projected in the coming century."

Maier *et al.* (2013) note "previous experiments examining the effect of ocean acidification on the cold-water corals *L. pertusa* and *M. oculata* have indicated that their rates of calcification remain positive even in waters where Ω_a is < 1 (Maier *et al.*, 2009; Thresher *et al.*, 2011; Form and Riebesell, 2012)." They add that Form and Riebesell (2012) and Maier *et al.* (2012, 2013) found "calcification rates of these species remained positive at a partial pressure of CO_2 (pCO_2) of 1000 µatm, a value that is at the high end of projected changes by 2100." Maier *et al.* measured respiration rates "for both short and long periods of time at pCO_2 levels ranging from ambient (350 µatm) to elevated (1100 µatm) levels," using "the same experimental setup as a previous study demonstrating that elevated pCO_2 had no effect on the rate of calcification in these two species (Maier *et al.*, 2013)."

The six scientists report, "in the range of pCO_2 studied so far, up to 1215 µatm, no significant change in respiration was found as a function of increasing pCO_2." As for what "this means," Maier *et al.* write, "for the maintenance of high calcification rates over a large range of pCO_2 of up to 1,000 ppm, there is no evidence for a direct energy allocation from food uptake to calcification in order to compensate for higher energy required to maintain calcification constant despite a decrease in pH."

6.3.3.2.2 Field Studies

Some scientists have predicted rates of coral calcification and the photosynthetic rates of their symbiotic algae will decline dramatically in response to lower ocean pH levels as the atmosphere's CO_2 concentration continues to rise. As research evidence accumulates, however, the true story appears to be just the opposite. This section examines such evidence obtained from field-based studies conducted in the natural ocean. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Theoretical calculations suggest rising atmospheric CO_2 over the past century should have led to a 6–14% decline in coral calcification via lower ocean pH levels , yet several studies show coral calcification rates have remained stable or increased.

- In contrast to model-based assumptions, the process of calcification in many corals is not correlated with aragonite saturation state or pH.

- Increases in calcification observed over the past century in many ocean regions have been shown to correlate strongly with increases in water temperature.

- Changes in pH did not affect the composition of associated microbial communities in two Mediterranean coral species.

- Cold-water corals are "likely to be much more resilient to decreasing seawater pH from ocean acidification than previously realized," because of their ability "to ameliorate or buffer external changes in seawater pH by up-regulating their internal (extracellular) pH at the site of calcification."

- The distribution and composition of deep-sea corals "are not constrained by carbonate levels below saturation."

- "The drawdown of total dissolved inorganic carbon due to photosynthesis and calcification of reef communities can exceed the drawdown of

total alkalinity due to calcification of corals and calcifying algae, leading to a net increase in aragonite saturation state." Although "carbon fluxes of benthic reef communities cannot significantly counter changes in carbon chemistry at the scale of oceans, they provide a significant mechanism of buffering ocean acidification impacts at the scale of habitat to reef."

Field studies hold an advantage over laboratory-based studies in more aptly representing conditions in the real world, as many of those conditions are impossible or impractical to recreate in a laboratory setting. The findings produced in field studies tend to hold more weight and establish greater clarity on a scientific topic or question under investigation than findings produced in a laboratory setting. Such is the case with lower ocean pH levels . Whereas positive, negative, and neutral effects from this phenomenon have been observed on corals in laboratories, field-based studies in the ocean reveal the situation is much less dire than IPCC predicts. Many studies suggest a modest decline in oceanic pH may actually favor coral calcification and growth.

Pelejero *et al*. (2005), for example, developed a reconstruction of seawater pH spanning the period 1708–1988, based on the boron isotopic composition ($\delta^{11}B$) of a long-lived massive coral (*Porites*) from Flinders Reef in the western Coral Sea of the southwestern Pacific. They found "no notable trend toward lower $\delta^{11}B$ values" over the 300-year period investigated. They write, "the dominant feature of the coral $\delta^{11}B$ record is a clear interdecadal oscillation of pH, with $\delta^{11}B$ values ranging between 23 and 25 per mil (7.9 and 8.2 pH units)," which "is synchronous with the Interdecadal Pacific Oscillation." They also calculated changes in aragonite saturation state from the Flinders pH record that varied between ~3 and 4.5, and these values encompass "the lower and upper limits of aragonite saturation state within which corals can survive." They report, "skeletal extension and calcification rates for the Flinders Reef coral fall within the normal range for *Porites* and are not correlated with aragonite saturation state or pH." Thus, contrary to claims of great sensitivity of coral calcification to changes in pH and aragonite saturation, they found large cyclical changes in these parameters had essentially no detectable effect on either coral calcification or skeletal extension rates.

In a study of historical calcification rates determined from coral cores retrieved from 35 sites on the Great Barrier Reef, Lough and Barnes (1997) observed a statistically significant correlation between

coral calcification rate and local water temperature. They found a 1°C increase in mean annual water temperature increased mean annual coral calcification rate by about 3.5 percent, but they also report there were "declines in calcification in *Porites* on the Great Barrier Reef over recent decades." They point out their data depict several extended periods of time when coral growth rates were either above or below the long-term mean, cautioning, "it would be unwise to rely on short-term values (say averages over less than 30 years) to assess mean conditions."

They report, "a decline in calcification equivalent to the recent decline occurred earlier this century and much greater declines occurred in the 18th and 19th centuries," long before anthropogenic CO_2 emissions had much of an impact on the air's CO_2 concentration. Over their entire dataset, Lough and Barnes write, "the 20th century has witnessed the second highest period of above average calcification in the past 237 years," not exactly to be expected in light of how dangerous high water temperatures are often said to be for corals, the claim that Earth is currently warmer than it has been at any other time during the entire past millennium, and the air's CO_2 content is currently much higher than it has been for more than a thousand years.

Bessat and Buigues (2001) reported similar findings after deriving a history of coral calcification rates, covering the period 1801–1990, from a core extracted from a massive *Porites* coral head on the French Polynesian island of Moorea. They note "recent coral-growth models highlight the enhanced greenhouse effect on the decrease of calcification rate," but instead of relying on theoretical calculations, they wanted to work with real-world data because the records preserved in ancient corals "may provide information about long-term variability in the performance of coral reefs, allowing unnatural changes to be distinguished from natural variability."

Bessat and Buigues found a 1°C increase in water temperature increased coral calcification rates at the site they studied by 4.5 percent. Then they found, "instead of a 6–14% decline in calcification over the past 100 years computed by the Kleypas group, the calcification has increased, in accordance with [the results of] Australian scientists Lough and Barnes." They also observed patterns of "jumps or stages" in the record, characterized by an increase in the annual rate of calcification, particularly at the beginning of the past century "and in a more marked way around 1940, 1960 and 1976," stating once again their results "do not confirm those predicted by the Kleypas *et al.* (1999) model."

Lough and Barnes (2000) delivered another major blow to the Kleypas *et al.* model when they assembled and analyzed the calcification characteristics of 245 similar-sized massive colonies of *Porites* corals obtained from 29 reef sites located along the length, and across the breadth, of Australia's Great Barrier Reef (GBR). The data spanned a latitudinal range of approximately 9° and an annual average sea surface temperature (SST) range of 25–27°C. To these data they added other published data from the Hawaiian Archipelago (Grigg, 1981, 1997) and Phuket, Thailand (Scoffin *et al.*, 1992), thus extending the latitudinal range of the expanded dataset to 20° and the annual average SST range to 23–29°C.

Lough and Barnes found the GBR calcification data were linearly related to the average annual SST data, as "a 1°C rise in average annual SST increased average annual calcification by 0.39 g cm^{-2} $year^{-1}$." Results were much the same for the extended dataset. They report, "the regression equation [calcification = 0.33(SST) - 7.07] explained 83.6% of the variance in average annual calcification (F = 213.59, p less than 0.00)," and "this equation provides for a change in calcification rate of 0.33 g cm^{-2} $year^{-1}$ for each 1°C change in average annual SST."

Lough and Barnes say their findings "allow assessment of possible impacts of global climate change on coral reef ecosystems," and between the two 50-year periods 1880–1929 and 1930–1979, they calculate a calcification increase of 0.06 g cm^{-2} $year^{-1}$, noting "this increase of ~4% in calcification rate conflicts with the estimated decrease in coral calcification rate of 6–14% over the same time period suggested by Kleypas *et al.* (1999) as a response to changes in ocean chemistry." Even more stunning is their observation that between the two 20-year periods 1903–1922 and 1979–1998, "the SST-associated increase in calcification is estimated to be less than 5% in the northern GBR, ~12% in the central GBR, ~20% in the southern GBR and to increase dramatically (up to ~50%) to the south of the GBR." Lough and Barnes conclude coral calcification rates "may have already significantly increased along the GBR in response to global climate change."

Carricart-Ganivet (2004) developed relationships between coral calcification rate and annual average SST based on data collected from colonies of the reef-building coral *Montastraea annularis* at 12 locations in the Gulf of Mexico and Caribbean Sea. He found the calcification rate in the Gulf of Mexico increased 0.55 g cm^{-2} $year^{-1}$ for each 1°C increase, and in the Caribbean Sea it increased 0.58 g cm^{-2} $year^{-1}$ for each

1°C increase. Pooling these data with data regarding *M. annularis* and *M. faveolata* growing to a depth of 10 m at Carrie Bow Cay, Belize, data from reefs at St. Croix in the U.S. Virgin Islands, and data of *M. faveolata* growing to a depth of 10 m at Curacao, Antilles, Carricart-Ganivet reports a mean increase in calcification rate of ~0.5 g cm^{-2} year^{-1} for each 1°C increase in annual average SST, even greater than what Lough and Barnes found for *Porites* corals.

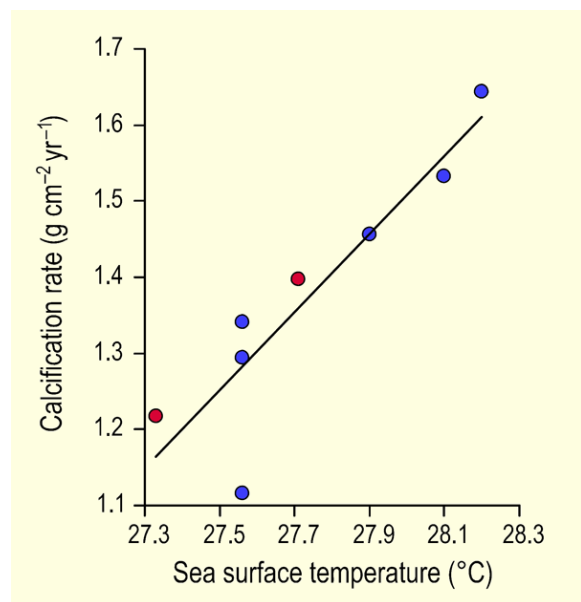
Working at two reef sites on the northwest coast of Cuba—one in the Guanahacabibes Gulf just off the Pinar del Rio Province and the other north of Havana Bay—Carricart-Ganivet and Gonzalez-Diaz (2009) measured yearly coral extension rates and densities of the dominant Caribbean reef-building coral *Montastraea annularis* for the period 1991 to 2003, from which data they calculated annual coral calcification rates. They plotted their results against mean annual sea surface temperature (SST, obtained from the UK's Hadley Centre) and compared their results with the earlier study of Carricart-Ganivet (2004). The results of these two investigations are illustrated in Figure 6.3.3.2.2.1, where it can be seen they are completely compatible with each other.


Figure 6.3.3.2.2.1. Mean yearly calcification rate of *Montastraea annularis* vs. mean annual sea surface temperature for the several sites studied by Carricart-Ganivet (2004) (blue circles) and the two sites studied by the authors (red circles). The line that has been fit to the data is defined by Calcification Rate = 0.51 SST - 12.85 (r^2 = 0.82, p < 0.002). Adapted from Carricart-Ganivet and Gonzalez-Diaz (2009).

Crabbe *et al.* (2006) determined the original growth rates of long-dead Quaternary corals found in limestone deposits on islands in the Wakatobi Marine National Park of Indonesia, which they compared to the growth rates of present-day corals of the same genera living in the same area. They found the Quaternary corals grew "in a comparable environment to modern reefs"—except, of course, for the air's CO_2 concentration, which is currently higher than it has been at any other time throughout the Quaternary, which spans the past 1.8 million years. Their measurements indicated the radial growth rates of the modern corals were 31 percent greater than those of their ancient predecessors in the case of *Porites* species, and 34 percent greater in the case of *Favites* species.

Cohen and Holcomb (2009) highlight several facts about the process of calcification in zooxanthellate corals. First, they report what is perhaps the most fundamental fact: "calcification is an active, physiological process that requires significant amounts of energy to drive it." Second, they note "increased photosynthesis [of coral symbiotic zooxanthellae] means increased photosynthate and more energy for calcification." Third, they report Atkinson *et al.* (1995) have shown "nutritionally replete zooxanthellate corals in naturally low [aragonite] saturation-state seawaters are capable of accreting skeletons at rates comparable to those achieved by conspecifics in high-saturation-state seawaters." Fourth, the two researchers write, "today, several reefs, including Galapagos, areas of Pacific Panama, and Jarvis (southern Line Islands), experience levels of aragonite saturation equivalent to that predicted for the open ocean under two times and three times pre-industrial CO_2 levels (Manzello *et al.*, 2008; Kathryn Shamberger [PMEL/NOAA] and colleagues, *pers. comm.*, August 2009)," and "available data on coral colony growth rates on these reefs, albeit limited, suggest that they are equivalent to and sometimes even rival those of conspecifics in areas where aragonite saturation states are naturally high, such as the western Pacific warm pool."

Probably the most important deduction from these observations, Cohen and Holcomb write, is "naturally elevated levels of inorganic nutrients and, consequently, high levels of primary and secondary production, may already be facilitating high coral calcification rates in regions with naturally high dissolved CO_2 levels." This further suggests Earth's corals, with their genetically diverse symbiotic zooxanthellae, are likely well-equipped to deal successfully with future increases in the air's CO_2

content.

The same phenomenon that powers the twin processes of coral calcification and phytoplanktonic growth (photosynthesis) tends to increase the pH of marine waters (Gnaiger *et al*., 1978; Santhanam *et al*., 1994; Brussaard *et al*., 1996; Lindholm and Nummelin, 1999; Macedo *et al*., 2001; Hansen, 2002). This phenomenon has been shown to have the ability to dramatically increase the pH of marine bays, lagoons, and tidal pools (Gnaiger *et al*., 1978; Macedo *et al*., 2001; Hansen, 2002) and significantly enhance the surface water pH of areas as large as the North Sea (Brussaard *et al*., 1996).

In an example of this phenomenon, Middelboe and Hansen (2007) studied the pH of a wave-exposed boulder reef in Aalsgaarde on the northern coast of Zealand, Denmark, and a sheltered shallow-water area in Kildebakkerne in the estuary Roskilde Fjord, Denmark. They report, in line with what would be expected if photosynthesis tends to increase surface-water pH, "daytime pH was significantly higher in spring, summer and autumn than in winter at both study sites," often reaching values of 9 or more during peak summer growth periods vs. 8 or less in winter. They also found "diurnal measurements at the most exposed site showed significantly higher pH during the day than during the night," sometimes reaching values above 9 during daylight hours but typically dipping below 8 at night, and "diurnal variations were largest in the shallow water and decreased with increasing water depth."

Middelboe and Hansen cite the work of Pearson *et al*. (1998), who found pH averaged about 9 during the summer in populations of *Fucus vesiculosus* in the Baltic Sea; Menendez *et al*. (2001), who found maximum pH was 9 to 9.5 in dense floating macroalgae in a brackish coastal lagoon in the Ebro River Delta; and Bjork *et al*. (2004), who found pH values as high as 9.8 to 10.1 in isolated rock pools in Sweden. Noting "pH in the sea is usually considered to be stable at around 8 to 8.2," the two Danish researchers conclude "pH is higher in natural shallow-water habitats than previously thought."

Meron *et al*. (2012) state ocean acidification "has the potential to cause significant perturbations to the physiology of ocean organisms, particularly those such as corals that build their skeletons/shells from calcium carbonate," and this phenomenon "could also have an impact on the coral microbial community, and thus may affect coral physiology and health." They note most studies of declining pH effects on corals and/or their associated microbiota typically have been done under "controlled laboratory conditions." This approach clearly ignores any impacts declining pH values may have on the coral holobiont, some of which may be negative and some positive, which in the latter case is referred to as the probiotic hypothesis, as per Reshef *et al*. (2006).

The six scientists took advantage of a natural pH gradient off the coast of Ischia (Gulf of Naples, Italy) created by an underwater CO_2 flux from volcanic vents (Hall-Spencer *et al*., 2008). They examined the potential impacts of a range of pH conditions (7.3 to 8.1) on coral microbial communities living under real-world conditions, focusing on two Mediterranean coral species: *Balanophyllia europaea* and *Cladocora caespitosa*.

The research team reports "pH did not have a significant impact on the composition of associated microbial communities in both coral species." They note "corals present at the lower pH sites exhibited only minor physiological changes" and "no microbial pathogens were detected." They conclude "at least for these two coral species, reduced pH does not seem to significantly reduce coral health," which suggests some of the contrary results obtained in laboratory studies could be due to the fact "laboratory environments cannot mimic the dynamism and microbial diversity present in nature," and the possibility "aquarium conditions themselves contribute to stress or disturbance in the microbial community." This view is supported in part by the finding of Kooperman *et al*. (2007), who noted, "the same coral species has different associated microbial communities in the laboratory compared with field conditions."

Shamberger *et al*. (2011) deployed "auto-samplers" to collect water samples from the barrier coral reef of Kaneohe Bay, Oahu, Hawaii, every two hours for six 48-hour periods, two each in June 2008, August 2009, and January/February 2010. Based on these seawater measurements, they calculated net ecosystem calcification (NEC) and net photosynthesis (NP) rates for these periods. The six scientists found "daily NEC was strongly negatively correlated with average daily pCO_2, which ranged from 421 to 622 ppm." They report, "daily NEC of the Kaneohe Bay barrier reef is similar to or higher than daily NEC measured on other coral reefs, even though Ω_{arag} levels (mean Ω_{arag} = 2.85) are some of the lowest measured in coral reef ecosystems." Shamberger *et al*. conclude "it appears that while calcification rate and Ω_{arag} are correlated within a single coral reef ecosystem," as in the case of the barrier reef of Kaneohe Bay, "this relationship does not necessarily hold between different coral reef systems," and it can

thus be expected "ocean acidification will not affect coral reefs uniformly and that some may be more sensitive to increasing pCO_2 levels than others." That implies (taking a more positive view of the subject) some coral reefs may be less sensitive to increasing pCO_2 than others.

McCulloch *et al.* (2012) state "for cold-water corals, which are already living at low levels of carbonate saturation, the shoaling of the saturation horizon as carbonate saturation states decrease [in response, for example, to rising atmospheric CO_2 concentrations] has the potential to cause dramatic declines in rates of calcification, or the dissolution of the carbonate skeletons of those living at or close to the saturation horizon." Since these corals are indeed living there, they speculate "they may have evolved adaptive strategies to counter the effects of low carbonate saturation states," one of which is to up-regulate their internal pH to a value that allows calcification to occur.

McCulloch *et al.* extended the novel approach of Trotter *et al.* (2011), based on boron isotopic systematics, to determine the relationship between seawater pH and the internal (extracellular) pH_{cf} at the site of calcification for several azooxanthellate cold-water scleractinian corals, collected from a large range of depths and geographically disparate sites, including southeast Australia, Chile's Comau Fjord, the Marmara Sea, a number of sites in the Mediterranean Sea, the northeast Atlantic Ocean, and the northwestern Hawaiian Islands.

The suite of "aragonitic cold-water coral species," as the 11 researchers describe them, "collectively show an overall trend of higher ΔpH [= pH_{cf} - seawater pH] values that is anti-correlated with seawater pH, with systematics generally consistent with biologically controlled pH up-regulation." This result indicates, "like symbiont-bearing tropical corals (Trotter *et al.*, 2011), they have the ability to ameliorate or buffer external changes in seawater pH by up-regulating their pH_{cf} at the site of calcification."

McCulloch *et al.* conclude "cold-water corals are likely to be much more resilient to decreasing seawater pH from ocean acidification than previously realized," because, as they see it, "decreasing seawater pH alone will only marginally affect calcification rates since this process would be largely countered by pH_{cf} up-regulation in cold-water corals, together with enhanced calcification rates from warming of the deep oceans."

Jantzen *et al.* (2013) write ocean acidification "is thought to negatively affect most marine-calcifying organisms, notably cold-water corals (CWC)," which might be expected to be especially sensitive due to the deep and cold waters in which they are typically found. They measured water profiles with a CTD (conductivity, temperature, depth) multi-probe profiler along the Comau fjord, extending down to 50–60 meters in 2010 and down to 225 meters in 2011, which allowed them to detect and describe the spatial distribution of the cold-water coral *Desmophyllum dianthus*.

The seven scientists determined *D. dianthus* grows along the fjord over its entire pH range, where "it occurs in shallow depths (below 12 m, pH 8.1) as part of a deep-water emergence community, but also in [water of] 225 m depth at a pH of 7.4." They report the cold-water coral thrives close to the aragonite saturation horizon and even below it, where they found "flourishing coral banks."

Jantzen *et al.* note other studies "question reduced calcification rates of corals in environments with lowered aragonite saturation state (Ω_{arg})," citing Marubini *et al.* (2008) and Jury *et al.* (2010), but they note "very recent studies hint at a higher acclimatization potential of cold-water corals to ocean acidification," citing Rodolfo-Metalpa *et al.* (2010), Trotter *et al.* (2011), Form and Riebesel (2012), and McCulloch *et al.* (2012a,b).

Thresher *et al.* (2011) state concerns about the effects of lower ocean pH levels on marine ecosystems "are based primarily on modeling studies and short-term laboratory exposure to low-carbonate conditions," citing Riegl *et al.* (2009), Veron *et al.* (2009), and Ries *et al.* (2010). They say "their relevance to long-term exposure in the field and the potential for ecological or evolutionary adjustment are uncertain," citing Maynard *et al.* (2008). In an effort "to determine the sensitivity of corals and allied taxa to long-term exposure to very low carbonate concentrations," Thresher *et al.* examined "the depth distribution and life-history characteristics of corals and other shell-forming megabenthos along the slopes of deep-sea seamounts and associated structure in the SW Pacific," where the gradient of water chemistry ranged from super-saturated in the case of aragonite and high-magnesium calcite (HMC) to under-saturated with calcite.

The five researchers "found little evidence that carbonate under-saturation to at least -30% affected the distribution, skeletal composition, or growth rates of corals and other megabenthos on Tasmanian seamounts." They found "both solitary scleractinian corals and colonial gorgonians were abundant at depths well below their respective saturation horizons and appeared healthy," and HMC echinoderms were

common as deep as they sampled (4,011 m), in water approximately 45% under-saturated. They also report, "for both anthozoan and non-anthozoan taxa, there was no obvious difference in species' maximum observed depths as a function of skeletal mineralogy." In other words, the community "was not obviously shifted towards taxa with either less soluble or no skeletal structure at increasing depth." They conclude, "it is not obvious from our data that carbonate saturation state and skeletal mineralogy have any effect on species' depth distributions to the maximum depth sampled," and they saw "little evidence of an effect of carbonate under-saturation on growth rates and skeletal features."

Thresher *et al*. write, "the observation that the distributions of deep-sea corals are not constrained by carbonate levels below saturation is broadly supported by the literature," noting "solitary scleractinians have been reported as deep as 6 km (Fautin *et al*., 2009) and isidid gorgonians as deep as 4 km (Roark *et al*., 2005)." They say their own data also "provide no indication that conditions below saturation per se dictate any overall shifts in community composition."

Explaining these results, the researchers note one or more cell membranes may envelop the organisms' skeletons, largely isolating the calcification process and its associated chemistry from the bulk seawater, citing McConnaughey (1989), Adkins *et al*. (2003), and Cohen and McConnaughey (2003), and this phenomenon could presumably protect "the skeleton itself from the threat of low carbonate dissolution." In addition, Thresher *et al*. note, "calcification is energetically expensive, consuming up to 30% of the coral's available resources, and … normal calcification rates can be sustained in relatively low-carbonate environments under elevated feeding or nutrient regimes," as described in detail by Cohen and Holcomb (2009). Thresher *et al*. conclude, "Although saturation levels in those studies are considerably higher than those experienced by the deep-sea taxa we observed, the principle that elevated food availability could compensate for the higher costs of calcification in heterotrophic deepsea species appears plausible."

Thresher *et al*. say their data clearly suggest, whatever the cause, "a change in carbonate saturation horizons per se as a result of ocean acidification is likely to have only a slight effect on most of the live deep-sea biogenic calcifiers."

Anthony *et al*. (2011) used "a carbon flux model for photosynthesis, respiration, calcification and dissolution coupled with Lagrangian transport to examine how key groups of calcifiers (zooxanthellate corals) and primary producers (macroalgae) on coral reefs contribute to changes in the seawater carbonate system as a function of water residence time." The examination showed "the carbon fluxes of corals and macroalgae drive Ω_a in opposing directions," and "areas dominated by corals elevate pCO_2 and reduce Ω_a, thereby compounding ocean acidification effects in downstream habitats, whereas algal beds draw CO_2 down and elevate Ω_a, potentially offsetting ocean acidification impacts at the local scale." They also report simulations for two significantly elevated CO_2 scenarios (600 and 900 ppm CO_2) suggest "a shift in reef community composition from coral to algal dominance in upstream areas under ocean acidification will potentially improve conditions for calcification in downstream areas."

Kleypas *et al*. (2011) provided field validation of the simulations of Anthony *et al*. by examining the roles of three key members of benthic reef communities—corals, macroalgae, and sand—in modifying the chemistry of open-ocean source water. They found "the drawdown of total dissolved inorganic carbon due to photosynthesis and calcification of reef communities can exceed the drawdown of total alkalinity due to calcification of corals and calcifying algae, leading to a net increase in aragonite saturation state." They note there were no seagrasses on the reef flat they studied, and "research suggests that seagrasses may have an additional impact on reef seawater chemistry because they enhance the alkalinity flux from sediments (Burdige and Zimmerman, 2002), and they respond to CO_2 fertilization (Palacios and Zimmerman, 2007)."

These observations suggest reef communities gradually could alter their spatial compositions in a CO_2-acreting world to the point where seagrasses and other macroalgae take up residence in upstream regions, while corals and other calcifying organisms lay claim to downstream regions. Anthony *et al*. (2011) conclude, "although the carbon fluxes of benthic reef communities cannot significantly counter changes in carbon chemistry at the scale of oceans, they provide a significant mechanism of buffering ocean acidification impacts at the scale of habitat to reef."

Manzello *et al*. (2012) note although many people expect future ocean acidification (OA) resulting from rising atmospheric CO_2 concentrations to reduce the calcification rates of marine organisms, we have little understanding of how OA will manifest in dynamic, real-world systems, because "natural CO_2, alkalinity, and salinity gradients can significantly alter local

carbonate chemistry, and thereby create a range of susceptibility for different ecosystems to OA." "To determine if photosynthetic CO_2 uptake associated with seagrass beds has the potential to create OA refugia," Manzello *et al*. repeatedly measured carbonate chemistry across an inshore-to-offshore gradient in the upper, middle, and lower Florida Reef Tract over a two-year period.

During times of heightened oceanic vegetative productivity, the five U.S. researchers found, "there is a net uptake of total CO_2 which increases aragonite saturation state (Ω_{arag}) values on inshore patch reefs of the upper Florida Reef Tract," and "these waters can exhibit greater Ω_{arag} than what has been modeled for the tropical surface ocean during preindustrial times, with mean Ω_{arag} values in spring equaling 4.69 ± 0.10." They report Ω_{arag} values on offshore reefs "generally represent oceanic carbonate chemistries consistent with present day tropical surface ocean conditions."

Manzello *et al*. hypothesize the pattern described above "is caused by the photosynthetic uptake of total CO_2 mainly by seagrasses and, to a lesser extent, macroalgae in the inshore waters of the Florida Reef Tract." They conclude these inshore reef habitats are "potential acidification refugia that are defined not only in a spatial sense, but also in time, coinciding with seasonal productivity dynamics," which further implies "coral reefs located within or immediately downstream of seagrass beds may find refuge from ocean acidification." They cite Palacios and Zimmerman (2007), whose work they describe as indicating "seagrasses exposed to high-CO_2 conditions for one year had increased reproduction, rhizome biomass, and vegetative growth of new shoots, which could represent a potential positive feedback to their ability to serve as ocean acidification refugia."

Noonan *et al*. (2013) write, "ocean acidification (OA) is expected to negatively affect coral reefs," but "little is known about how OA will change the coral-algal symbiosis on which reefs ultimately depend." They state, "to date it remains unknown if corals are able to respond to rising CO_2 concentrations by changing to better adapted dominant *Symbiodinium* types after long-term exposure to elevated pCO_2 in the field," the field being the ocean, in this case. Noonan *et al*. investigated "the dominant types of *Symbiodinium* associating with six species of scleractinian coral that were exposed to elevated partial pressures of carbon dioxide (pCO_2) *in situ* from settlement and throughout their lives." They did so "at three naturally occurring volcanic CO_2 seeps

(pCO_2 ~500 to 900 ppm, pH_{Total} 7.8–7.9) and adjacent control areas (pCO_2 ~390 ppm, pH_{Total} ~8.0–8.05) in Papua New Guinea," and "*Symbiodinium* associated with corals living in an extreme seep site (pCO_2 >1000 ppm) were also examined."

In five of the six species studied, the researchers report, "85–95% of samples exhibited the same *Symbiodinium* type across all sites, with remaining rare types having no patterns attributable to CO_2 exposure." The sixth species of coral did display "site specific differences in *Symbiodinium* types," but these were "unrelated to CO_2 exposure." The scientists write, "*Symbiodinium* types from the coral inhabiting the extreme CO_2 seep site were found commonly throughout the moderate seeps and control areas." These findings suggest the six species of coral Noonan *et al*. studied, plus the various *Symbiodinium* types they encountered, were able not only to survive but to function well throughout the full range of CO_2-induced pH values to which they had been exposed.

Wall and Edmunds (2013) note laboratory studies "typically are performed under conditions that do not replicate the natural environment perfectly, notably by providing light at a constant low intensity through-out the day, and with a spectral composition differing from ambient sunlight," citing Kinzie *et al*. (1984) and Schlacher *et al*. (2007). "Also of great importance," they write, "is the hydrodynamic regime of reef environments (Monismith, 2007), which is difficult to recreate in tanks and yet is critical for multiple aspects of coral physiology (Dennison and Barnes, 1988; Patterson *et al*., 1991)."

Wall and Edmunds collected juvenile *Porites* spp. from 2–3 m depths on the back reef of Moorea, attached them to plastic bases with epoxy, and after allowing them to recover in a 1,000-L flow-through tank placed them in nine 150-L reservoirs consisting of three replicates each of filtered seawater maintained at three conditions: Treatment 1 (un-manipulated seawater), Treatment 2 (seawater equilibrated with pCO_2 at 98.9 Pa), and Treatment 3 (same as Treatment 2 but augmented with baking soda to increase $[HCO_3^-]$ to 2730 µmol kg^{-1} at a pH_T of 7.69). They conducted three experiments on 4, 6, and 8 February 2012, where in each case the custom-cast, UV-transparent acrylic chambers they created remained on the reef for 28 hours.

They found no differences between the behaviors of the juvenile massive *Porites* corals in Treatments 1 and 2, but calcification was enhanced by fully 81% in Treatment 3 relative to Treatments 1 and 2. The two U.S. researchers conclude, "these findings indicate that juvenile massive *Porites* spp. are resistant to

short exposures to OA *in situ*," and "they can increase calcification at low pH and low Ω_{arg} if $[HCO_3^-]$ is elevated." The latter finding leads them also to suggest calcification of juvenile *Porites* spp. may "be limited by dissolved inorganic carbon under ambient pCO_2 condition."

6.3.3.3 Crustaceans

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on marine crustaceans. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Survival of shrimp larvae was not reduced by lower ocean pH levels .

- At reduced seawater pH the velvet swimming crab was able to "buffer changes to extra-cellular pH over 30 days exposure" and do so "with no evidence of net shell dissolution." In addition, "tolerance to heat, carapace mineralization, and aspects of immune response were not affected by hypercapnic conditions."

- The early life larval stages of the bay barnacle "are generally tolerant to near-future levels of ocean acidification," and this observation "is in line with findings for other barnacle species." In addition, its "substantial genetic variability in response to low pH may confer adaptive benefits under future ocean acidification."

- Vertically migrating adult Arctic copepods daily cross a pCO_2 range of less than140 μatm and show

"only minor responses to manipulated high CO_2," suggesting "the natural range of pCO_2 experienced by an organism determines its sensitivity to future OA."

Noting "there is a particular need to study effects of OA [ocean acidification] on organisms living in cold-water environments due to the higher solubility of CO_2 at lower temperatures," Bechmann *et al*. (2011) maintained shrimp (*Pandalus borealis*) larvae, from day 1 through day 36 post-hatching, under the OA scenario predicted for the year 2100 (pH 7.6) and compared them against batches of larvae held under the current oceanic pH of 8.1 (the control treatment), while water temperature was kept at a constant 5°C. Bechmann *et al*. report survival of the larvae was not reduced at any time during the experiment, but there was "a significant delay in zoeal progression (development time)," which "may increase the chance of loss by predation." They note "a multi-generation experiment with the copepod *Acartia tonsa* showed that effects of OA observed in the first generation were no longer present in the second and third generation (Dupont and Thorndyke, 2009)," implying that could also prove true in the situation they investigated. The eight Norwegian researchers conclude, "there are different opinions about how to extrapolate the effects of OA from a single species examined in relatively short-term experiments to the population and ecosystem level," noting "all agree that more data from relevant long-term experiments are needed to better predict effects at higher levels of biological organization," citing Dupont *et al*. (2010a,b), Hendriks and Duarte (2010), and Hendricks *et al*. (2010).

Small *et al*. (2010) investigated the potential effects of lower ocean pH levels on the velvet swimming or "devil" crab (*Necora puber*). Working with adult individuals collected from the lower intertidal zone of Mount Batten Beach, Plymouth, UK, the authors tested the effect of 30 days' exposure of the crabs to seawater maintained in 4-L aquaria at pH values of 8.0 (control), 7.3, and 6.7. They found "*Necora puber* was able to buffer changes to extra-cellular pH over 30 days exposure," and to do so "with no evidence of net shell dissolution." They report, "tolerance to heat, carapace mineralization, and aspects of immune response were not affected by hypercapnic conditions"— i.e., conditions that lead to more than the normal level of carbon dioxide in an organism's blood. About the only negative finding was a decline in whole-animal oxygen consumption, which they described as being "marginal" between the control and medium hypercapnic conditions, but "significant" at the unrealistic future pH value of 6.7. Small *et al*. conclude their results "confirm that most physiological functions in *N. puber* are resistant to low pH/hypercapnia over a longer period than previously investigated."

In two experiments conducted over two successive years, Pansch *et al*. (2013) first assessed larval survival and development of the bay barnacle *Amphibalanus improvisus* while rearing nauplius larvae in six-well plates over 10 days in response to three pH treatments (8.02, 7.80, and 7.59). In the second experiment they assessed larval stage and size by rearing nauplius larvae in 5-L glass bottles over six days with two pH treatments (8.09 and 7.80). The three scientists report the "larval development of the barnacle was not significantly affected by the level of reduced pH that has been projected for the next 150 years," noting, "after 3 and 6 days of incubation, we found no consistent effects of reduced pH on developmental speed or larval size at pH 7.8 compared with the control pH of 8.1." They write, "after 10 days of incubation, there were no net changes in survival or overall development of larvae raised at pH 7.8 or 7.6 compared with the control pH of 8.0." In their many individual trials, they determined "there was significant variation in responses between replicate batches (parental genotypes) of some larvae," with some batches responding positively to reduced pH.

Pansch *et al*. say their results suggest "the non-calcifying larval stages of *A. improvisus* are generally tolerant to near-future levels of ocean acidification," and "this result is in line with findings for other barnacle species and suggests that barnacles do not show the greater sensitivity to ocean acidification in early life history reported for other invertebrate species." They also state the barnacle's "substantial genetic variability in response to low pH may confer adaptive benefits under future ocean acidification."

According to Lewis *et al*. (2013), "copepods comprise the dominant Arctic zooplankton; hence, their responses to OA [ocean acidification] have important implications for Arctic ecosystems, yet there is little data on their current under-ice winter ecology on which to base future monitoring or make predictions about climate-induced change." Lewis *et al*. examined "the natural distributions of the dominant Arctic copepods found under winter sea ice in relation to the current seawater carbonate chemistry conditions and compared these with their short-term responses to future high CO_2 conditions." They conducted this work "at the temporary Catlin Arctic

Survey Ice Base (CIB) during late winter to early spring in 2011," where "the zooplankton were dominated by adult calanoid copepods, comprising mainly the Arctic endemics *Calanus glacialis* and *Calanus hyperboreus* but also the smaller, globally occurring *Oithona similis*, together with the nauplii of various copepod species." They conducted a series of OA experiments "using these copepod species and life history stages to compare their response to future high CO_2 conditions with natural under-ice pCO_2 exposures."

The five researchers' data revealed "species and life stage sensitivities to manipulated conditions were correlated with their vertical migration behavior and with their natural exposures to different pCO_2 ranges," and "vertically migrating adult *Calanus* spp. crossed a pCO_2 range of >140 µatm daily and showed only minor responses to manipulated high CO_2," whereas "*Oithona similis*, which remained in the surface waters and experienced a pCO_2 range of <75 µatm, showed significantly reduced adult and nauplii survival in high CO_2 experiments."

Lewis *et al*. conclude, "the natural range of pCO_2 experienced by an organism determines its sensitivity to future OA," adding, "certainly, ubiquitous species in their adult form, living across a range of physicochemical conditions, are likely capable of surviving change." They also note the "larvae of many marine organisms are released at very specific times to coincide with favorable environmental or food conditions," and it seems logical to conclude the same would hold true in the future, making it easier for copepod larvae to survive future OA conditions as well.

Pedersen *et al*. (2013) investigated "the impact of medium-term exposure to CO_2 acidified seawater on survival, growth and development … in the North Atlantic copepod *Calanus finmarchicus*." Using a custom-developed experimental system, "fertilized eggs and subsequent development stages were exposed to normal seawater (390 ppm CO_2) or one of three different levels of CO_2-induced acidification (3,300, 7,300, 9,700 ppm CO_2)." The four Norwegian researchers report, "following the 28-day exposure period, survival was found to be unaffected by exposure to 3,300 ppm CO_2, but significantly reduced at 7,300 and 9,700 ppm CO_2," values far beyond any atmospheric concentration predicted under even the most extreme of circumstances. Pedersen *et al*. conclude, "the absence of any apparent reduction in the overall survival during the present medium-term exposure to 3,300 ppm CO_2, indicates that survival of *Calanus* eggs and nauplii may be robust against the direct effects of the worst-case CO_2 scenario predicted for year 2300."

6.3.3.4 Echinoderms

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on marine echinoderms. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- The common sea star *C. papposus* is "positively impacted by ocean acidification," as "larvae and juveniles raised at low pH grow and develop faster, with no negative effect on survival or skeletogenesis."

- Adults of the sea star *Luidia clathrata* exposed to end-of-century pH conditions "are relatively unimpaired in their regenerative capacity," which "encompasses not only their ability to re-grow their arms, but their ability to allocate materials and energy to regenerated somatic body components."

- "*Paracentrotus lividus* appears to be extremely resistant to low pH, with no effect on fertilization success or larval survival."

- "Polar and sub-polar sea urchin larvae can show a certain degree of resilience to acidification" and do not appear to be more susceptible to lower seawater pH than their temperate and tropical counterparts.

- Gametes from *Sterechinus neumayeri* are "relatively robust to pH change, especially to changes within the range predicted for the near future (i.e. a decrease of 0.3–0.5 pH units)."

- "Sea urchins inhabiting stressful intertidal environments produce offspring that may better resist future ocean acidification."

- In studies designed to reveal the effects of atmospheric CO_2 enrichment upon marine life, treatment comparisons should be made at equivalent development stages of the organism being studied. At such points along the life cycle, studies have shown there to be no significant physical differences between individuals raised under control or CO_2-enriched conditions.

- Lower ocean pH levels induced a developmental delay in *P. lividus*, yet "at a given developmental state (or size), larvae present the same calcium incorporation rate regardless of pH."

- *Strongylocentrotus purpuratus* sea urchins "demonstrate the capacity for rapid evolution in the face of ocean acidification and show that standing genetic variation could be a reservoir of resilience to climate change in [a] coastal up-welling ecosystem."

According to Dupont *et al.* (2010), "echinoderms are among the most abundant and ecologically successful groups of marine animals (Micael *et al.*, 2009), and are one of the key marine groups most likely to be impacted by predicted climate change events," presumably because "the larvae and/or adults of many species from this phylum form skeletal rods, plates, test, teeth, and spines from an amorphous calcite crystal precursor, magnesium calcite, which is 30 times more soluble than normal calcite (Politi *et al.*, 2004)." This fact normally would be thought to make it much more difficult for echinoderms (relative to most other calcifying organisms) to produce calcification-dependent body parts.

Dupont *et al.* studied naturally fertilized eggs of the common sea star *Crossaster papposus*, which they collected and transferred to five-liter culture aquariums filled with filtered seawater (a third of which was replaced every four days). They regulated the pH of the tanks to values of either 8.1 or 7.7 by adjusting environmental CO_2 levels to either 372 ppm or 930 ppm, documenting settlement success as the percentage of initially free-swimming larvae that affixed themselves to the aquarium walls, larval length at various time intervals, and degree of calcification. The three researchers report results the opposite of what is often predicted: The echinoderm larvae and juveniles were "positively impacted by ocean acidification." They found "larvae and juveniles raised at low pH grow and develop faster, with no negative effect on survival or skeletogenesis within the time frame of the experiment (38 days)." They report the sea stars' growth rates were "two times higher" in the low pH seawater, and "*C. papposus* seem to be not only more than simply resistant to ocean acidification, but are also per-forming better."

The Swedish scientists conclude, "in the future ocean, the direct impact of ocean acidification on growth and development potentially will produce an increase in *C. papposus* reproductive success," and "a

decrease in developmental time will be associated with a shorter pelagic period with a higher proportion of eggs reaching settlement," leading the sea stars to become "better competitors in an unpredictable environment."

Schram *et al.* (2011) investigated the effects of lower ocean pH levels on another sea star, *Luidia clathrata*. The write, "two groups of sea stars, each with two arms excised, were maintained on a formulated diet in seawater bubbled with air alone (pH 8.2, approximating a pCO_2 of 380 ppm) or with a controlled mixture of air/CO_2 (pH 7.8, approximating a pCO_2 of 780 ppm)," and "arm length, total body wet weight, and righting responses were measured weekly." After 97 days, "a period of time sufficient for 80% arm regeneration," they state "protein, carbohydrate, lipid and ash levels were determined for body wall and pyloric caecal tissues of intact and regenerating arms of individuals held in both seawater pH treatments."

The four U.S. researchers report, "adults of the common soft bottom predatory sea star *Luidia clathrata* exposed to end-of-century conditions of ocean acidification (pH 7.8) are relatively unimpaired in their regenerative capacity," which "encompasses not only their ability to re-grow their arms, but their ability to allocate materials and energy to regenerated somatic body components." They found "no discernable pattern arising from exposure to a reduced seawater pH of 7.8 for 97 days on righting behavior," which they say is "an integrative measure of stress." Schram *et al.* conclude, "the demonstration of an organism's ability to sustain normal functions under these conditions is as equally important to document as those that are negatively impacted," because "this information will be critical to future assessments of prospective impacts of ocean acidification at the community level."

Schlegel *et al.* (2012) note "environmental factors directly affect populations by selecting resilient individuals," and "selection at the gametic level, or during early life, has strong and immediate effects at the population level, carrying over into subsequent life stages," as "heritability of this resilience leads to cascading adaptive effects in subsequent generations." As an example of this process, they report, "in free-spawning marine organisms, sperm selection during fertilization plays a key role by determining the nature and diversity of genotypes in the subsequent generation (Levitan, 1996; 2008) and thus their resilience to environmental change."

Schlegel *et al.* investigated "the effects of CO_2-induced ocean acidification on the early life history

stages in the Australasian sea urchin *Heliocidaris erythrogramma*, focusing on intra-specific variation in responses, which can be highly variable for this species (Evans and Marshall, 2005)." They followed "the A1FI-scenario from IPCC's 4th assessment report" and "compared the effects of present day conditions for southeast Australia with the end-of-century scenario (pCO_2=970 ppm; pH=0.3 unit reduction) and a high-CO_2 scenario (pCO_2=1600 ppm; pH=0.5 unit reduction)." The write, "observed effects on sperm swimming behavior were applied within an established fertilization kinetics modeling framework (Vogel *et al.*, 1982; Styan *et al.*, 2008) to predict fertilization outcomes of single urchin pairs at each pCO_2 level." These results "were then compared to observed results from fertilization experiments conducted in the laboratory."

Schlegel *et al.* found "acidification significantly decreased the proportion of motile sperm but had no effect on sperm swimming speed," and the four researchers state the subsequent fertilization experiments "showed strong inter-individual variation in responses to ocean acidification, ranging from a 44% decrease to a 14% increase in fertilization success." They say their results indicate "some individuals will exhibit enhanced fertilization success in acidified oceans, supporting the concept of 'winners' and 'losers' of climate change at an individual level." If these differences are heritable, they say, it is likely "ocean acidification will lead to selection against susceptible phenotypes as well as to rapid fixation of alleles that allow reproduction under more acidic conditions," and these phenomena "may ameliorate the biotic effects of climate change if taxa have sufficient extant genetic variation upon which selection can act."

Moulin *et al.* (2011) supplied real-world data indicating phenotypic adaptation to seawater of lower pH by conducting a field experiment on the sea urchin *Paracentrotus lividus* in an attempt "to compare the effect of pH on the progeny of individuals collected from the same shore, i.e., same population, but from distinct tide pools: one where night pH was significantly reduced and the other where this decline was not so important." The four Belgian researchers report the pH of coastal seawater at the site they studied (Aber, Crozon peninsula, southern Brittany, France) was 8.14, but they say at the end of the night low tides, tide pools 1 (subtidal) and 2 (intertidal) had pH values of, respectively, 7.8 and 7.4. Under these conditions, they detected "no significant difference in gonad maturity between individuals from the two tide pools," and "the offspring of sea urchins from the tide

pool with higher pH decrease (tide pool 2) showed a better resistance to acidification at pH 7.4 than that of sea urchins from the tide pool with low pH decrease (tide pool 1) in terms of fertilization, viz. a reduction of over 30% [for tide pool 1] compared to about 20% for tide pool 2."

Moulin *et al*. conclude "sea urchins inhabiting stressful intertidal environments produce offspring that may better resist future ocean acidification." They also note "the fertilization rate of gametes whose progenitors came from the tide pool with higher pH decrease was significantly higher," suggesting "a possible acclimation or adaptation of gametes to pH stress."

Martin *et al*. (2011) write, "ocean acidification is predicted to have significant effects on benthic calcifying invertebrates, in particular on their early developmental states," and "echinoderm larvae could be particularly vulnerable to decreased pH, with major consequences for adult populations." The authors explored the effect of a gradient of decreasing pH from 8.1 to 7.0—corresponding to atmospheric CO_2 concentrations of ~400 ppm to ~6,630 ppm—on the larvae of the sea urchin *Paracentrotus lividus*, a common, economically and ecologically important species widely distributed throughout the Mediterranean Sea and the northeast Atlantic from Ireland to southern Morocco. The scientists used "multiple methods to identify the response of *P. lividus* to CO_2-driven ocean acidification at both physiological (fertilization, growth, survival and calcification) and molecular (expression of genes involved in calcification and development) levels."

They found "*Paracentrotus lividus* appears to be extremely resistant to low pH, with no effect on fertilization success or larval survival." They reported "larval growth was slowed when exposed to low pH," as larvae of *P. lividus* "collected at pH 7.5 at 46 hours post-fertilization (real age) were smaller than in the control treatment [pH 8.1] and corresponded to a virtual age of 36 hours (a delay in development of 10 hours)." They further report, "down to a pH of 7.25, the larvae at Day 3 have a normal morphology but are delayed in development," so the apparent decrease in calcification at that point in time is, as they put it, "simply an indirect consequence of the impact of low pH on developmental rate." They continue, "at a given developmental state (or size), larvae present the same calcium incorporation rate regardless of pH." The scientists also report "genes involved in development and biomineralization were upregulated by factors of up to 26 at low pH," which suggests "plasticity at the gene expression level" in *P. lividus*

"allows a normal, but delayed, development under low pH conditions."

Ericson *et al*. (2010) note in polar latitudes "the effects of changing pCO_2 and pH on gametes may be influenced by the carbonate chemistry of cold water, such as the already higher pCO_2 and lower seawater pH," and "it has also been predicted that ocean acidification effects on organisms may be more apparent and appear earliest in polar waters." Ericson *et al*. "investigated the effects of present-day pH 8.0, predicted ocean surface pH for the years 2100 and 2300 (pH 7.7 and pH 7.3, respectively) and an extreme pH (pH 7.0) on fertilization and embryogenesis in the Antarctic nemertean worm *Parborlasia corrugatus* and sea urchin *Sterechinus neumayeri*."

The four researchers found "fertilization success was not affected by pH in *P. corrugatus* across a range of sperm concentrations," and "fertilization success in *S. neumayeri* declined significantly in pH 7.0 and 7.3 seawater, but only at low sperm concentration." They observe, "seawater pH had no effect on the rate of egg cleavage in *S. neumayeri*, or the proportion of abnormal embryos 1-day post-fertilization," and "*P. corrugatus* embryogenesis was also relatively robust to pH changes, with a significant effect detected only when the seawater pH was decreased to 7.0." Ericson *et al*. conclude, "as in a number of other studies (see reviews by Byrne *et al*., 2010; Dupont *et al*., 2010), that gametes appeared relatively robust to pH change, especially to changes within the range predicted for the near future (i.e. a decrease of 0.3–0.5 pH units)," and they say their initial findings "do not support a view that polar species are more affected by lowered pH compared with temperate and tropical counterparts (as has also been shown for the later developmental stages of *S. neumayeri* (Clark *et al*., 2009))."

Yu *et al*. (2013) tested the effects of high CO_2/low pH on early development and larval growth by exposing *Sterechinus neumayeri* to environmental levels of CO_2 in McMurdo Sound (control: 410 ppm) and mildly elevated CO_2 levels, both near the level of the aragonite saturation horizon (510 ppm), and to under-saturating conditions (730 ppm). Over the course of development from egg to late four-arm pluteus, they found, "(1) early embryological development was normal with the exception of the hatching process, which was slightly delayed, (2) the onset of calcification as determined by the appearance of $CaCO_3$ spicule nuclei was on schedule, (3) the lengths of the spicule elements, and the elongation of the spicule nuclei into the larval skeleton, were significantly shorter in the highest CO_2 treatment four

days after the initial appearance of the spicule nuclei, and (4) finally, without evidence of true developmental delay, larvae were smaller overall under high CO_2 treatments; and arm length, the most plastic morphological aspect of the echinopluteus, exhibited the greatest response to high CO_2/low pH/low carbonate conditions." Yu *et al*. conclude, "effects of elevated CO_2 representative of near future climate scenarios are proportionally minor on these early development stages."

Yu *et al*. (2011) raised larvae of the purple sea urchin (*Strongylocentrotus purpuratus*) in seawater maintained at pCO_2 levels ranging from ambient to 1,000 and 1,450 ppm CO_2 (pH 7.7 and 7.5, respectively) while measuring, after three and six days of development, "total larval length (from the spicule tip of the postoral arm to the spicule tip of the aboral point) along the spicules, to assess effects of low pH upwelling water on morphology." They found "even at the highest pCO_2 treatments, larval development was normal in terms of timing and morphological appearance," although at both days 3 and 6 larvae in the 1,450 ppm CO_2 treatment were 7–13% smaller than control larvae. Yu *et al*. also report "the observed developmental progression and survival of cultures was within the norm typically observed for this species at this temperature range." They note, "a lack of developmental deformities at early stages for pCO_2 ~1000 ppm has been previously reported for this species (Todgham and Hofmann, 2009), and another local species, *Lytechinus pictus*, with a similar overlapping portion of its range in southern California (O'Donnell *et al*., 2010)." They also remark, "there are even reports survival is increased in this species and its congener *S. droebachiensis* under some low pH conditions (Dupont and Thorndyke, 2008)."

Yu *et al*. conclude, "the effects of small magnitude in these urchin larvae are indicative of a potential resilience to near-future levels of ocean acidification."

Stumpp *et al*. (2011a) evaluated the impacts of elevated seawater pCO_2 (1,264 ppm vs. 375 ppm) on the early development of, and the larval metabolic and feeding rates of, *Strongylocentrotus purpuratus*. The researchers assessed growth and development daily, for three weeks, in terms of total body length, body rod length, postoral rod length, and posterolateral rod length, as well as mortality and feeding and metabolic rates. They found daily mortality rate (DMR) was higher under control conditions (DMR = 2.7% per day) than under high seawater pCO_2 (DMR = 2.2% per day). They also observed, in the elevated CO_2 treatment, larval development was about 8% slower, such that it took slightly longer for the organisms to reach equivalent development stages in the high CO_2 treatment.

As a result of the slower development of the larvae in the high CO_2 treatment, at any given time the individuals in this treatment were smaller and less well-developed than those in the control treatment, and if that were the only comparison made in this study, the effects of elevated CO_2 would seem to be negative. However, the researchers also made comparisons on the basis of development stage, and they found there were no long-term physical differences between the larvae living in the high and low CO_2 treatments.

Thus in studies designed to reveal the effects of atmospheric CO_2 enrichment on various species of marine life, treatment comparisons should be made at equivalent development stages of the organism being studied. At such points along the life cycle of the purple sea urchin, there were no significant physical differences between individuals raised in the control and CO_2-enriched conditions. Stumpp *et al*. conclude, "we suggest that body length is a useful scale of reference for studies in sea urchin larvae where a morphological delay in development occurs," and "using time post-fertilization as a reference may lead to misinterpretation of data"—by wrongly assuming a negative result when in fact there may be no deleterious effect of lower ocean pH levels . Stumpp *et al*. (2011b) reached essentially the same conclusion in a companion paper, writing, "in studies in which a stressor induces an alteration in the speed of development, it is crucial to employ experimental designs with a high time resolution in order to correct for developmental artifacts," as this protocol "helps prevent misinterpretation of stressor effects on organism physiology."

Pespeni *et al*. (2013) note "little is known about the adaptive capacity of species to respond to an acidified ocean," and, as a result, "predictions regarding future ecosystem responses remain incomplete." They demonstrated lower ocean pH levels generate striking patterns of genome-wide selection in purple sea urchins (*Strongylocentrotus purpuratus*) cultured under CO_2 levels of 400 and 900 ppm. Working with seven populations collected along a 1,200 km mosaic of coastal upwelling-driven acidification of the California Current System, Pespeni *et al*. combined sequencing across the transcriptome of the purple sea urchin, growth measurements under experimental acidification, and tests of frequency shifts in 19,493 polymorphisms

during development, detecting in the process "the widespread occurrence of genetic variation to tolerate ocean acidification."

Although larval development and morphology showed little response to elevated CO_2, the 11 researchers found "substantial allelic change in 40 functional classes of proteins involving hundreds of loci." They state "pronounced genetic changes, including excess amino acid replacements, were detected in all populations and occurred in genes for biomineralization, lipid metabolism, and ion homeostasis—gene classes that build skeletons and interact in pH regulation." They note "such genetic change represents a neglected and important impact of ocean acidification that may influence populations that show few outward signs of response to acidification." The researchers conclude "our results demonstrate the capacity for rapid evolution in the face of ocean acidification and show that standing genetic variation could be a reservoir of resilience to climate change in this coastal upwelling ecosystem."

Catarino *et al.* (2012) studied the development of larvae produced by adults of the *Arbacia dufresnei* urchin, which they collected from a sub-Antarctic population in the Straits of Magellan near Punta Arenas, Chile, immersed in high (8.0), medium (7.7), and low (7.4) pH seawater. The five scientists found "the proportion of abnormal larvae did not differ according to [pH] treatment." Although "lower pH induced a delay in development," which also was noted by Dupont *et al.* (2010), it "did not increase abnormality." Catarino *et al.* report, "even at calcium carbonate saturation states <1, skeleton deposition occurred," and they note specimens of *Heliocidaris erythrogramma* also "seem not to be affected by a pH decrease (until 7.6)," citing Byrne *et al.* (2009a,b). They note the Antarctic *Sterechinus neumayeri* is thought to be "more robust to ocean acidification than tropical and temperate sub-tidal species," citing Clark *et al.* (2009) and Ericson *et al.* (2010). The findings of Catarino *et al.*, and those of the other researchers they cite, indicate "polar and sub-polar sea urchin larvae can show a certain degree of resilience to acidification." They conclude *A. dufresnei* has the potential to "migrate and further colonize southern regions."

Sunday *et al.* (2011) note the presumed acidification of Earth's oceans is predicted to impact marine biodiversity via "physiological effects impacting growth, survival, reproduction and immunology, leading to changes in species abundances and global distributions." They point out "the degree to which these changes will play out

critically depends on the evolutionary rate at which populations will respond to natural selection imposed by ocean acidification," and this phenomenon "remains largely unquantified," citing Stockwell *et al.* (2003) and Gienapp *et al.* (2008). Sunday *et al.* measured the potential for an evolutionary response to lower ocean pH levels in the larval development rate of the two coastal invertebrates, a sea urchin (*Strongylocentrotus franciscanus*) and a mussel species (*Mytilus trossulus*).

The four researchers report their experiment revealed "the sea urchin species *Stronglyocentrotus franciscanus* has vastly greater levels of phenotypic and genetic variation for larval size in future CO_2 conditions compared to the mussel species *Mytilus trossulus*." They demonstrate "*S. franciscanus* may have faster evolutionary responses within 50 years of the onset of predicted year-2100 CO_2 conditions despite having lower population turnover rates." Sunday *et al.* conclude their comparisons suggest "information on genetic variation, phenotypic variation, and key demographic parameters, may lend valuable insight into relative evolutionary potentials across a large number of species," thereby also indicating simplistic climate envelope models of species redistributions in a future CO_2-enriched and possibly warmer world are not up to the task of providing an accurate picture of future biological reality. They note "a genetic basis for variation in CO_2 responses has been found in the three previous studies in which it has been sought (Langer *et al.*, 2009; Parker *et al.*, 2011; Pistevos *et al.*, 2011), supporting the notion that genetic variation exists at some level for almost all quantitative characters (Roff, 1997)."

6.3.3.5 Fish

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on marine fish. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Negative effects of lower ocean pH levels on fish are generally not manifested until the water reaches pH concentrations associated with atmospheric CO_2 levels several times the present value.

- Otoliths of fish grown in seawater of lower pH and aragonite saturation associated with higher CO_2 conditions are usually significantly larger than those of fish grown under present-day conditions.

- "CO_2-induced acidification up to the maximum values likely to be experienced over the next 100 years had no noticeable effect on embryonic duration, egg survivorship and size at hatching for *A. percula*, and tended to have a positive effect on the length and weight of larvae."

- "Most shallow-water fish tested to date appear to compensate fully their acid-base balance within several days of exposure to mild hypercapnia."

- "Future ocean acidification will probably not pose a problem for sperm behavior, and hence fertilization success, of Baltic cod."

- Lower ocean pH levels "neither affected the embryogenesis nor the hatch rate" of Atlantic herring. It also "showed no linear relationship between CO_2 and total length, dry weight, yolk sac area and otolith area of the newly hatched larvae."

- "Cobia exhibited resistance to treatment effects on growth, development, swimming ability, and swimming activity at 800 and 2100 μatm pCO_2," whereas "these scenarios resulted in a significant increase in otolith size (up to 25% larger area)."

- The larval clown fish "is robust to levels of ocean chemistry change that may occur over the next 50–100 years."

- Lower ocean pH levels significantly increased the size, density, and relative mass of larval cobia otoliths, which changes "could affect auditory sensitivity including a ~50% increase in hearing range at 2100 ppm CO_2."

- Lower ocean pH levels "did not appear to negatively affect size or condition of early larval walleye pollock." It induced "a trend toward larger body sizes among fish reared at elevated CO_2 levels."

Ishimatsu *et al*. (2005) note fish "constitute a major protein source in many countries," and the "potential reduction of fish resources by high-CO_2 conditions due to the diffusion of atmospheric CO_2 into the surface waters ... can be considered as another potential threat to the future world population." They conducted a survey of the scientific literature regarding the potential negative consequences for the health of marine fish of atmospheric CO_2 enrichment that could arise from continued anthropogenic CO_2 emissions.

Focusing on the possible threat of hypercapnia—a condition characterized by an excessive amount of CO_2 in the blood that typically results in acidosis, a serious and sometimes fatal condition—they say their survey revealed "hypercapnia acutely affects vital physiological functions such as respiration, circulation, and metabolism, and changes in these functions are likely to reduce growth rate and population size through reproduction failure." Although this potential threat sounds dire, it represents an egregious flight of the imagination away from what could realistically be expected to happen to fish in the future.

Ishimatsu *et al*. report "predicted future CO_2 concentrations in the atmosphere are lower than the known lethal concentrations for fish," noting "the expected peak value is about 1.4 torr [just under 1,850 ppm CO_2] around the year 2300 according to Caldeira and Wickett (2003)." As to just how far below the lethal CO_2 concentration for fish 1.4 torr is, in the case of short-term exposures on the order of a few days, Ishimatsu *et al*. cite a number of studies that yield median lethal concentrations ranging from 37 to 50 torr, values 26 and 36 times greater than the maximum CO_2 concentration expected some 300 years from now.

Regarding long-term exposures, the results are even more comforting. Ishimatsu *et al*. report Fivelstad *et al*. (1999) observed only 5 and 8% mortality at the end of 62 days of exposure to CO_2 concentrations of 5 and 9 torr, respectively, for freshwater Atlantic salmon smolts, and mere 1 and 5% mortalities for seawater postsmolts of the same species at 12 and 20 torr after 43 days (Fivelstad *et al*., 1998). Ishimatsu *et al*. note Smart *et al*. (1979) found little difference in mortality for freshwater rainbow trout reared for 275 days at 4 to 17 torr, and no mortality occurred by the tenth week of exposure of juvenile spotted wolf fish to 20 torr (Foss *et al*., 2003).

Fish embryos and larvae are often more vulnerable to environmental stresses than are adult fish. Yet even here, Ishimatsu *et al*. report the 24-hour median lethal concentration of CO_2 for eggs and larvae of several marine fish studied by Kikkawa *et al*. (2003) "ranged widely from 10 torr to 70 torr among species," with the smaller of these two values being more than seven times greater than the CO_2 concentration expected 300 years from now.

Ishimatsu *et al*.'s review reveals growth reductions of 24 to 48%, but again the CO_2 concentrations that induced those growth reductions ranged from 17 to 20 torr, or 12 to 14 times more than the CO_2 concentration expected 300 years from now. Consequently, Ishimatsu *et al*.'s scientific literature review suggests both freshwater and marine fish will most likely never experience any ill effects from elevated atmospheric CO_2 concentrations.

Melzner *et al*. (2009) state several of Earth's 30,000 species of teleost fish, which include virtually all the important sport and commercial fishes, have been shown able to "fully compensate extra cellular fluid pH" and "maintain oxygen consumption rates and growth performance under ocean acidification conditions (e.g. Larsen *et al*., 1997; Foss *et al*., 2003; Fivelstad *et al*., 1998, 2003; Deigweiher *et al*., 2008)." Noting no studies of these phenomena have lasted for more than a few days, they maintained a group of Atlantic Cod (*Gadus morhua*) for four months in a recirculating aquaculture system of 15 cubic meters at an atmospheric CO_2 partial pressure of 0.3 kPa (~3,000 ppm) and another group for 12 months at a CO_2 partial pressure of 0.6 kPa (~6,000 ppm). They then investigated the fishes' swimming metabolism in a swim-tunnel respirometer and took tissue samples of their gills for various chemical analyses, including gill Na^+/K^+-ATPase capacity, which serves as a general indicator for ion regulatory effort.

The six German scientists report, "motor activity in adult Atlantic Cod is not compromised by long-term exposure to water pCO_2 levels of 0.3–0.6 kPa," which are "scenarios exceeding the 0.2 kPa value

predicted for surface ocean waters around the year 2300 (Caldeira and Wickett, 2003)." Melzner *et al*. conclude "adults of active fish species with a high ion regulatory capacity [which is employed to eliminate metabolic CO_2] are well equipped to cope with projected scenarios of global climate change."

Checkley *et al*. (2009) report on their work with fish otoliths—bony structures consisting of aragonite-protein bilayers which fish use to sense orientation and acceleration. Noting atmospheric CO_2 enrichment had been calculated to decrease the saturation state of carbonate minerals such as aragonite in the world's oceans, the six scientists "hypothesized that otoliths in eggs and larvae reared in seawater with elevated CO_2 would grow more slowly than they do in seawater with normal CO_2." To test this hypothesis, they "grew eggs and pre-feeding larvae of white sea bass (*Atractoscion nobilis*) under a range of CO_2 concentrations [380, 993 and 2,558 ppm] and measured the size of their sagittal otoliths."

"Contrary to expectations," Checkley *et al*. write, "the otoliths of fish grown in seawater with high CO_2, and hence lower pH and aragonite saturation, were significantly larger than those of fish grown under simulations of present-day conditions." They found "for 7- to 8-day-old fish grown under 993 and 2558 ppm CO_2, the areas of the otoliths were 7 to 9% and 15 to17% larger, respectively, than those of control fish grown under 380 ppm CO_2." The marine researchers note young fish are "able to control the concentration of ions (H^+ and Ca^{2+}) ... in the endolymph surrounding the otolith," where "with constant pH, elevated CO_2 increases CO_3^{2-} concentration and thus the aragonite saturation state, accelerating formation of otolith aragonite."

Munday *et al*. (2009) note "there is concern that continued increases in atmospheric CO_2 over the next century could have significant impacts on a wide range of marine species, not just those with calcified skeletons." In the case of fish, which "control their tissue pH by bicarbonate buffering and the exchange of ions, mostly across the gills," they write, "small changes in internal or external pH can readily be compensated (Heisler, 1989; Claiborne *et al*., 2002)." Fish embryos and young larvae are possibly "more sensitive to pH changes than are juveniles and adults," and "significant effects of ocean acidification are most likely to be detected in these early life stages."

Munday *et al*. grew wild-caught pairs of the orange clownfish (*Amphiprion percula*) in a 70,000-liter recirculating seawater system at James Cook University's experimental marine aquarium facility.

They filled 70-liter tanks with seawater simulating a range of ocean acidification scenarios for the next 50–100 years—390 (current day), 550, 750, and 1,030 ppm atmospheric CO_2—while documenting egg, embryo, and larval development. The four researchers from the School of Marine and Tropical Biology of Australia's James Cook University determined "CO_2 acidification had no detectable effect on embryonic duration, egg survival and size at hatching," and it "tended to increase the growth rate of larvae." They observed, for example, 11 days after hatching, "larvae from some parental pairs were 15 to 18 per cent longer and 47 to 52 per cent heavier in acidified water compared to controls." There was a "positive relationship between length and swimming speed," and, they note, "large size is usually considered to be advantageous for larvae and newly settled juveniles."

Munday *et al*. note "the most common prediction is that ocean acidification could [negatively] affect individual performance (e.g. development, growth, survival, swimming ability)," especially during the early life history of the fish. However, they write, "contrary to expectations," their findings indicate "CO_2-induced acidification up to the maximum values likely to be experienced over the next 100 years had no noticeable effect on embryonic duration, egg survivorship and size at hatching for *A. percula*, and tended to have a positive effect on the length and weight of larvae." As for adult fish, they state "most shallow-water fish tested to date appear to compensate fully their acid-base balance within several days of exposure to mild hypercapnia," citing Michaelidis *et al*. (2007) and Ishimatsu *et al*. (2008).

Frommel *et al*. (2010) state, "elevated CO_2 concentrations can disturb the acid-base regulation, blood circulation, and respiration, as well as the nervous system of marine organisms, leading to long term effects such as reduced growth rates and reproduction," especially in fish, because most "are external fertilizers, and sperm are activated by seawater as they are expelled into the open ocean during a spawning event," citing Westin and Nissling (1991). Frommel *et al*. collected sperm from ripe adult male cod fish (*Gadus morhua*) caught during an August cruise through their spawning grounds in the Baltic Sea's Bornholm Basin. They exposed the fish to seawater that had been brought into equilibrium (by bubbling) with air of either 380 or 1,400 ppm CO_2 (leading to seawater pH values of 8.080 and 7.558, respectively), and they recorded sperm swimming behavior during the exposure period using a digital camera.

905

The scientists "found no significant effect of decreased pH on sperm speed, rate of change of direction or percent motility for the population of cod analyzed." Frommel *et al*. conclude "future ocean acidification will probably not pose a problem for sperm behavior, and hence fertilization success, of Baltic cod."

Franke and Clemmesen (2011) conducted a study in which eggs of Atlantic herring (*Clupea harengus* L.) were fertilized and incubated in artificially acidified seawater corresponding to atmospheric CO_2 concentrations of 1,260, 1,859, 2,626, 2,903, and 4,635 ppm and compared to a control treatment of 480 ppm CO_2 until the main hatch of the herring larvae occurred. "The development of the embryos was monitored daily and newly hatched larvae were sampled to analyze their morphometrics." The scientists report elevated CO_2 "neither affected the embryogenesis nor the hatch rate," and "the results showed no linear relationship between CO_2 and total length, dry weight, yolk sac area and otolith area of the newly hatched larvae." Franke and Clemmesen conclude "herring eggs can cope at current temperature conditions with an increase in CO_2," even one "exceeding future predictions of CO_2-driven ocean acidification."

Bignami *et al*. (2013a) state "there is a critical need to understand the effects of acidification on the vulnerable larval stages of marine fishes, as there is a potential for large ecological and economic impacts on fish populations and the human economies that rely on them." They studied "the larvae of *Rachycentron canadum* (cobia), a large, highly mobile, pelagic-spawning, widely distributed species with a life history and fishery value contrasting other species studied to date." Bignami *et al*. raised larval cobia through the first three weeks of ontogeny under conditions of predicted future ocean pH levels to determine effects on somatic growth, development, swimming ability, swimming activity, and the formation of otoliths.

The three U.S. researchers report "cobia exhibited resistance to treatment effects on growth, development, swimming ability, and swimming activity at 800 and 2100 µatm pCO_2," and "these scenarios resulted in a significant increase in otolith size (up to 25% larger area)." Bignami *et al*. conclude, "this study demonstrates that cobia is unlikely to experience a strong negative impact from CO_2-induced acidification predicted to occur within the next several centuries," which they speculate "may be due to the naturally variable environmental conditions this species currently encounters throughout ontogeny

in coastal environments," and "may lead to an increased acclimatization ability even during long-term exposure to stressors."

Munday *et al*. (2011a) state "in general, marine fish appear to be relatively tolerant to mild increases in ambient CO_2, presumably because well-developed mechanisms for acid-base regulation allow them to compensate for cellular acidosis caused by exposure to elevated pCO_2 (Portner *et al*., 2005; Ishimatsu *et al*., 2008; Melzner *et al*., 2009)." However, because "fish otoliths (earbones) are composed of aragonite," there is a concern they "could be susceptible to the declining carbonate ion concentrations associated with ocean acidification." Such an effect could be quite serious because "fish ears detect sound, body orientation and acceleration from the position of the otoliths in the inner ear and movement of the otoliths over sensory hair cells (Helfman *et al*., 1997; Popper and Lu, 2000)."

Munday *et al*. reared larvae of the marine clown fish *Amphiprion percula* throughout their larval phase at three pH levels—ambient or control conditions ($CO_2 \sim$ 390 ppm, pH $\sim$ 8.15) and higher CO_2/lower pH conditions ($CO_2 \sim$ 1,050 ppm, pH $\sim$ 7.8; $CO_2 \sim$ 1,721 ppm, pH $\sim$ 7.6) representative of conditions predicted to prevail in AD 2100 and AD 2200–2300, respectively—to ascertain whether the elevated CO_2/reduced pH conditions would alter otolith size, shape, symmetry (between left and right otoliths), or chemistry compared to current conditions. The four researchers report "there was no effect of the intermediate treatment on otolith size, shape, symmetry between left and right otoliths, or otolith elemental chemistry, compared with controls." In the more extreme treatment, otolith area and maximum length were slightly larger than for the controls, and "no other traits were significantly affected." Munday *et al*. state the larval clown fish appears "capable of regulating endolymphic fluid chemistry even in waters with pH values significantly lower than open ocean values," and they conclude "the larval clown fish is robust to levels of ocean chemistry change that may occur over the next 50–100 years." This conclusion is similar to that reached by Munday *et al*. (2011b), who "detected no effects of ~850 ppm CO_2 on size, shape or symmetry of otoliths on juvenile spiny damselfish, a species without a larval phase."

Miller *et al*. (2013) assessed the impact of lower ocean pH levels on the breeding success of cinnamon anemone fish. They employed three 8,000-L recirculating aquarium systems, each set to a different CO_2 and corresponding pH level. The treatments consisted of a current-day Control CO_2 (430 µatm), a

mid-century Moderate CO_2 (584 µatm), and an end-of-century High CO_2 (1,032 µatm). They placed 18 pairs of cinnamon anemone fish (*Amphiprion melanopus*) collected from Australia's Great Barrier Reef into each of these three aquariums after all individuals had been weighed and measured for length. At the start of the experiment, they placed pairs of fish in individual 45-L tubs with continuous water flow at winter non-breeding temperatures and ambient pCO_2 values, which the scientists gradually adjusted over a two-week period to the desired levels. Then, they increased temperature by 0.5°C per week, until the average summer breeding temperature was reached, after which they kept the pairs of fish in these conditions for a nine-month period that included the summer breeding season, and the researchers recorded various assessments of breeding success.

The four Australian researchers report, "unexpectedly, increased CO_2 dramatically stimulated breeding activity." More than twice as many pairs of the fish bred in the Moderate and High CO_2 treatments (67% and 55%) compared to the Control treatment (27%). In addition, "pairs in the High CO_2 group produced double the number of clutches per pair and 67% more eggs per clutch compared to the Moderate and Control groups." The researchers determined "reproductive output in the High group was 82% higher than that in the Control group and 50% higher than that in the Moderate group." They note, "despite the increase in reproductive activity, there was no difference in adult body condition among the three treatment groups," and "there was no significant difference in hatchling length between the treatment groups." Miller *et al*. conclude "this study provides the first evidence of the potential effects of ocean acidification on key reproductive attributes of marine fishes and, contrary to expectations, demonstrates an initially stimulatory effect in response to increased pCO_2."

Bignami *et al*. (2013b) write, "the days- to month-long pelagic larval period is an ecologically vital ontogenetic phase in marine fishes because it constitutes the primary mode of dispersal in many species (Cowen and Sponaugle, 2009) and represents the life stage most susceptible to mortality (Houde, 1997)." They say, "during this phase, the sensory abilities of larval fishes are important determinants of survival (Montgomery *et al*., 2006) and ultimately influence the persistence of viable populations." The five researchers "used new 3D microcomputed tomography to conduct *in situ* analysis of the impact of ocean acidification on otolith (ear stone) size and density of larval cobia (*Rachycentron canadum*), a large, economically important pantropical fish species that shares many life history traits with a diversity of high-value, tropical pelagic fishes."

According to the researchers, at an atmospheric partial pressure of 2,100 ppm CO_2 there was a significant increase in otolith size (up to 49% greater volume and 58% greater relative mass) and a 6% increase in otolith density, and the estimated relative mass of larval cobia otoliths in an end-of-century 800 ppm CO_2 treatment was 14% greater. Bignami *et al*. demonstrate "these changes could affect auditory sensitivity including a ~50% increase in hearing range at 2100 ppm CO_2." They say "this is a potentially optimistic result, indicating some resistance to acidification and suggesting that under near-future scenarios these impacts may be most relevant in habitats already experiencing high pCO_2 levels."

Hurst *et al*. (2013) examined the direct effects of projected ocean pH levels on the eggs and larvae of walleye pollock in a series of laboratory experiments to determine the effects of elevated CO_2 levels on size-at-hatch and early larval growth rates. They selected treatments to reflect ambient conditions and conditions predicted to occur in high latitude seas in the next century (a 400–600 ppm increase), as well as a significantly higher CO_2 treatment (~1,200 ppm). The three U.S. researchers report, "ocean acidification did not appear to negatively affect size or condition of early larval walleye pollock." They found "a trend toward larger body sizes among fish reared at elevated CO_2 levels," and they note this trend also has been observed in experiments with orange clownfish (Munday *et al*., 2009) and in a study of juvenile walleye pollock conducted by Hurst *et al*. (2012). Such findings, the authors write, suggest "the growth dynamics of early life stages of walleye pollock are resilient to projected levels of ocean acidification."

6.3.3.6 Miscellaneous Animal Studies

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on other marine animals not discussed in prior subsections. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- For the common cuttlefish (*Sepia officinalis*), a decrease in pH to 7.85 "should lead to some possibly beneficial effects, such as a larger egg and presumably hatchling size and a better incorporation of the essential element[s] such as Zn in the embryonic tissue," and these phenomena "may improve the survival [of] the newly hatched juveniles."

- Adults of the branched calcitic bryozoan *Myriapora truncata* "are able to up-regulate their

calcification rates and survive in areas with higher levels of pCO_2 than are predicted to occur due to anthropogenic ocean acidification."

- The gastropod *Concholepas concholepas* demonstrates "the ability to maintain calcification even at pCO_2 levels of 1036 µatm." In addition, exposure to elevated pCO_2 during their early ontogeny "may actually increase the likelihood of *C. concholepas* surviving after being overturned by an exogenous cause."

- Juveniles of the Arctic pteropod *Limacina helicina* are able to extend their shells at an aragonite saturation state as low as 0.6, which may result from "the presence of a thin periostracal layer covering the calcareous surface" that might act to protect the shell in seawater of reduced pH.

- "Copepods, as a group, may be well equipped to deal with the chemical changes associated with ocean acidification."

- Sea anemone abundance along a natural seawater pH gradient of 8.2–7.6 was observed to be higher at the lowest pH.

- Lower ocean pH levels will have no impact on the oceans' "transparency to sound."

Lacoue-Labarthe *et al.* (2009) placed fertilized eggs of the common cuttlefish (*Sepia officinalis*) in five-liter plastic bottles filled with filtered and UV-sterilized Mediterranean seawater pumped from a depth of 30 meters at a site adjacent to Monaco Bay, after which the eggs were maintained throughout their full development time at controlled conditions of temperature (16 or 19°C) and pH (8.1, 7.85 or 7.6), with the latter values maintained within ± 0.05 of a pH unit by periodically bubbling pure CO_2 into the bottles (which were continuously aerated with CO_2-free air), resulting in mean CO_2 concentrations of the air in contact with the surface of the water of 400, 900, or 1,400 ppm.

According to the authors, "decreasing pH resulted in higher egg weight at the end of development at both temperatures ($p < 0.05$), with maximal values at pH 7.85 (1.60 ± 0.21 g and 1.83 ± 0.12 g at 16°C and 19°C, respectively)." They found "hatchlings were smaller when they developed at 16°C than at 19°C ($p < 0.05$)." They also observed zinc (Zn) accumulation "was higher at pH 7.85 during the full developmental period," when "high embryonic requirements for Zn

are not fully covered by the maternal pool," so the higher accumulation of Zn "was associated with a greater rate of growth of both egg and embryo." Concurrently, there was a greater accumulation of potentially detrimental silver in the tissues of the hatchlings, but any deleterious effects of the extra silver apparently were overcome by the positive effects of lowered pH on beneficial zinc accumulation. Toxic cadmium accumulation was reduced in the lower pH (higher CO_2) treatments.

The seven scientists conclude, "decreasing pH until 7.85," as could be expected to occur in air enriched with carbon dioxide to a concentration of 900 ppm, "should lead to some possibly beneficial effects, such as a larger egg and presumably hatchling size and a better incorporation of the essential element[s] such as Zn in the embryonic tissue." These phenomena, they write, "may improve the survival [of] the newly hatched juveniles." They note Gutowska *et al*. (2008) demonstrated "calcification was enhanced in sub-adult cuttlefish reared at 6,000 ppm CO_2."

Gutowska *et al*. found, over a six-week test period, "juvenile *S. officinalis* maintained calcification under ~4000 and ~6000 ppm CO_2, and grew at the same rate with the same gross growth efficiency as did control animals," gaining approximately 4% body mass daily and increasing the mass of their calcified cuttlebone by more than 500%. Gutowska *et al*. conclude "active cephalopods possess a certain level of pre-adaptation to long-term increments in carbon dioxide levels," and they suggest our "understanding of the mechanistic processes that limit calcification must improve before we can begin to predict what effects future ocean acidification will have on calcifying marine invertebrates."

Rodolfo-Metalpa *et al*. (2010) conducted "the first coastal transplant experiment designed to investigate the effects of naturally acidified seawater on the rates of net calcification and dissolution of the branched calcitic bryozoan *Myriapora truncata*." Bryozoans or "moss animals" are a geologically important group of small animals that resemble corals; they are major calcifiers found on rocky shores in cool-water areas of the planet, where they comprise a significant component of the carbonate sediments in shallow sublittoral habitats, and where they form long-lived three-dimensional structures that provide attachment sites for numerous epifauna and trap sediment and food for a variety of infauna.

Rodolfo-Metalpa *et al*. transplanted colonies of the species to normal (pH 8.1), high (pH 7.66), and extremely high (pH 7.43) CO_2 conditions at gas vents located just off Italy's Ischia Island in the Tyrrhenian Sea. They calculated the net calcification rates of live colonies and the dissolution rates of dead colonies by weighing them before and after 45 days of *in situ* residence in May–June (when seawater temperatures ranged from 19 to 24°C) and after 128 days of *in situ* residence in July–October (when seawater temperatures ranged from 25–28°C). They found throughout the first and cooler observation period, "dead *M. truncata* colonies dissolved at high CO_2 levels (pH 7.66), whereas live specimens maintained the same net calcification rate as those growing at normal pH." At the extremely high CO_2 level, the net calcification rate of the live specimens was reduced to only about 20% of what it was at normal pH, though the moss animals survived. Throughout the second and warmer observation period, by contrast, calcification ceased in both the normal and the high CO_2 treatments, and in the extremely high CO_2 treatment the transplants died.

The five scientists conclude, "at moderate temperatures," such as those to which they are currently adapted, "adult *M. truncata* are able to up-regulate their calcification rates and survive in areas with higher levels of pCO_2 than are predicted to occur due to anthropogenic ocean acidification, although this ability broke down below mean pH 7.4." That level is far below what even IPCC predicts will occur in response to continued burning of fossil fuels.

According to Manriquez *et al*. (2013), in Chile "the gastropod *Concholepas concholepas* is both an economically and ecologically important species inhabiting subtidal and intertidal marine habitats." In these rocky environments, "the gastropods are often exposed to highly turbulent conditions," during which times they adhere tightly to the rock surface with their foot. The scientists note, "when feeding and handling prey items the foot of *C. concholepas* is often removed from the rock leaving it vulnerable to being dislodged." Thus it is in the gastropod's best interests to right itself as quickly as possible whenever this occurs.

To explore the impact of lower ocean pH levels on this self-preservation response, as well as the more basic phenomena of growth and calcification, Manriquez *et al*. collected small individuals of *C. concholepas* from a rocky intertidal area in northern Chile, transported them to a laboratory, and reared them in natural seawater for one month, after which 10 individuals were randomly assigned to one of three pCO_2 concentrations: 388 µatm (current), 716 µatm (medium), or 1,036 µatm (high). There they

remained, under well-fed conditions, for 83 days, while the researchers made various measurements on days 0, 11, 45, 52, 62, 73, and 83 after the beginning of treatments.

At the end of the study period, the 11 researchers report, there were no significant among-treatment differences in peristomal length, wet weight, or buoyant weight, nor the shell weight of empty shells. They also determined, "on average, self-righting time was three times faster in individuals reared under increased pCO_2 levels than under normal seawater conditions." Manriquez *et al*. conclude "*C. concholepas* have the ability to maintain calcification even at pCO_2 levels of 1036 µatm ... in agreement with similar results reported in the literature for other invertebrates (Ries *et al*., 2009; Manzello, 2010; Rodolfo-Metalpa *et al*., 2011)." And they state, "during their early ontogeny, exposure to elevated pCO_2 may actually increase the likelihood of *C. concholepas* surviving after being overturned by an exogenous cause."

Citing Hunt *et al*. (2008), authors Comeau *et al*. (2012) write, "pteropods are pelagic mollusks that play an important role in the food web of extensive oceanic regions, particularly at high latitudes, where they are a major dietary component for zooplankton and higher predators, such as herring, salmon, whales and birds." Comeau *et al*. investigated the effect of lower ocean pH levels "using juveniles of the Arctic pteropod *Limacina helicina* from the Canada Basin of the Arctic Ocean," where they caught and extracted overwintering individuals from depths of 100 to 200 meters through a hole in the ice, thereafter maintaining the mollusks at three pH levels (8.05, 7.90, and 7.75) for eight days, after which they assessed them for mortality and shell growth.

Comeau *et al*. found pH did not impact the mortality of the pteropods, but the degree of linear extension of their shells decreased as pH declined. Nevertheless, the pteropods were able to extend their shells at an aragonite saturation state as low as 0.6, suggesting "the presence of a thin periostracal layer covering the calcareous surface, as shown on the Antarctic pteropod *Limacina helicina antarctica* (Sato-Okoshi *et al*., 2010), might, among other mechanisms, protect the shell from a corrosive environment." Although much remains to be known about pteropod responses to a potential decline in seawater pH, these findings indicate pteropods possess a certain degree of adaptability to low pH levels, and the results of similar studies of other calcifying sea creatures suggest pteropods may be able to evolve in their ability to cope with declining seawater pH.

Weydmann *et al*. (2012) note the Arctic copepod *Calanus glacialis* "can comprise up to 70–80% of the zooplankton biomass in Arctic shelf seas (Blachowiak-Samolyk *et al*., 2008; Conover, 1988; Hirche and Mumm, 1992), and is a key herbivore (Mumm *et al*., 1998; Soreide *et al*., 2008; Tande, 1991) as well as an important prey item for other zooplankton species (Falk-Petersen *et al*., 2002, 2004), fish (Fortier *et al*., 2001), and seabirds (Karnovsky *et al*., 2003; Weslawski *et al*., 1999; Wojczulanis *et al*., 2006)." Noting "testing the potential impacts of ocean acidification on *C. glacialis* reproduction is vital," they investigated "how the reduction of sea surface pH from present day levels (pH 8.2) to a realistic model-based level of pH 7.6, and to an extreme level of pH 6.9, would affect the egg production and hatching success of *C. glacialis* under controlled laboratory conditions," where "reduced pH seawater was prepared by bubbling compressed CO_2 through filtered seawater, until the appropriate level of pH was reached."

The four researchers report, "CO_2-induced seawater acidification had no significant effect on *C. glacialis* egg production," and a reduction in pH to 6.9 only delayed hatching at what they called this "extreme level of pH." They also state there was no significant effect "on the survival of adult females"; this observation, they write, "is in agreement with previous studies on other copepod species," citing Mayor *et al*. (2007) and Kurihara and Ishimatsu (2008). Weydmann *et al*. conclude their results are "in agreement with previous studies on other copepod species and would indicate that copepods, as a group, may be well equipped to deal with the chemical changes associated with ocean acidification."

Suggett *et al*. (2012) state "non-calcifying anthozoans such as soft corals and anemones, play important ecological and biogeochemical roles in reef environments (e.g. Fitt *et al*., 1982; Bak and Borsboom, 1984; Muller-Parker and Davy, 2001)." They collected pertinent data from 11–26 May 2011 on a sea anemone (*Anemonia viridis*) along a natural seawater pH gradient of 8.2–7.6—which would be expected to prevail across an atmospheric CO_2 gradient of 365–1,425 ppm—produced by a shallow cold vent system (Johnson *et al*., 2011; 2012) that released CO_2 to coastal waters near Vulcano, Italy, about 25 km northeast of Sicily. The nine researchers found an increase in gross maximum photosynthesis, respiration rates, and dinoflagellate endosymbiont abundance (but unchanged diversity) with increasing CO_2. Sea anemone abundance increased with CO_2 and

"dominated the invertebrate community at high CO_2 conditions." The enhanced productivity in the sea anemones they studied, Suggett *et al.* write, implies "an increase in fitness that may enable non-calcifying anthozoans to thrive in future environments, i.e. higher seawater CO_2." As they declare in the title of their paper, "Sea anemones may thrive in a high CO_2 world."

Meron *et al.* (2013) studied the physiology of *Anemonia viridis* growing naturally along a CO_2-vent-induced pH gradient near Ischia, Italy, also studying the nature of the associated microbial community (bacteria and endosymbiotic *Symbiodinium*), focusing on two specific locations that could be characterized as ambient (pCO_2 330 ppm, pH 8.1) and very CO_2-enriched (pCO_2 9,341 ppm, pH 7.0). Although the four researchers found reduction in pH had an impact on the composition and diversity of the anemones' associated microbial communities, "no significant changes were observed in *A. viridis* physiology, and no microbial stress indicators (i.e., pathogens, antibacterial activity, etc.) were detected." Meron *et al.* conclude, "it appears that elevated CO_2 does not have a negative influence on *A. viridis* that live naturally in the [very CO_2-enriched] site." They say "this suggests that natural long-term exposure and dynamic diverse microbial communities may contribute to the acclimation process of the host in a changing pH environment."

Mukherjee *et al.* (2013) "investigated the proteomic response of metamorphosing larvae of the tubeworm *Hydroides elegans*, challenged with two climate change stressors, ocean acidification (pH 7.6) and hypoxia (2.8 mg O_2 per liter)," as well as with both of the stressors combined. The seven scientists found concomitant exposure to the two climate change stressors "caused several proteins involved in energy metabolism, calcification and stress tolerance to be differentially expressed." This phenomenon "seemed to allow the tubeworm larvae to successfully metamorphose and carry out calcification." Mukherjee *et al.* conclude "the aragonite tube-forming tubeworm larvae have a high tolerance to hypoxia and may possess the capacity to acclimate over time, even in the face of ocean acidification."

Some researchers have recently looked at the possible effects of lower ocean pH levels on the oceans' "transparency to sound." Reeder and Chiu (2010) state "it has been reported that, given a 0.3 reduction in pH, from 8.1 to 7.8, a reduction in the acoustic absorption at low frequencies could result, suggesting a significant increase in ocean noise," and more recently "it has been suggested that low-frequency

sound will travel farther due to the ocean pH reduction expected by 2050," and most recently, researchers have suggested "in an ocean more transparent to sound, the resultant changes in propagation range will be noticeable in the operation of scientific, commercial and naval applications that are based on ocean acoustics."

Reeder and Chiu reviewed "the fundamental principles of acoustic transmission loss in the ocean and how the multiple transmission loss mechanisms impact ocean noise levels within the context of changing ocean pH." They conducted "an analytical analysis involving physical and empirical models of all relevant transmission loss mechanisms," focusing on "three ocean acoustic environments ... to elucidate the expected change in ocean noise level from sources at the surface as a function of frequency: shallow water, the acoustic surface duct and the deep ocean."

The two researchers in the Department of Oceanography of the Naval Postgraduate School in Monterey California (USA) report for even a large reduction in ocean pH from 8.1 to 7.4, there was "no observable change in ocean noise in the shallow water and surface duct environments for all frequencies—two environments which host a large portion of the marine mammal population." They also found "a negligible change in ocean noise level in the deep water environment for all frequencies ... which also provides an upper bound to the maximum expected increase in ocean noise level due to the fact that it does not fully account for the range-dependent water column sound speed, bottom topography and distributed sources."

Putting their results in the context of average background ocean noise levels as represented by Wenz (1962) curves, they found "a statistically insignificant change compared to the inherent variability of ocean noise associated with shipping and surface-generated mechanisms." Thus, "after 250 years," they write, "there would still be no significant modifications to the Wenz curves," which suggests lower ocean pH levels will have no negative impact on ocean noise.

6.3.3.7 Multiple Animal Studies

The studies reviewed in this section examine what scientists have learned about potential impacts of lower ocean pH levels on animals as obtained from studies in which multiple species are discussed. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- The impact of elevated atmospheric CO_2 on marine calcification "is more varied than previously thought."

- Different stress effects on interacting species resulting from lower ocean pH levels "may not only enhance but also buffer community level effects."

- "Biological processes can provide homeostasis against changes in pH in bulk waters of the range predicted during the 21st century."

- The world's marine biota are "more resistant to ocean acidification than suggested by pessimistic predictions identifying ocean acidification as a major threat to marine biodiversity" and "may not be the widespread problem conjured into the 21st century."

Ries *et al.* (2009) "reared 18 calcifying species for 60 days in isothermal (25°C) experimental seawaters equilibrated with average [atmospheric] CO_2 values of 409, 606, 903 and 2856 ppm, corresponding to modern CO_2, and ~2, 3 and 10 times pre-industrial levels (~280 ppm), respectively, and yielding average seawater saturation states of 2.5, 2.0, 1.5 and 0.7 with respect to aragonite," after which "the organisms' net rates of calcification (total calcification minus total dissolution) under the various CO_2 treatments were estimated from changes in their buoyant weight and verified with dry weight measurements after harvesting." The three Woods Hole Oceanographic Institution (USA) researchers report, "in ten of the 18 species (temperate corals, pencil urchins, hard clams, conchs, serpulid worms, periwinkles, bay scallops, oysters, whelks, soft clams), net calcification decreased with increasing CO_2," and "in six of the ten negatively impacted species (pencil urchins, hard clams, conchs, periwinkles, whelks, soft clams) [they] observed net dissolution of the shell in the highest CO_2 treatment."

They continue, "in four of the 18 species (limpets, purple urchins, coralline red algae, calcareous green algae), net calcification increased relative to the control under intermediate CO_2 levels (605 and 903 ppm), and then declined at the highest CO_2 level (2856 ppm)." Finally, they write, "in three species (crabs, lobsters, and shrimps), net calcification was greatest under the highest level of CO_2 (2856 ppm),"

and "one species, the blue mussel, exhibited no response to elevated CO_2."

Ries *et al.* conclude "the impact of elevated atmospheric CO_2 on marine calcification is more varied than previously thought," with responses ranging from negative to neutral to positive.

Kurihara *et al.* (2007) extracted sedimentary mud from the seafloor of Tanabe Bay on the Kii Peninsula of Japan and incubated it in marine microcosms continuously aerated for 56 days with air of either 360 or 2,360 ppm CO_2 while they periodically measured the abundance and biomass of different members of the meiobenthic community contained in the sediments. Meiofauna are small benthic invertebrates larger than microfauna but smaller than macrofauna; they are metazoan animals that can pass through a 0.5–1 mm mesh but are retained by a 30–45 μm mesh. In marine environments, they typically are found between grains of damp sand on the seashore or in muddy sediments at the bottoms of water bodies.

The authors "observed no significant differences in the abundance of total meiofauna, nematodes, harpacticoid copepods (including adults and copepodites) and nauplii by the end of the experiment." They say there "may have been successful recruitments under elevated CO_2 conditions" and "elevated CO_2 had not impacted the reproduction of nematodes and harpacticoid copepods." These observations, the three researchers write, "suggest that the projected atmospheric CO_2 concentration in the year 2300 does not have acute effects on the meiofauna."

Appelhans *et al.* (2012) note "the impact of seawater acidification on calcifying organisms varies at the species level," and "if the impact differs between predator and prey in strength and/or sign, trophic interactions may be altered." This consequence, if true, could play havoc with many marine ecosystems as currently constituted. In a study designed to explore the potential for such interactions in the brackish western Baltic Sea, Appelhans *et al.* investigated the impacts of three seawater pCO_2 levels (650, 1,250 and 3,500 ppm) on the growth of two predatory species (the common sea star *Asterias rubens* and the shore crab *Carcinus maenas*), also determining whether the conditions affected the quantity or size of prey consumed (the blue mussel *Mytilus edulis*). The five German scientists found "growth of *Mytilus edulis* was generally very low and not significantly affected by acidification." They write, "a trend toward a lower shell mass with increasing seawater pCO_2 was observed," and "the mean maximum breaking resistance of mussel shells

was significantly lowered by ~20% at the highest level of 3500 ppm."

As for the predators, they report, "acidification did not provoke a measurable shift in prey size preferred by either predator." They also found intermediate acidification levels (corresponding to 1,250 ppm CO_2) "had no significant effect on growth or consumption in either predator species," but the highest acidification level (corresponding to 3,500 ppm CO_2) "reduced feeding and growth rates in sea stars by 56%, while in crabs a 41% decrease in consumption rates of mussels could be demonstrated." "Interestingly," Appelhans *et al.* conclude, "the enhanced vulnerability of mussels seems to be neutralized by the decreased consumption of the predators under high acidification." They write, "these results illustrate that different stress effects on interacting species may not only enhance but also buffer community level effects," noting, "when stress effects are similar (and weak) on interacting species, biotic interactions may remain unaffected."

Hurd *et al.* (2011) observe, "most ocean acidification studies so far have been simplistic" because they have not "jointly considered physical, chemical and biological interactions." They note "the emerging discipline of marine ecomechanics (Denny and Helmuth, 2009; Denny and Gaylord, 2010) provides a valuable framework in which such inter-disciplinary research can be conducted." The old experimental approach, they write, "overlooks the existence of a discrete micro-layer (i.e., diffusion boundary layer, DBL) at the surface of many aquatic organisms that buffers them from the surrounding mainstream seawater (Vogel, 1996)." This is achieved by metabolic processes that alter the water chemistry within the DBL, with photosynthesis increasing pH, and calcification and respiration reducing pH (Hurd *et al.*, 2009). They continue, "the chemical environment within the DBL differs from that in the mainstream seawater just micrometers away, with implications for both the dissolution of, and formation of, calcium carbonate (Borowitzka and Larkum, 1976; Ries *et al.*, 2009)."

In a study employing the still-evolving ecomechanic approach, Hurd *et al.* used pH microelectrodes and oxygen micro-optodes to measure the DBL thickness at the surface of the coralline seaweed *Sporolithon durum*, the sea urchin *Evechinus chloroticus,* and the abalone *Haliotis iris*, at a range of seawater velocities (0–10 cm/sec) that reflected those found within a temperate reef in Southern New Zealand (45.38°S) that may be vulnerable to ocean acidification (OA). For *S. durum*, they also deter-

mined whether DBL thickness would be affected when mainstream seawater pH was reduced to 7.5, the projected worst-case scenario for the year 2215 as calculated by Caldeira and Wickett (2003). In addition, they measured pH fluctuations at the surface of *S. durum* on a timescale of hours at ambient seawater pH and pH 7.5 at two different flows (1.5 and 6.3 cm/sec), and for the invertebrates they measured surface pH fluctuations at ambient pH and a flow of 1.5 cm/sec.

The seven scientists determined coralline seaweeds encounter a wide range of pH values over each daily cycle, but they are able to increase their pH substantially due to photosynthesis and to withstand periods of very low pH (relative to the present day and comparable to values predicted for coming centuries) under low flows. As to sea urchins, the scientists found they are currently subjected to—and readily survive—very low pH values (7.5) at their surfaces in slow seawater flows, values equivalent to those predicted to occur in the future. And abalone, the researchers write, "have a very thin DBL and hence their outer surface is subjected to the pH in the mainstream seawater, in all flow conditions," yet they too persist, probably because they are "internal calcifiers" and "the reduced pH predicted for future oceans may not directly alter their rates of calcification."

Hurd *et al*. conclude their findings "support the view that although the role of chemistry on OA is well understood, the biological responses to OA will be complex," citing their own work and that of Fabry *et al*. (2008). They also note, "both the site of calcification and the ecomechanics of the biota, i.e., the interactions between their morphology, physiology and the surrounding hydrodynamic environment, must be considered." Their work suggests marine calcifiers are much more robust to OA than originally thought.

Findlay *et al*. (2011) provide further evidence of the importance of biology in controlling calcification. They note, "calcifying marine organisms such as molluscs and foraminifera, crustaceans, echinoderms, corals and coccolithophores are predicted to be most vulnerable to decreasing oceanic pH (ocean acidification)." They point out there is a possibility for "increased or maintained calcification under high carbon dioxide conditions," and their experiment demonstrates the reality of this phenomenon in different types of calcifying marine animals. Working with five calcifying organisms—two gastropods (the limpet *Patella vulgata* and the periwinkle *Littorina littorea*), a bivalve mussel (*Mytilus edulis*), one

crustacean (the cirripede *Semibalanus balanoides*), and one echinoderm (the brittlestar *Amphiura filiformis*)—Findlay *et al*. "measured either the calcium (Ca^{2+}) concentration in the calcified structures or shell morphological parameters as a proxy for a net change in calcium carbonate in live individuals exposed to lowered pH," where the lower pH of the seawater employed was created by the bubbling of CO_2 into header tanks.

"Contrary to popular predictions," they write, the results indicated "the deposition of calcium carbonate can be maintained or even increased in acidified seawater." In fact, four of the five species they studied actually exhibited increased levels of calcium in low pH conditions. In the case of *Littorina littorea*, for example, all morphological shell parameters— width, height, thickness, area, perimeter, aperture area, and aperture perimeter—"increased in low pH treatments compared to the control," and "there was ~67% more growth in shell height, ~30% more growth in shell width and ~40% more growth in shell thickness under low pH conditions compared to the control." They also observed a large amount of dissolution taking place on isolated shells and arms of the creatures they studied, but they found "the presence of a live animal within its calcium carbonate structure offset this dissolution."

Findlay *et al*. say their findings demonstrate "there is a great degree of biological control on calcification with complex links to other physiological processes," and "increasing evidence in the literature agrees with the results of [our] study," noting, "McDonald *et al*. (2009) showed calcification in another barnacle species (*Amphibalaus amphitrite*) to continue, and possibly even increase, under low pH conditions (pH 7.4); Arnold *et al*. (2009) demonstrated larval lobsters (*Homarus gammarus*) were able to lay down calcium carbonate structure in pH conditions 0.3 units below the control levels; Checkley *et al*. (2009) showed young fish have enhanced aragonite otolith growth when grown under elevated CO_2; Maier *et al*. (2009) showed that, although there was a decrease in calcification in cold-water corals, overall they showed a positive net calcification at aragonite saturation states below 1, and longer-term experiments suggest these corals may actually maintain or even increase calcification over longer timescales at low pH (Schubert *et al*., 2010)."

In what was at the time the most comprehensive analysis ever conducted of experimental studies that have explored the effects of rising atmospheric CO_2 concentrations on marine biota, Hendriks *et al*. (2010) assembled a database of 372 experimentally evaluated

responses of 44 marine species to lower ocean pH levels induced by equilibrating seawater with CO_2-enriched air. They note, "warnings that ocean acidification is a major threat to marine biodiversity are largely based on the analysis of predicted changes in ocean chemical fields," which are derived from theoretical models that do not account for numerous biological phenomena and have only "limited experimental support."

Of the published reports they scrutinized, only 154 assessed the significance of responses relative to controls. Of those reports, 47 reported no significant response, so "only a minority of studies" demonstrated "significant responses to acidification." When the results of that minority group of studies were pooled, there was no significant mean effect. Nevertheless, the three researchers found some types of organisms and certain functional processes did exhibit significant responses to lower seawater pH levels.

Since their analyses to this point had included some extremely high acidification treatments, they repeated their analyses for only those pH levels induced by atmospheric CO_2 concentrations of 2,000 ppm or less, as that concentration had been predicted to occur around the year 2300 by Caldeira and Wickett (2003). In this second analysis, Hendriks et al. once again found the overall response, including all biological processes and functional groups, was not significantly different from that of the various control treatments, although calcification was reduced by $33 \pm 4.5\%$ and fertility by $11 \pm 3.5\%$ across groups, whereas survival and growth showed no significant overall responses. When the upper limiting CO_2 concentrations were in the range of 731–759 ppm, just below the value predicted by IPCC (2007) for the end of the twenty-first century (790 ppm)—calcification rate reductions of only 25% were observed.

The three researchers say this decline "is likely to be an upper limit, considering that all experiments involve the abrupt exposure of organisms to elevated pCO_2 values, while the gradual increase in pCO_2 that is occurring in nature may allow adaptive and selective processes to operate," citing Widdicombe et al. (2008) and noting "these gradual changes take place on the scale of decades, permitting adaptation of organisms even including genetic selection."

Even this mitigating factor is not the end of the good news, for Hendriks et al. also write, "most experiments assessed organisms in isolation, rather than [within] whole communities," and the responses of other entities and processes within the community

may buffer the negative impacts of CO_2-induced acidification. As an example, they note "sea-grass photosynthetic rates may increase by 50% with increased CO_2, which may deplete the CO_2 pool, maintaining an elevated pH that may protect associated calcifying organisms from the impacts of ocean acidification."

Describing another phenomenon that benefits corals, the researchers write, "seasonal changes in pCO_2 are in the range of 236–517 ppm in the waters of the northern East China Sea (Shim et al., 2007)," and "metabolically-active coastal ecosystems experience broad diel changes in pH, such as the diel changes of >0.5 pH units reported for sea grass ecosystems (Invers et al., 1997)," which they say represent "a broader range than that expected to result from ocean acidification expected during the 21st century." They note these fluctuations also "offer opportunities for adaptation to the organisms involved."

Hendriks et al. additionally state the models on which the ocean "acidification" threat is based "focus on bulk water chemistry and fall short of addressing conditions actually experienced by [marine] organisms," which are "separated from the bulk water phase by a diffusive boundary layer" and "photosynthetic activity"—such as that of the zooxanthellae hosted by corals—"depletes pCO_2 and raises pH (Kuhl et al., 1995) so that the pH actually experienced by organisms may differ greatly from that in the bulk water phase (Sand-Jensen et al., 1985)."

Hendriks et al. also note "calcification is an active process where biota can regulate intracellular calcium concentrations," so "marine organisms, like calcifying coccolithophores (Brownlee and Taylor, 2004), actively expel Ca^{2+} through the ATPase pump to maintain low intracellular calcium concentrations (Corstjens et al., 2001; Yates and Robbins, 1999)." They note, "as one Ca^{2+} is pumped out of the cell in exchange for $2H^+$ pumped into the cell, the resulting pH and Ca^{2+} concentrations increase the $CaCO_3$ saturation state near extracellular membranes and appear to enhance calcification (Pomar and Hallock, 2008)"—so much so, in fact, that "there is evidence that calcification could even increase in acidified seawater, contradicting the traditional belief that calcification is a critical process impacted by ocean acidification (Findlay et al., 2009)."

Hendriks et al. note the world's marine biota are "more resistant to ocean acidification than suggested by pessimistic predictions identifying ocean acidification as a major threat to marine biodiversity," and thus this phenomenon "may not be the widespread

problem conjured into the 21st century" by the world's climate alarmists, echoing a similar conclusion reached at the turn of the last millennium (Idso *et al.*, 2000). Hendriks *et al.* conclude, "biological processes can provide homeostasis against changes in pH in bulk waters of the range predicted during the 21st century."

6.4 Freshwater "Acidification"

The vast majority of studies of the effects of lower pH levels examine the topic as it pertains to marine life. However, a growing body of research investigates its potential effects on aquatic species inhabiting the world's freshwater lakes, rivers, and streams. That research suggests there may be great benefits in store for such aquatic life as the air's CO_2 concentration continues to rise.

6.4.1 Algae

The studies reviewed in this section examine what scientists have learned about potential impacts of falling freshwater pH levels on algae. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- A "doubled atmospheric CO_2 concentration would affect the growth of *C. pyrenoidosa* when it grows under bright solar radiation, and such an effect would increase by a great extent when the cell density becomes high."

- The effects of lower freshwater pH levels on algal production could be such that a "doubling of atmospheric CO_2 may result in an increase of the productivity of more than 50%."

- "Contrary to the dominating hypotheses in the literature," lower freshwater pH levels may lead to "positive, bottom-up effects on secondary production in some stream food webs."

- Lower freshwater pH levels may prevent bloom development and ambient toxicity of certain harmful algae.

Xia and Gao (2003) cultured cells of the freshwater alga *Chlorella pyrenoidosa* in Bristol's solution within controlled environment chambers maintained at low and high light levels (50 and 200 µmol/m²/s) during 12-hour light periods followed by 12-hour dark periods for a total of 13 days, while the solutions in which the cells grew were continuously aerated with air of either 350 or 700 ppm CO_2. When they harvested the cells (in the exponential growth phase) at the conclusion of this period, they found the biomass (cell density) of the twice-ambient CO_2 treatment was 10.9% and 8.3% greater than that of the ambient-air treatment in the low- and high-light regimes, respectively, although only the high-light result was statistically significant. The two scientists conclude a "doubled atmospheric CO_2 concentration would affect the growth of *C. pyrenoidosa* when it grows under bright solar radiation, and such an effect would increase by a great extent when the cell density becomes high." Their data also suggest the same may happen, perhaps only to a lesser extent, when the alga grows under less-bright conditions.

Andersen and Andersen (2006) placed six 1.5-m-diameter flexible plastic cylinders in the littoral zone of Lake Hampen in central Jutland, Denmark. Three of the cylinders were maintained at the ambient CO_2 concentration of the air and three were enriched to 10 times ambient, and the researchers measured the CO_2-induced growth response of a mixture of several species of filamentous freshwater algae dominated by *Zygnema* species but also containing some *Mougeotia* and *Spirogyra*. After one full growing season (May to November), they determined the biomass of the microalgal mixture in the CO_2-enriched cylinders was increased by 220% in early July, by 90% in mid-August, and by 3,750% in mid-November.

Schippers *et al*. (2004a) note "it is usually thought that unlike terrestrial plants, phytoplankton will not show a significant response to an increase of atmospheric CO_2," but "most analyses have not examined the full dynamic interaction between phytoplankton production and assimilation, carbon-chemistry and the air-water flux of CO_2," and "the effect of photosynthesis on pH and the dissociation of carbon (C) species have been neglected in most studies."

Schippers *et al*. developed "an integrated model of phytoplankton growth, air-water exchange and C chemistry to analyze the potential increase of phytoplankton productivity due to an atmospheric CO_2 elevation." As a test of their model, they let the freshwater alga *Chlamydomonas reinhardtii* grow in 300 ml bottles filled with 150 ml of a nutrient-rich medium at enclosed atmospheric CO_2 concentrations of 350 and 700 ppm maintained at two air-water exchange rates characterized by CO_2 exchange coefficients of 2.1 and 5.1 m day^{-1}, as Shippers *et al*. (2004b) describe it, periodically measuring the biovolume of the solutions by means of an electronic particle counter.

The results of this effort, they write, "confirm the theoretical prediction that if algal effects on C chemistry are strong, increased phytoplankton productivity because of atmospheric CO_2 elevation should become proportional to the increased atmospheric CO_2," which suggests algal productivity "would double at the predicted increase of atmospheric CO_2 to 700 ppm." Although "strong algal effects (resulting in high pH levels) at which this occurs are rare under natural conditions," they predict effects on algal production in freshwater systems could be such that a "doubling of atmospheric CO_2 may result in an increase of the productivity of more than 50%."

Collins *et al*. (2006) propagated 10 replicate lines from each of two clones of *Chlamydomonas reinhardtii* within a phytotron by batch-culturing them in flasks through which air of 430 ppm CO_2 was continuously bubbled or air of gradually increasing CO_2 concentration was bubbled over the course of development of 600 generations of the microalga, when a concentration of 1,050 ppm was reached and maintained throughout the development of 400 more algal generations. They grew each of these sets of plants (low-CO_2-adapted and high-CO_2-adapted) for a short period of time at both 430 and 1,050 ppm CO_2 and determined their steady-state CO_2 uptake rates.

For the algae whose atmospheric CO_2 concentration had been continuously maintained at 430 ppm,

Collins *et al*. report abruptly increasing it to a value of 1,050 ppm led to a 143% increase in steady-state CO_2 uptake rate. For the algae that had experienced the gradual CO_2 increase from 430 to 1,050 ppm, there was a 550% increase in CO_2 uptake rate when the rate in the 1,050-ppm air was compared to the rate that prevailed when the air's CO_2 concentration was abruptly lowered to 430 ppm. For the algae experiencing the most realistic scenario—gradually going from a state of continuous 430-ppm CO_2 exposure to one of 1,050 ppm exposure over a period of 600 generations and then maintaining the higher CO_2 level for a further 400 generations, the increase in steady-state CO_2 uptake rate due to the long-term 620-ppm increase in atmospheric CO_2 concentration was a more modest 50%, which roughly translates to a 25% increase in growth for the more typical 300 ppm increase in atmospheric CO_2 concentration employed in numerous CO_2 enrichment studies of terrestrial plants.

If the results obtained by Collins *et al*. for the freshwater *Chlamydomonas reinhardtii* are typical of what to expect of marine microalgae—which Field *et al*. suggest may provide nearly half of the primary production of the planet—the totality of Earth's plant life may provide a significant brake upon the rate at which the air's CO_2 content may increase in the future, as well as the ultimate level to which it may rise. Collins *et al*. provide a rough indication of just how powerful this phenomenon may be when they note, "mathematical simulations have estimated that pre-industrial levels of CO_2 would have been as high as 460 ppm" without the operation of the well-known "biological pump" (Sarmiento and Toggweiler, 1984) by which dying phytoplankton sink carbon into deep ocean sediments, "whereas pre-industrial atmospheric CO_2 levels were [actually] around 280 ppm (Etheridge *et al*., 1996)," or 180 ppm less.

Logothetis *et al*. (2004) note "the function and structure of the photosynthetic apparatus of many algal species resembles that of higher plants (Plumley and Smidt, 1984; Brown, 1988; Plumley *et al*., 1993)," and "unicellular green algae demonstrate responses to increased CO_2 similar to those of higher plants in terms of biomass increases (Muller *et al*., 1993)." Noting "little is known about the changes to their photosynthetic apparatus during exposure to high CO_2," they grew batches of the unicellular green alga *Scenedesmus obliquus* (wild type strain D3) autotrophically in liquid culture medium for several days in a temperature-controlled water bath of 30°C at low (55 μmol m^{-2} s^{-1}) and high (235 μmol m^{-2} s^{-1}) light intensity while continuously aerating the water

with air of either 300 or 100,000 ppm CO_2. Exposure to the latter high CO_2 concentration produces a "reorganization of the photosynthetic apparatus" and "leads to enhanced photosynthetic rates, which ... leads to an immense increase of biomass." After five days under low light conditions, the CO_2-induced increase in biomass was approximately 300%, and under high light conditions it was approximately 600%.

Hargrave *et al*. (2009) "used free air CO_2 enrichment to compare effects of eCO_2 (i.e., double ambient ~ 720 ppm) relative to ambient CO_2 (aCO_2 ~ 360 ppm) on several ecosystem properties and functions in large, outdoor, experimental mesocosms that mimicked shallow sand-bottom prairie streams." They found the primary productivity of benthic algae inhabiting the streams "was about 1.6, 1.9, 2.5, and 1.3 times greater in the eCO_2 treatment on days 30, 45, 60, and 75, respectively." The carbon/phosphorus (C/P) ratio of the algae was on average 2 and 1.5 times greater in the eCO_2 treatment than in the aCO_2 treatment on days 45 and 90, respectively, implying a reduced availability of phosphorus, which would make the algae less nutritious and, therefore, less beneficial for its consumers.

However, the researchers observed eCO_2 "had positive effects on benthic invertebrates, significantly increasing chironomid density, biomass, and average size." Hargrave *et al*. state "chironomid density was about 3, 5, and 2.5 times greater in the eCO_2 treatment than in the aCO_2 treatment on days 30, 60, and 90, respectively," "biomass was about 4, 3, and 3 times greater in the eCO_2 treatment than in the aCO_2 treatment on days 30, 60, and 90, respectively," and "individual mass was about two times greater on days 30 and 60." Thus, "contrary to the dominating hypotheses in the literature," Hargrave *et al*. conclude "eCO_2 might have positive, bottom-up effects on secondary production in some stream food webs." They state their experimental findings and "the large literature from terrestrial and marine ecosystems suggests that future [i.e., higher] atmospheric CO_2 concentrations are likely to have broad reaching effects on autotrophs and consumers across terrestrial and aquatic biomes."

Joint *et al*. (2011) write "marine and freshwater assemblages have always experienced variable pH conditions," noting "phytoplankton blooms can rapidly reduce pCO_2, with a concomitant increase in pH," which subsequently declines as the blooms die out, demonstrating "pH is naturally variable and that marine organisms—particularly microbes—must already be capable of adapting to rapid and some-

times large changes in pH." They note "oceanic pH can change by up to 0.06 pH unit during the year even in the oligotrophic Central Pacific, which does not experience the dramatic phytoplankton blooms of temperate oceans."

In the case of freshwater ecosystems, Joint *et al*. report, "Maberly (1996) showed that diel variations in a lake can be as much as 2–3 pH units," and "Talling (2006) showed that in some English lakes, pH could change by >2.5 pH units over a depth of only 14 m." They note, "phytoplankton, bacteria, archaea and metazoans are all present in lakes, and appear to be able to accommodate large daily and seasonal changes in pH."

Noting the "the impacts of elevated atmospheric CO_2 on freshwater habitats are still poorly understood," Wu *et al*. (2012) isolated specimens of the freshwater N_2-fixing cyanobacterium *Cylindrospermopsis raciborskii* from a pond near Dianchi Lake in Kunming (China). They cultured them semi-continuously for 18 days at low and high inorganic phosphorus (Pi) levels (0.022 µM and 22 µM, respectively) in contact with air of either 380 or 1,000 ppm CO_2, while measuring several important physiological functions of the cyanobacterium.

In the case of light-saturated net photosynthesis, the 620-ppm increase in the air's CO_2 content resulted in 37% and 74% increases in the low and high Pi treatments, respectively. The CO_2 increase resulted in 26% and 23% increases in biomass in the low and high Pi treatments, respectively. And the CO_2 increase resulted in 36% and 14% increases in nitrogen fixation in the low and high Pi treatments, respectively. Wu *et al*. say the cyanobacterial growth increase they observed "confirms previous studies with other algae (Burkhardt and Riebesell, 1997; Burkhardt *et al*., 1999; Clark and Flynn, 2000; Kim *et al*., 2006; Posselt *et al*., 2009; Kranz *et al*., 2010)," as well as the finding of Chinnasamy *et al*. (2009) that "the nitrogenase activity of *Anabaena fertilissima* increased with increasing levels of CO_2."

Prosser *et al*. (2012) write, "harmful algal blooms of *Prymnesium parvum* are global phenomena occur-ring in marine, estuarine and inland ecosystems," citing Moestrup (1994), Edvardsen and Paasche (1998), and Lundholm and Moestrup (2006). They note *P. parvum*, commonly known as "golden algae" or "Texas tide," is "a mixotrophic flagellated hapto-phyte known to produce toxins that may severely impact aquatic organisms," citing Brooks *et al*. (2010). Prosser *et al*. evaluated "whether pH influences *P. parvum* bloom development and ambient toxicity" by manipulating pH levels (7, 7.5,

8.5) of *in situ* experimental enclosures during 21-day pre-bloom development experiments in Lake Granbury, Texas (USA).

The 10 U.S. researchers report neutral pH levels preempted *P. parvum* bloom development, as "population densities never reached bloom proportions and no ambient toxicity to fish or cladocerans resulted." They found "higher pH (8.5) allowed bloom formation to occur" and "resulted in ambient toxicity," whereas at the other end of the pH spectrum, "reducing pH to 7 and 7.5 did not adversely affect phytoplankton or zooplankton biomass."

The results of the studies reviewed above are encouraging, suggesting the growth and productivity of freshwater algae may be enhanced as the air's CO_2 concentration rises and the pH levels of freshwater lakes, rivers, and streams decline, while also making it more difficult for blooms of some harmful algae to occur.

6.4.2 Macrophytes

The studies reviewed in this section examine what scientists have learned about potential impacts of lower freshwater pH levels on macrophytes—aquatic plants. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- The ongoing rise in the air's CO$_2$ content will likely induce significant positive impacts on most freshwater macrophytes, including submersed, floating, and emergent species.

- The CO$_2$-induced growth enhancement of Corkscrew vallisneria (*Vallisneria tortifolia*) has been observed to increase linearly out to CO$_2$ concentrations 10 times the ambient value.

- Total biomass accumulation of *Vallisneria spinulosa* plants grown at an elevated CO$_2$ concentration of 1,000 ppm was "2.3 times that of plants grown in ambient CO$_2$, with biomass of leaves, roots, and rhizomes increasing by 106%, 183%, and 67%, respectively."

- A tenfold increase in aquatic CO$_2$ concentration enhanced the biomass production of *Littorella uniflora* by 78% across an entire growing season.

- A 300 ppm increase in CO$_2$ produced a 3.7-fold increase in total dry matter production in the water lily *Nymphaea marliac*.

- In a CO$_2$ enrichment study of the common water fern *Azolla pinnata*, "the debilitating effects of high temperatures were [found to be] reduced: in one case to a much less severe negative growth rate, in another case to merely a short period of zero growth rate, and in a third case to no discernible ill effects whatsoever—in spite of the fact that the ambient treatment plants in this instance all died."

- Elevated CO$_2$ and temperature—both singly and in combination—positively impacted root growth of water horsetail (*Equisetum fluviatile*).

Idso (1997) grew specimens of corkscrew vallisneria (*Vallisneria tortifolia*) for several multiweek periods in several 10- and 29-gallon glass tanks (containing 10-cm bottom-layers of common aquarium gravel) filled with tap water maintained within 0.5°C of either 18.2°C or 24.5°C. He maintained the semi-sealed air spaces above these "poor man's biospheres," as he named them, at a number of CO$_2$ concentrations. Upon harvesting the plants at the end of the study, he found the CO$_2$-induced growth enhancement was linear, and this linear relationship extended to the highest atmospheric CO$_2$ concentration studied: 2,100 ppm. In addition, he found the CO$_2$-induced growth increase of the plants in the higher of the two water

temperature treatments (a 128% increase in going from an atmospheric CO_2 concentration of 365 ppm to one of 2,100 ppm) was 3.5 times greater than that of the plants in the lower water temperature treatment. Idso reports Titus *et al.* (1990), who studied the closely related *Vallisneria americana*, "observed that the biomass of their experimental plants also rose linearly with the CO_2 content of the air above the water within which they grew, and that [it] did so from the value of the [then] current global mean (365 ppm) to a concentration fully ten times larger."

Yan *et al.* (2006) collected turions of *Vallisneria spinulosa* from Liangzi Lake, Hubei Province (China) and planted them in tanks containing 15-cm-deep layers of fertile lake sediments, topped with 40 cm of lake water, placed in two glasshouses—one maintained at the ambient atmospheric CO_2 concentration of 390 ppm and the other at an elevated concentration of 1,000 ppm. They allowed the plants to grow for 120 days, harvested them, and determined the dry weights of their various organs. They found the "total biomass accumulation of plants grown in the elevated CO_2 was 2.3 times that of plants grown in ambient CO_2, with biomass of leaves, roots, and rhizomes increasing by 106%, 183%, and 67%, respectively." They report, "turion biomass increased 4.5-fold," because "the mean turion numbers per ramet and mean biomass per turion in elevated CO_2 were 1.7–4.3 and 1.9–3.4 times those in ambient CO_2."

Andersen *et al.* (2006) studied small, slow-growing evergreen perennials called isoetids that live submersed along the shores of numerous freshwater lakes. They obtained specimens of *Littorella uniflora* from sediment cores removed from Lake Hampen, Denmark, which they grew in 75-liter tanks with 10-cm overburdens of filtered lake water for 53 days. They measured various plant, water, and sediment properties throughout the experiment's duration, and then the researchers destructively harvested the plants and measured their biomass. Throughout this period, half of the tanks had ambient air bubbled through their waters, while the other half were similarly exposed to a mixture of ambient air and pure CO_2 that produced a tenfold increase in the air's CO_2 concentration. This ultra-CO_2-enrichment led to a 30% increase in plant biomass and "higher O_2 release to the sediment which is important for the cycling and retention of nutrients in sediments of oligotrophic softwater lakes." When the ultra-CO_2-enrichment was maintained for an entire growing season (May–November), Andersen and Andersen (2006a) report the tenfold increase in aquatic CO_2 concentration enhanced the biomass production of *Littorella uniflora* by 78%.

Andersen and Andersen (2006b) propagated *Littorella uniflora* under sterile conditions in the absence of symbiotic arbuscular mycorrhizal fungi (AMF), after which they re-infected half of the plants with AMF and allowed both groups to grow for 60 days in water of either high (150 μM) or low (ambient, about 15 μM) CO_2 concentration in conditions where concentrations of NO_3- and PO^3_4- were low enough to limit plant growth. Under this experimental setup, the authors report, "both in treatments with and without AMF, high CO_2 concentration resulted in a significantly higher total biomass of *L. uniflora*, and the same was observed for both shoots and roots," although "the biomass of roots increased more than the biomass of shoots." They report, "in treatments without AMF, increasing the CO_2 concentration 10 times resulted in a change from a slightly negative growth to a twofold increase in biomass over the 60-day period," and "in treatments with AMF, the increase in CO_2 concentration resulted in a fourfold increase in biomass."

The researchers' work also demonstrated "*L. uniflora's* symbiosis with mycorrhiza improved the retention of N and P in the plants at very low nutrient concentrations in the water." Consequently, as they observed "hyphal infection increased fivefold under the raised CO_2 concentration," it is evident elevated aquatic CO_2 concentrations may also help isoetids by enhancing the magnitude and stability of their AMF symbiosis, which helps them retain vital nutrients.

Idso *et al.* (1990) studied an "in-between" type of plant—water lily (*Nymphaea marliac*)—which has submersed roots and rhizomes anchored in water-body sediments but also has floating leaves on the surface of the water and emergent flowers that protrude above the water surface. The water lilies were grown for two consecutive years in sunken metal stock tanks located out-of-doors at Phoenix, Arizona (USA) and enclosed within clear-plastic-wall open-top chambers through which air of either 350 or 650 ppm CO_2 was continuously circulated. In addition to the leaves of the plants being larger in the CO_2-enriched treatment, there were 75% more of them than in the ambient-air tanks at the conclusion of the initial five-month-long growing season, the scientists report. Each of the plants in the high-CO_2 tanks also produced twice as many flowers as the plants growing in ambient air, and the flowers that blossomed in the CO_2-enriched air were more substantial than those that bloomed in the air of ambient CO_2 concentration—they had more petals, the petals were

longer, and they had a greater percent dry matter content, so the flowers weighed on average about 50% more than those in the ambient-air treatment. In addition, the stems that supported the flowers were slightly longer in the CO_2-enriched tanks, and the percent dry matter contents of both the flower and leaf stems were greater, so the total dry matter in the flower and leaf stems in the CO_2-enriched tanks exceeded that of the flower and leaf stems in the ambient-air tanks by approximately 60%.

There were also noticeable differences just above the surface of the soil that covered the bottoms of the tanks. Plants in the CO_2-enriched tanks had more and bigger basal rosette leaves, which were attached to longer stems of greater percent dry matter content, which led to the total biomass of these portions of the plants being 2.9 times greater than the total biomass of the corresponding portions of the plants in the ambient-air tanks. In addition, plants in the CO_2-enriched tanks had more than twice as many unopened basal rosette leaves.

The greatest differences of all, however, were within the soil that covered the bottoms of the stock tanks. When half of the plants were harvested at the conclusion of the first growing season, the number of new rhizomes produced over that period was 2.4 times greater in the CO_2-enriched tanks than in the ambient-air tanks, and the number of major roots produced there was 3.2 times greater. The percent dry matter contents of the new roots and rhizomes were also greater in the CO_2-enriched tanks. Overall, the total dry matter production within the submerged soils of the water lily ecosystems was 4.3 times greater in the CO_2-enriched tanks than in the ambient-air tanks, and the total dry matter production of all plant parts—those in the submerged soil, those in the free water, and those in the air above—was 3.7 times greater in the high-CO_2 enclosures.

Over the second growing season, the growth enhancement in the high-CO_2 tanks was somewhat less, but the plants in those tanks were so far ahead of the plants in the ambient-air tanks that in their first five months of growth they produced what it took the plants in the ambient-air tanks fully 21 months to produce.

Idso (1997) focused on an exclusively floating freshwater macrophyte, growing many batches of the common water fern (*Azolla pinnata*) over a wide range of atmospheric CO_2 concentrations at two water temperatures (18.2°C and 24.5°C) for periods of several weeks. A 900 ppm increase in the CO_2 concentration of the air above the tanks led to a 19% increase in the biomass production of the plants floating in the cooler water, but a 66% biomass increase in the plants floating in the warmer water.

In another study of *Azolla pinnata*, Idso *et al.* (1989) conducted three separate two- to three-month experiments in which they grew batches of the floating fern out-of-doors in adequately fertilized water contained in sunken metal stock tanks located within clear-plastic-wall open-top chambers continuously maintained at atmospheric CO_2 concentrations of either 340 or 640 ppm. At weekly intervals, the researchers briefly removed the plants from the water and weighed them, and they measured their photosynthetic rates at hourly intervals from dawn to dusk on selected cloudless days. They found the photosynthetic and growth rates of the plants growing in ambient air "first decreased, then stagnated, and finally became negative when mean air temperature rose above 30°C." In the high CO_2 treatment, they found "the debilitating effects of high temperatures were reduced: in one case to a much less severe negative growth rate, in another case to merely a short period of zero growth rate, and in a third case to no discernible ill effects whatsoever—in spite of the fact that the ambient treatment plants in this instance all died."

Ojala *et al.* (2002) studied an emergent freshwater macrophyte, growing water horsetail (*Equisetum fluviatile*) plants at ambient and double-ambient atmospheric CO_2 concentrations and ambient and ambient + 3°C air temperatures for three years, although the plants were subjected to the double-ambient CO_2 condition only for approximately five months of each year. The increase in air temperature boosted maximum shoot biomass by 60%, but the elevated CO_2 had no effect on this aspect of plant growth. Elevated CO_2 and temperature—both singly and in combination—positively impacted root growth, which was enhanced by 10, 15, and 25% by elevated air temperature, CO_2, and the two factors together, respectively.

The experimental findings discussed here indicate the ongoing rise in the air's CO_2 content likely will have significant positive impacts on most freshwater macrophytes, including submersed, floating, and emergent species.

6.5 Simultaneous Ocean Warming and "Acidification"

6.5.1 Effects on Marine Plants

The studies reviewed in this section examine what scientists have learned about potential impacts of rising ocean temperatures and lower ocean pH levels on various types of marine phytoplankton and macroalgae. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Strains of one phytoplankton species, and even of a single population, can yield responses opposite to changes in temperature and CO_2, which can lead to contrasting predictions about the future.

- Laboratory experiments suggest increases in the air's temperature and CO_2 content may improve the productivity of two dominating filamentous cyanobacteria species of the Baltic Sea.

- Future ocean warming and acidification will significantly increase the biological extraction of nitrogen and carbon dioxide from the atmosphere by diazotrophic cyanobacteria.

- Atmospheric CO_2 enrichment and sea-surface warming likely will have a large positive influence on the growth of *Emiliania huxleyi*, based on findings of laboratory studies.

- Consistent with findings of laboratory experiments, over the past 220 years of warming and lower ocean pH levels , there has been a 40% increase in average *E. huxleyi* coccolith mass in the subpolar North Atlantic Ocean, based on analyses of real-world sediment-core data.

- Sediment cores taken from the Santa Barbara Basin on the North American Pacific margin indicate an approximate 33% increase in mean coccolith weight over the 87-year period 1917–2004.

- Modern *Coccolithus* populations in the Southern Ocean are, on average, more heavily calcified than their fossil counterparts from the Last Glacial Maximum (21.6–19.9 ka), the Holocene (4.2–3.1 ka), and the Transition between the two periods (16.2–15.6 ka).

- A literature review of experiments conducted on more than 100 marine macroalgae (macro-autotrophs) species finds "photosynthetic and growth rates of marine macro-autotrophs are likely to increase under elevated CO_2 similar to terrestrial C_3 species."

Fiorini *et al*. (2011) note coccolithophores "are considered to be the most productive calcifying organisms on the planet," and "they play a crucial role in the marine carbon cycle through calcification and photosynthetic carbon production (Rost and Riebesell, 2004)." They also note coccolithophores "contribute significantly to the flux of organic matter from the sea surface to deep waters and sediments

(Klaas and Archer, 2002)" and are "responsible for about half of the global surface ocean calcification."

Fiorini *et al*. (2011) examined the effects of the pCO_2 and temperature levels projected for the end of this century on photosynthesis, growth, and calcification during both life stages (haploid and diploid) of strain AC418 of the coccolithophore *Syracosphaera pulchra*, via a series of culture studies conducted in the laboratory, where they focused on both particulate inorganic carbon (PIC) and particulate organic carbon (POC). The three researchers report "neither the rate of calcification (production of particulate inorganic carbon) nor the PIC:POC ratio were significantly affected by elevated pCO_2, temperature or their interaction." They further state, "our results confirm that the expected 3°C increase in the present seawater temperature will not strongly affect the physiology of this eurythermal species" and "the effect of an elevated pCO_2 in seawater will not be significant on calcification or on the PIC:POC ratio in either life stage."

Feng *et al*. (2008) grew *Emiliania huxleyi*, which they isolated from the Sargasso Sea, by semi-continuous culture methods at two light intensities (low 50 and high 400 μmol photons/m^2/sec), two temperatures (low 20 and high 24°C), and two CO_2 concentrations (low 375 and high 750 ppm). They found in the low-light environment, the chlorophyll *a*-normalized photosynthetic rates of the cocco-lithophores in all four temperature/CO_2 treatments attained maximum values at an irradiance of approximately 200 μmol photons/m^2/sec. The maximum photosynthetic rate was lowest in the low-temperature, low-CO_2 (ambient) treatment, but was significantly increased by elevated temperature alone (by 55%) and by elevated CO_2 alone (by 95%). In the high-temperature, high-CO_2 (greenhouse) treatment the maximum photosynthetic rate was increased by 150% relative to the ambient treatment.

In the high-light environment, the chlorophyll *a*-normalized photosynthetic rates did not max out below the maximum irradiance tested (900 μmol photons/m^2/sec) for any but the ambient treatment. Consequently, the equations fit to the data of the other treatments were extrapolated to their respective photosynthetic maxima, which produced correspond-ing maximum photosynthetic rate increases of 58%, 67%, and 92% for the elevated temperature alone, elevated CO_2 alone, and greenhouse treatments, respectively.

In the high-light greenhouse treatment charac-teristic of the expected future condition of Earth, the maximum photosynthetic rate was 178% greater than

in the low-light ambient treatment characteristic of the present. The seven researchers say their results indicate "future trends of CO_2 enrichment, sea-surface warming and exposure to higher mean irradiances from intensified [surface water] stratification will have a large influence on the growth of *Emiliania huxleyi*."

Another important group of phytoplankton are diatoms, which Sobrino *et al*. (2008) say "are responsible for almost 40% of the ocean primary productivity (Nelson *et al*., 1995)." According to Kremp *et al*. (2012), "most of the laboratory studies investigating the effects of climate stressors on phytoplankton have been performed on single strains," and "the significant effects often found in such experiments are contrasted by the general lack of clear responses in natural populations," citing Engel *et al*. (2008). They hypothesize the "contradictory responses to changed climate conditions sometimes observed within the same species might be partly attributable to strain variability between or within populations," citing Langer *et al*. (2009) and noting these observations emphasize "the need to consider variability in studies aiming to understand the effects of climate change on phytoplankton species."

Kremp *et al*. studied "the effects of increased temperature and CO_2 availability, as predicted consequences of global change, on 16 genetically different isolates of the diatom *Skeletonema marinoi* from the Adriatic Sea and the Skagerrak (North Sea), and on eight strains of the PST (paralytic shellfish toxin)-producing dinoflagellate *Alexandrium ostenfeldii* from the Baltic Sea." They assessed maximum growth rates of acclimated isolates grown in batch cultures for five to 10 generations in a factorial design at 20 and 24°C, and present-day and next-century atmospheric CO_2 concentrations (385 and 750 ppm), respectively. The seven scientists found strains of one species, and even of a single population, "can be impacted in very different ways by climate stressors," noting "a particularly wide response range was found in the population of *S. marinoi* from the NW Adriatic sea, where temperature and CO_2 caused positive, negative or no effect at all."

Kremp *et al*. conclude, "depending on the strain of choice," experiments using single isolates of the population they studied "could have given opposite response patterns," which likely would have led to "contrasting predictions" about the future. Therefore, they write, "responses observed in single strain experiments may not be representative" of the species or population in question, and predictions for specific

species behavior under future climatic conditions must "be treated with caution."

Noting "cyanobacteria such as *Synechococcus* and *Prochlorococcus* have a major impact on the global carbon cycle and contribute up to 50% of fixed carbon in marine systems (Partensky *et al*., 1999)," Fu *et al*. (2007) studied "how CO_2 and temperature individually and together affect the physiology of these two species under identical growth conditions." They grew stock cultures of the two picocyano-bacteria in one-liter bottles of autoclaved and filtered seawater maintained at temperatures of either 20 or 24°C in equilibrium with air of either 380 or 750 ppm CO_2. The five researchers discovered the growth rate and maximum photosynthetic rate in *Synechococcus* increased about 2.3-fold and 4-fold, respectively, in the high-temperature and high-CO_2 treatment relative to ambient conditions, but they remained unchanged in *Prochlorococcus*.

Fu *et al*. say their observations "could be taken to mean that in the future, rising temperature and CO_2 would stimulate growth or photosynthesis of [the] *Synechococcus* isolate but would have much less effect on [the] Procholrococcus strain," and such a result could "potentially influence competition between particular *Synechococcus* and *Prochloro-coccus* ecotypes." However, they add, "we need to be very cautious about inferring ecosystem-scale shifts in broad taxonomic groups like picocyanobacteria from studies using only two isolates." They report stimulation of algal growth rates by elevated CO_2 also has been observed by Burkhardt and Riebesell (1997), Burkhardt *et al*. (1999), Yang and Gao (2003), Beardall and Raven (2004), and Kim *et al*. (2006).

Hutchins *et al*. (2007) note *Trichodesmium* species and other diazotrophic cyanobacteria support a large fraction of the total biological productivity of Earth's tropical and subtropical seas, and they exert a significant influence on the planet's carbon cycle by supplying much of the nitrogen that enables marine phytoplankton to maintain a level of productivity that removes vast amounts of CO_2 from the atmosphere. They hypothesized that if an increase in the air's CO_2 content or its temperature led to an increase in oceanic N_2 fixation, it also could lead to the biological extraction of more CO_2 from the atmosphere and a tempering of the CO_2 greenhouse effect via this negative feedback process.

To explore this possibility, the eight researchers grew cultures of Pacific and Atlantic Ocean isolates of *Trichodesmium* ecotypes across a range of atmos-pheric CO_2 concentrations characteristic of Earth's past (150 ppm), its current state (380 ppm), and

possible future conditions (750, 1,250, and 1,500 ppm) at two temperatures (25 and 29°C) and at sufficient and limiting phosphorus concentrations (20 and 0.2 μmol L^{-1} of phosphate, respectively), in situations where the carbonate buffer system para-meters in their artificial seawater culture media were "virtually identical to those found in natural seawater across the relevant range of CO_2 values."

Hutchins *et al*. found, at atmospheric CO_2 con-centrations projected for the year 2100 (750 ppm), "N_2 fixation rates of Pacific and Atlantic isolates increased 35–100%, and CO_2 fixation rates increased 15–128% relative to present day CO_2 conditions (380 ppm)." In what they call one of their "most striking results," they found "increased CO_2 enhanced N_2 and CO_2 fixation and growth rates even under severely phosphorus-limited steady-state growth conditions." They also report "neither isolate could grow at 150 ppm CO_2," but "N_2 and CO_2 fixation rates, growth rates, and nitrogen:phosophorus ratios all increased significantly between 380 and 1500 ppm," and, "in contrast, these parameters were affected only minimally or not at all by a 4°C temperature change."

Hutchins *et al*. note current global estimates of N_2 fixation by *Trichodesmium* are about 60 x 10^9 kg N yr^{-1}, and if their experimental results can be extrapolated to the world's oceans, by 2100 this amount could increase to 81–120 x 10^9 kg N yr^{-1}. "If these estimates are coupled with modeling predictions of a 27% warming-induced expansion of suitable habitat (Boyd and Doney, 2002), calculations suggest that global N_2 fixation by *Trichodesmium* alone could range from 103–152 x 10^9 kg N yr^{-1} by the end of this century," which is to be compared to recent estimates for total pelagic N_2 fixation of 100–200 x 10^9 kg N yr^{-1} (Galloway *et al*., 2004). They also note free-living unicellular cyano-bacteria in the ocean are believed to fix at least as much nitrogen as *Trichodesmium* (Montoya *et al*., 2004), and endosymbiotic cyanobacteria also con-tribute substantially to N_2 fixation. Hence they conclude, "if N_2 fixation rates in these groups show commensurate increases with rising CO_2, the cumulative effect on the global nitrogen cycle could be considerably larger (e.g., a doubling)." In addition, they state their results indicate "like N_2 fixation, CO_2 fixation by *Trichodesmium* should also increase dramatically in the future because of CO_2 enrichment."

Hutchins *et al*. conclude, "many of our current concepts describing the interactions between oceanic nitrogen fixation, atmospheric CO_2, nutrient biogeo-chemistry, and global climate may need re-evaluation

to take into account these previously unrecognized feedback mechanisms between atmospheric composition and ocean biology."

Karlberg and Wulff (2013) investigated the ramifications of potential future increases in the air's CO_2 content on the productivity of two dominating filamentous cyanobacteria species of the Baltic Sea (*Nodularia spumigena* and a mix of *Aphanizomenon* sp.) during the summer bloom of the Baltic Proper. The pair of researchers set out to experimentally determine the response of these two species to changes in that region's environment predicted to occur in response to IPCC's business-as-usual A1FI scenario described by Meehl *et al.* (2007): a temperature increase of 4°C, an atmospheric pCO_2 increase from 380 to 960 ppm, and a reduction in salinity from 7 to 4. Working in the laboratory, Karlberg and Wulff measured numerous responses of the two species of cyanobacteria, growing both separately and together, to different combinations of these environmental changes.

The two researchers report "increased temperature, from 12 to 16°C, had a positive effect on the biovolume and photosynthetic activity of both species," and "compared when growing separately, the biovolume of each species was lower when grown together." They also note "decreased salinity, from 7 to 4, and elevated levels of pCO_2, from 380 to 960 ppm, had no effect on the biovolume, but on [the photosynthetic activity] (Fv/Fm) of *N. spumigena* with higher Fv/Fm in salinity 7." Karlberg and Wulff say their results suggest "the projected A1FI scenario might be beneficial for the two species dominating the extensive summer blooms in the Baltic Proper." They caution their results "further stress the importance of studying interactions between species." They conclude, "long-term studies together with multifactorial and mesocosm/field experiments are needed to elucidate the future impact of climate change effects on Baltic filamentous cyanobacteria."

Grelaud *et al.* (2009) investigated "the morphometry (size, weight) of selected species of the order Isochrysidales (i.e., *E. huxleyi*, *G. muellerae* and *G. oceanica*) to understand how coccolithophores' carbonate mass is influenced by recent oceanographic global changes." They analyzed sediment cores taken from "the deep center of the Santa Barbara Basin (SBB) on the North American Pacific margin in the interval from AD 1917 to 2004." They found "morphometric parameters measured on *E. Huxleyi*, *G. muellerae* and *G. oceanica* indicate increasing coccolithophore shell carbonate mass from ~1917 until 2004 concomitant with rising pCO_2 and

sea surface temperature in the region of the SBB." Specifically, they note "a >33% increase in mean coccolith weight was determined for the order Isochrysidales over 87 years from ~1917 until 2004."

The three researchers note "the last century has witnessed an increasing net influx of atmospheric carbon dioxide into the world's oceans, a rising of pCO_2 of surface waters, and under-saturation with respect to aragonite, especially along the North American Pacific margin," which was the site of their study. They note those concerned about lower ocean pH levels predicted such conditions will "result in reduced coccolithophore carbonate mass and a concomitant decrease in size and weight of coccoliths." They discovered just the opposite appears to have occurred in the real world, even in places where the predicted calcification reductions were expected to be greatest.

Iglesias-Rodriguez *et al.* (2008) grew several batch incubations of the coccolithophore species *Emiliania huxleyi* in the laboratory, bubbling air of a number of different atmospheric CO_2 concentrations through the culture medium and determining the amounts of particulate inorganic carbon (PIC) and particulate organic carbon (POC) produced by the coccolithophores within the CO_2 treatments. In addition, they determined the change in average coccolithophore mass of *Emiliania huxleyi* over the past 220 years in the real world of nature, based on data they obtained from a sediment core extracted from the subpolar North Atlantic Ocean, over which period of time temperatures increased and the air's CO_2 concentration rose by approximately 90 ppm. The 13 researchers from the United Kingdom, France, and United States observed an approximate doubling of both PIC and POC between the culture media in equilibrium with air of today's CO_2 concentration and air of 750 ppm CO_2. They report the field evidence obtained from the deep-ocean sediment core they studied "is consistent with these laboratory conclusions, indicating that over the past 220 years there has been a 40% increase in average coccolith mass."

Cubillos *et al.* (2012) set out to adapt "an existing method to estimate coccolith calcite weight using birefringence (Beaufort, 2005)," which they decided was needed "to suit the large coccoliths of *Coccolithus pelagicus*," focusing "only on the central area, which is the thickest and most robust part of the coccolith." They applied this technique "to fossil and sediment trap material from the South Tasman Rise area of the Southern Ocean," based on three sediment samples each from the Last Glacial Maximum (21.6–19.9 ka), the Holocene (4.2–3.1 ka), and the

Transition between the two periods (16.2–15.6 ka), as well as modern-day trap samples. "Most strikingly," the five researchers report, "it appears that modern *Coccolithus* populations in the Southern Ocean are, on average, more heavily calcified than their fossil counterparts," a positive and encouraging finding. Cubillos *et al.* say their work reveals "substantial non-linearity and independency of variations (plasticity) in coccolith size, shape and volumetric weight between the investigated time intervals." They say they hope to study these phenomena "in more detail" in order to "unravel what environmental conditions are related to intra-specific phenotypic variability in ancient and modern coccolithophores."

Koch *et al.* (2013) write, "although seagrasses and marine macroalgae (macro-autotrophs) play critical ecological roles in reef, lagoon, coastal and open-water ecosystems, their response to ocean acidification (OA) and climate change is not well understood." They reviewed the scientific literature on these subjects, examining "marine macro-autotroph biochemistry and physiology relevant to their response to elevated dissolved inorganic carbon (DIC), carbon dioxide (CO_2), and lower carbonate (CO_3^{2-}) and pH," and also exploring "the effects of increasing temperature under climate change and the interactions of elevated temperature and CO_2."

The four researchers determined their "literature review of >100 species revealed marine macro-autotroph photosynthesis is overwhelmingly C_3 (>=85%) with most species capable of utilizing HCO_3^-," and "most are not saturated at current ocean DIC." They conclude, "photosynthetic and growth rates of marine macro-autotrophs are likely to increase under elevated CO_2 similar to terrestrial C_3 species." In addition, as "the photosynthesis of the majority of the species examined was not saturated at the current levels of DIC in the ocean and responded to an increase in CO_2," they conclude seagrasses and many marine macroalgae have the potential to respond positively, in terms of photosynthesis and growth, under elevated ocean CO_2 and OA.

6.5.2 Effects on Marine Animals

6.5.2.1 Corals

6.5.2.1.1 Review Papers

Few studies have investigated the interactive effects of lower ocean pH levels and rising temperature. This section examines what scientists have learned from such studies, focusing on the impacts of these variables on coral reefs as reported in review papers on the topic. The key findings, all of which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- "Neither climate nor sea-level nor chemical changes in the oceans can elucidate the waxing and waning of reefs" throughout their history on Earth. The "boom and bust pattern" observed through geologic time is "impossible to explain by linear responses to physicochemical changes."

- Shallow water tropical reef organisms existed throughout the entire 540 million years of the Phanerozoic, which included times when sea surface temperatures were more than 7°C higher than those of today and the air's CO₂ concentration was as much as 6,000 ppm higher.

- Although the Paleocene-Eocene Thermal Maximum, some 55.8 million years ago, was "characterized by rapid sea surface temperature rise and a similar order of magnitude of CO₂ increase as present," there is evidence "reef assemblages in at least one oceanic setting were

unaffected." Other reefs also have shown "greater resilience to past rapid warming and acidification than previously thought."

- Emerging evidence indicates there is variability in the coral calcification response to lower seawater pH levels, geographical variation in bleaching susceptibility and recovery, and potential adaptation to rapid warming and declining pH, supporting "an alternative scenario in which reef degradation occurs with greater temporal and spatial heterogeneity than current projections suggest."

Kiessling (2009), from the Museum fur Naturkunde of the Leibniz Institute for Research on Evolution and Biodiversity at the Humboldt University in Berlin, reviewed the state of knowledge of the long-term effects of changes in ocean temperature and the atmosphere's CO_2 concentration on the vigor of the planet's coral reefs as of 2009. With respect to global warming, Kiessling reports, "on geologic timescales, there is little evidence for climate change affecting reefs in a linear fashion," and "changes in mean global temperature as reconstructed from stable oxygen isotopes and the distribution of non-reef climate-sensitive sediments do not correspond to changes in reef abundance or latitudinal distribution," citing some of his own analyses of the subject (Kiessling, 2001a, 2002). He also states, "reports linking reef expansions and declines to climate change fail to explain why other changes in temperature did not lead to a similar response in reefs and why the reported (fairly modest) temperature changes would have such a dramatic effect."

Regarding lower ocean pH levels, the German researcher reports, "just like temperature," it is currently receiving much attention as "a control of reef development," but "the boom and bust pattern of reefs and hyper-calcifiers is difficult to explain with inferred long-term changes in the saturation state of ocean water, at least if the major trigger is atmospheric pCO_2," because "previous analyses failed to find any significant cross-correlation between changes in pCO_2 and changes in reef attributes," citing Kiessling (2001b, 2002).

In light of these and many other observations, Kiessling concludes "neither climate nor sea-level nor chemical changes in the oceans can elucidate the waxing and waning of reefs" throughout their history on Earth, and their "boom and bust pattern" is "impossible to explain by linear responses to physico-chemical changes." Furthermore, Kiessling writes,

"ecologically complex reef systems have been around for hundreds of millions if not billions of years," and "geologic models of CO_2 concentrations in the atmosphere suggest that these were much greater during most of Earth's history than today." This further suggests something other than CO_2-induced global warming and lower ocean pH levels must have been responsible for their prior "boom and bust" pattern of behavior.

In a major review article published in *Science*, Pandolfi *et al.* (2011) summarize "the most recent evidence for past, present and predicted future responses of coral reefs to environmental change, with emphasis on rapid increases in temperature and lower ocean pH levels and their effects on reef-building corals." They note, "many physiological responses in present-day coral reefs to climate change are interpreted as consistent with the imminent disappearance of modern reefs globally because of annual mass bleaching events, carbonate dissolution and insufficient time for substantial evolutionary responses." All of these interpretations, they demonstrate, may be incorrect.

The four researchers report shallow water tropical reef organisms existed throughout the entire 540 million years of the Phanerozoic, which included times when sea surface temperatures (SSTs) were more than 7°C higher than those of today and the air's CO_2 concentration was as much as 6,000 ppm higher. As to what they call "the most recent reef crisis," they report "the Paleocene-Eocene Thermal Maximum (PETM; 55.8 million years ago), was characterized by rapid SST rise and a similar order of magnitude of CO_2 increase as present," yet there is evidence "reef assemblages in at least one oceanic setting were unaffected (Robinson, 2011)" and other reefs also have shown "greater resilience to past rapid warming and acidification than previously thought."

More recently, during the Holocene, Pandolfi *et al.* state, "evidence from high-resolution proxy records suggests that tropical SSTs had the potential to repeatedly warm over centennial to millennial time scales (Rosenthal *et al.*, 2003; Schmidt *et al.*, 2004)." In one location, they report, SSTs rose "at rates comparable to those projected for the coming century (Lea *et al.*, 2003)," yet "none of these post-Last Glacial Maximum warming episodes appear to have interrupted reef growth."

As for current coral responses to SST increases, the four scientists note "numerous characteristics of coral hosts have the potential to confer differences in bleaching susceptibility," and "these characteristics vary substantially within and among coral species

(Baird *et al*., 2009a; Csaszar *et al*., 2010)." They note "some coral species also harbor multiple strains of zooxanthellae, which confer differential susceptibility of their hosts to bleaching (Rowan, 2004)." They note there is also "substantial variation in reef recovery in the aftermath of bleaching events (Baker *et al*., 2008)."

The story is much the same regarding coral responses to lower ocean pH levels. Pandolfi *et al*. note, for example, studies have shown calcification has "increased under moderately elevated partial pressure of CO_2 (Rodolfo-Metalpa *et al*., 2010; Jury *et al*., 2010; Reynaud *et al*., 2003), as has also been observed for some coralline algae, crustacea and echinoderms (Ries *et al*., 2009)." They also note sensitivity of calcification to lower ocean pH levels "appears to be reduced when (i) studies are conducted over weeks or months (Ries *et al*., 2009; Rodolfo-Metalpa *et al*., 2010; Marubini *et al*., 2001; Reynaud *et al*., 2003) as opposed to less than one day (Langdon and Atkinson, 2005; Ohde and Hossain, 2004) or (ii) corals are reared under nutritionally replete conditions by feeding or elevating inorganic nutrient concentrations (Langdon and Atkinson, 2005; Ries *et al*., 2009)."

The four researchers write, "because bleaching-susceptible species often have faster rates of recovery from disturbances, their relative abundances will not necessarily decline" in the future. They continue, "such species could potentially increase in abundance, depending on how demographic characteristics and competitive ability are correlated with thermal toler-ance and on the response of other benthic taxa, such as algae." They further note "the shorter generation times typical of more-susceptible species (Baird *et al*., 2009b) may also confer faster rates of evolution of bleaching thresholds, which would further facilitate maintenance of, or increases to, the relative abundance of thermally sensitive but faster-evolving species (Baskett *et al*., 2009)."

Pandolfi *et al*. state emerging evidence for variability in the coral calcification response to lower ocean pH levels, geographical variation in bleaching susceptibility and recovery, responses to past climate change, and potential rates of adaptation to rapid warming "supports an alternative scenario in which reef degradation occurs with greater temporal and spatial heterogeneity than current projections suggest." Further noting "non-climate-related threats already confronting coral reefs are likely to reduce the capacity of coral reefs to cope with climate change," they conclude "the best and most achievable thing we can do for coral reefs currently to deal with climate change is to seek to manage them well" by reducing more direct anthropogenic impacts such as fishing, pollution, and habitat destruction, which fragment populations or decrease population sizes and reduce the potential of coral reefs to adapt to warmer, lower pH conditions.

6.5.2.1.2 A Model-based Study

This section reviews one model-based study that focuses on the impact of lower ocean pH levels in combination with higher temperatures on coral reefs.

Couce *et al*. (2013) note "there is concern that the growing frequency and severity of mass bleaching episodes may lead to species composition shifts and functional collapse in coral reefs in the near future." They also note global warming "has the potential to improve currently marginal environmental conditions and extend the range of tropical coral reefs into higher latitudes," as is "demonstrated in the fossil record in response to warmer geological periods (e.g., Lighty *et al*., 1978; Veron, 1992; Precht and Aronson, 2004; Greenstein and Pandolfi, 2008; Woodroffe *et al*., 2010; Kiessling *et al*., 2012)." Less is known about the interacting effects of global warming and lower ocean pH levels, although these phenomena are projected to occur concurrently.

Couce *et al*. employed "a suite of statistical models based on the environmental factors thought to be limiting to the present equilibrium distribution of shallow-water coral reefs, perturbing them with Earth System Model projected future sea surface temperatures and aragonite saturation changes (the simulations used in Turley *et al*., 2010)," while considering "a range of potential future CO$_2$ emissions scenarios" but focusing on "the consequences of the 'A2' scenario (characterized by regionally oriented economic development and high population growth, expecting ca. 850 ppm CO$_2$ by 2100)."

The three UK researchers write of their model-based results, "contrary to expectations, the combined impact of ocean surface temperature rise and acidification leads to little, if any, degradation in future habitat suitability across much of the Atlantic and areas currently considered 'marginal' for tropical corals, such as the eastern Equatorial Pacific." They note, "these results are consistent with fossil evidence of range expansions during past warm periods." Such findings, Couce *et al*. conclude, "present important implications for future coral reef management, as they suggest that more emphasis should be placed on conservation efforts on marginal reefs as they are not necessarily a 'lost cause'."

6.5.2.1.3 Laboratory Studies

Several laboratory studies have focused on the combined impacts of rising temperatures and falling ocean pH levels on coral reefs.. The key findings, all of which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- The "enhanced kinetics of calcification owing to higher temperatures has the potential to counter the effects of ocean acidification."

- The conventional belief that calcification rates will be affected by lower ocean pH levels may be unfounded for temperate zone corals.

- The study of a Mediterranean zooxanthellate coral, *Cladocora caespitosa*, revealed "an increase in CO_2, alone or in combination with elevated temperature, had no significant effect on photosynthesis, photosynthetic efficiency and calcification."

- Lower seawater pH due to atmospheric CO_2 enrichment and increased temperature (but short of reaching the bleaching level) "will both enhance active biotic calcification" of *Agaricia agaricites* corals.

- "The immediate effects of rising seawater temperature and ocean acidification may be tolerable for some species," possibly because the increased availability of $CO_{2(aq)}$ under ocean acidification conditions may enhance algal productivity, especially in *Symbiodinium* phylotypes with less efficient carbon-concentrating mechanisms that rely to a greater extent on the passive, diffusive uptake of $CO_{2(aq)}$ and its fertilization effect.

In a paper published in *Nature Climate Change*, McCulloch *et al.* (2012) describe how biogenic calcification occurs within an extracellular calcifying fluid located in the semi-isolated space between a coral's skeleton and its calicoblastic ectoderm, where during active calcification the pH of the calcifying fluid (pH_{cf}) is often increased relative to ambient seawater pH. At a typical seawater pH of ~8.1, for example, the pH of aragonitic corals shows a species-dependent range of 8.4 to 8.7, representing a systematic increase in pH_{cf} relative to ambient sea water (ΔpH) of ~0.3–0.6 units. They report *in situ* measurements of pH within the calcifying medium of live coral polyps using microelectrodes (Al-Horani *et al.*, 2003; Ries, 2011a) and pH-sensitive dyes (Venn *et al.*, 2011) have registered enhanced pH_{cf} values between 0.6 and 1.2—and sometimes up to 2—pH units above seawater during the day, when both net production and calcification are highest.

Using a model of pH regulation combined with abiotic calcification, McCulloch *et al.* show "the enhanced kinetics of calcification owing to higher temperatures has the potential to counter the effects of ocean acidification," and "the extra energy required to up-regulate pH is minor, only <1% of that generated by photosynthesis," which highlights the importance of maintaining the zooxanthellae-coral symbiosis for sustaining calcification. They further note their model predicts "a ~15% increase in calcification rates from the Last Glacial Maximum to the late Holocene," an increase they describe as being "consistent with the expansion of tropical habitats that occurred during

this time despite P_{CO2} increasing."

Projecting into the future with their experimentally verified model, the four researchers assess the response of coral reefs "to both global warming, with mean tropical sea surface temperatures ~ 2°C higher, and with P_{CO2} increasing from present-day levels to ~1,000 ppm by the year 2100." For this scenario, they report their model predicts "either unchanged or only minimal effects on calcification rates." Thus, from a strictly chemical and kinetic perspective, their model indicates "ocean acidification combined with rising ocean temperatures should have only minimal effects on coral calcification," which they describe as "a direct outcome" of corals' ability to up-regulate pH at the site of calcification.

Rodolfo-Metalpa *et al.* (2010) collected three live colonies of the Mediterranean zooxanthellate coral *Cladocora caespitosa* in the Bay of Villefranche (Ligurian Sea, France) at about 25 meters depth in July 2006, plus three other colonies in February 2007. They divided the colonies into fragments and removed single polyps they attached to PVC plates and randomly assigned to aquariums continuously supplied with unfiltered seawater maintained at ambient or elevated water temperature (T or T + 3°C) in equilibrium with air of ambient or elevated CO_2 concentration (400 or 700 ppm). They subjected the polyps to "(1) mid-term perturbations (1 month) in summer and winter conditions of irradiance and temperature, and (2) a long-term perturbation (1 year), mimicking the seasonal changes in temperature and irradiance."

They found "an increase in CO_2, in the range predicted for 2100, does not reduce [the coral's] calcification rate," and "an increase in CO_2, alone or in combination with elevated temperature, had no significant effect on photosynthesis, photosynthetic efficiency and calcification." They report a 3°C rise in temperature in winter resulted in a 72% increase in gross photosynthesis and a significant increase in daytime calcification rate.

Rodolfo-Metalpa *et al.* conclude "the conventional belief that calcification rates will be affected by ocean acidification may not be widespread in temperate corals." They note Ries *et al.* (2009) have reported the calcification rate of the temperate coral *Oculina arbuscula* is also unaffected by an increase in atmospheric CO_2 concentration of up to 840 ppm, and a large decrease in calcification was found only at a CO_2 concentration in excess of 2,200 ppm. In addition, they write, "some marine invertebrates may be able to calcify in the face of ocean acidification or, contrary to what is generally

expected, may increase their calcification rates as reported on the ophiourid brittlestar *Amphiura filiformis* (Wood *et al.*, 2008), the seastar *Pisaster ochraceus* (Gooding *et al.*, 2009) exposed to lower pH (7.8–7.3), the Caribbean coral *Madracis mirabilis* at pH 7.6 (Jury *et al.*, 2010), and shown for coralline red algae, calcareous green algae, temperate urchins, limpets, crabs, lobsters and shrimp (Ries *et al.*, 2009)." They note there are many cases where "rates of photosynthesis are either not affected (e.g. Langdon *et al.*, 2003; Reynaud *et al.*, 2003; Schneider and Erez, 2006; Marubini *et al.*, 2008) or slightly increased (e.g. Langdon and Atkinson, 2005) at the level of CO_2 expected in 2100."

In a study designed to explore what controls calcification in corals, Sandeman (2012) suspended—by means of a torsion microbalance (as per Kesling and Crafts, 1962)—small pieces of coral he carefully removed from the edges of thin plates of *Agaricia agaricites* corals and lowered into gently stirred temperature-controlled seawater, after which he used the microbalance to measure coral net calcification rates over a range of seawater temperature and pH. He reported calcification rates of live *A. agaricites* coral increased by 15–17.7% per °C as seawater temperature rose from 27 to 29.5°C, and in his experiments in which the pH of the seawater was reduced from an average of 8.2 to 7.6, he observed calcification in living corals increased significantly. Similar experiments conducted with small portions of dead coral skeleton revealed "when the average pH was reduced from 8.2 to 7.5, calcification rate decreased." He determined the difference between calcification rates in going from seawater of pH 8.2 to seawater of pH 7.8 ranged from +30% for coral with no dead areas to –21.5% for coral with 30% dead exposed surface area.

The Trent University researcher from Peter-borough, Ontario (Canada) says his findings suggest lower seawater pH due to atmospheric CO_2 enrichment and increased temperature (but short of reaching the bleaching level) "will both enhance active biotic calcification." He states the wide range of results between his and other scientists' studies of calcification rate and carbon dioxide "may be explainable in terms of the ratio of 'live' to 'dead' areas of coral," as is also suggested by the work of Rodolfo-Metalpa *et al.* (2011) and Ries (2011b), all of which leads him to conclude coral species that typically have smaller areas of exposed dead surface "may have a better chance of survival as pH levels drop."

Schoepf *et al.* (2013) note "since scleractinian corals are calcifying organisms that already live close

to their upper thermal tolerance limits, both ocean warming and acidification severely threaten their survival and role as reef ecosystem engineers." They observe "no studies to date have measured energy reserve pools (i.e., lipid, protein, and carbohydrate) together with calcification under ocean acidification conditions under different temperature scenarios." Schoepf *et al*. studied the single and interactive effects of *p*CO$_2$ (382, 607, and 741 ppm) and temperature (26.5 and 29.0°C) on coral calcification, energy reserves (i.e., lipid, protein, and carbohydrate), chlorophyll *a,* and endosymbiont concentrations in four species of Pacific coral having different growth morphologies (*Acropora millepora, Pocillopora damicornis, Montipora monasteriata,* and *Turbinaria reniformis*).

The 13 researchers found coral energy reserves were largely *not* metabolized "in order to sustain calcification under elevated *p*CO$_2$ and temperature," as "maintenance of energy reserves has been shown to be associated with higher resistance to coral bleaching and to promote recovery from bleaching (Rodrigues and Grottoli, 2007; Anthony *et al*., 2009)." They report lipid concentrations increased under lower ocean pH levels conditions in both *A. millepora* and *P. damicornis* and "were fully maintained in *M. monasteriata* and *T. reniformis*." Protein, carbohydrate, and tissue biomass also were "overall maintained under ocean acidification conditions in all species." Thus "only one of the four corals species studied [*Acropora millepora*] decreased calcification in response to average ocean acidification levels expected by the second half of this century (741 ppm), even when combined with elevated temperature (+2.5°C)."

Schoepf *et al*. conclude "some corals could be more resistant to combined ocean acidification and warming expected by the end of this century than previously thought," so "the immediate effects of rising seawater temperature and ocean acidification may be tolerable for some species," possibly because the increased availability of CO$_{2(aq)}$ under lower ocean pH levels conditions may enhance algal productivity, especially in *Symbiodinium* phylotypes with less efficient carbon-concentrating mechanisms that rely to a greater extent on the passive, diffusive uptake of CO$_{2(aq)}$ and its fertilization effect, citing Herfort *et al*. (2008) and Brading *et al*. (2011).

6.5.2.1.4 Field Studies

Several field studies have focused on the combined effects of lower ocean pH levels and higher temperatures. The key findings of these studies are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- Over the period 1937–1996, *Montastraea faveolata* colonies located in the upper Florida Keys maintained rates of extension and calcification in spite of the combination of local environmental and climatic changes.

- A nearly three-century-long history of coral calcification in the South China Sea reveals an 11% increase between 1716 and 2005.

- Between 1900 and 2010, increases in *Porites* coral calcification on reefs in the southeast Indian Ocean ranged from small, non-significant positive trends, to increases as high as 23% per decade. In these regions, "the rate of change in the thermal environment of coral reefs is currently the primary driver of change in coral calcification rates," and "the large-scale phenomenon of ocean acidification is not currently limiting calcification on coral reefs uniformly at a global scale."

- Flexibility in community composition observed along latitudinal environmental gradients across the Great Barrier Reef "indicates that climate change is likely to result in a re-assortment of coral reef taxa rather than wholesale loss of entire reef ecosystems."

According to Cantin *et al*. (2009), "zooxanthellae (symbiotic dinoflagellates of the genus *Symbiodinium*) are critical to the survival of reef-building corals, providing a major source of energy from photosynthesis for cell maintenance, growth and reproduction of their coral hosts," and these services include the energetically expensive process of calcification (Idso *et al*., 2000). Cantin *et al*. studied the amount of photosynthetic "rent" paid by two clades of *Symbiodinium* (C1 and D) to their coral hosts (juvenile *Acropora millepora*) for the privilege of living within the latter's calcareous "houses." This was done by measuring the "financial transfer" to nine-month-old corals developed "from crosses involving the same parent corals." This "planned

parenthood" minimized any host genetic differences that otherwise might have influenced the physiology of the host-symbiont "lease agreement."

They found "*Symbiodinium* C1 exhibited a 121% greater capacity for translocation of photosynthate to *A. millepora* juveniles along with 87% greater relative electron transport through photosystem II under identical environmental conditions." In addition, the five researchers note "*A. tenuis* and *A. millepora* juveniles in a previous study exhibited 2 to 3 times faster growth rates when associated with *Symbiodinium* C1 compared to those associated with *Symbiodinium* D (Little *et al*., 2004) at the same field site where juveniles were reared in the present study."

Cantin *et al*. conclude "the differences in carbon-based energy transfer between symbiont types may provide a competitive advantage to corals associating with *Symbiodinium* C1, particularly during their early life histories, when greater energy investment into rapid tissue and skeletal growth can prevent overgrowth of juveniles by competitors and mortality from grazers." They write, "as the community structure of coral reefs shift in response to global climate change and water quality impacts, opportunistic corals harboring symbionts that enable maximum rates of growth may similarly gain a competitive advantage." Consequently, in the economy of nature ample provision evidently has been made for corals to weather all sorts of environmental challenges that may come their way, including those IPCC contends will be driven by rising atmospheric CO_2 concentrations.

In studying coral calcification rates on Australia's Great Barrier Reef, De'ath *et al*. (2009) report there was a 14% drop in *Porites* calcification rate from 1990 to 2005 (although a graphical view of their data indicates the decline began around 1970) and this decline "is unprecedented in at least the past 400 years," which is indeed what their data show. Such statements, however, do not reveal the full story.

If, for example, their calcification history is followed back in time a mere 33 more years, from 1605 to 1572—when the air's CO_2 concentration was more than 100 ppm less than it is today and, therefore, was supposedly so much healthier for corals (according to the ocean "acidification" hypothesis)—it shows the coral calcification rate at that earlier time was approximately 21% lower than it was at its twentieth century peak.

Another way of looking at De'ath *et al*.'s data is to realize that from 1572 to 1970, *Porites* calcification rates on the Great Barrier Reef increased by about 27% as the atmospheric CO_2 concentration and air

temperature rose concurrently. After 1970, calcification rates declined, but by a much smaller 14%, even as air temperature and CO_2 concentrations continued to increase, further obscuring the issue. De'ath *et al*. note, "the causes for the [1990 to 2005] Great Barrier Reef-wide decline in coral calcification of massive *Porites* remain unknown."

Three years later, the work of another research team provided a possible answer. Uthicke *et al*. (2012) state, "tropical coral reefs are currently under threat by a variety of regional and global stressors," with examples of the former being "land runoff and overfishing (e.g., Pandolfi *et al*., 2003; Fabricius, 2005)," and examples of the latter "sea temperature increase and ocean acidification (Hoegh-Guldberg *et al*., 2007; Fabricius *et al*., 2011)." To determine which set of stressors is the most significant threat, Uthicke *et al*. analyzed sediment cores collected from inshore fringing coral reefs in the Whitsunday area of the Great Barrier Reef (GBR) of Australia. They collected these cores from three locations: inner near-shore reefs with low coral cover and high macroalgal abundance, intermediate reefs, and reefs at outer islands with low algal and high coral cover. They chose these three locations because inner near-shore reefs are typically the first to produce evidence of regional human impacts; reefs at outer islands are the last to experience the negative effects of human influence, as well as the most likely to exhibit evidence of global stressors; and intermediate reefs often show evidence of both.

The three researchers report benthic foraminiferal assemblages found in the cores of outer-island reefs unaffected by increased land runoff have been "naturally highly persistent over long (>2000 years) timescales." In both of the other zones, assemblages were also persistent, but only until 150 years ago, and assemblages less than 55 years old from inner near-shore and intermediate reefs were significantly different from older assemblages.

Uthicke *et al*. conclude they found support for the likelihood "increased land runoff since the start of land clearing and agriculture in the catchment of the Whitsunday Region of the GBR has left a signature in the foraminiferal assemblages of inner and inter-mediate areas of the study area," when previously the assemblages of these areas had been "persistent for at least several thousand years." In addition, and based on the fact "no changes were observed on outer reefs located away from land runoff," they propose "changes observed on inner and intermediate reefs were mainly driven by enhanced agricultural runoff after European settlement." And finally, they affirm

"the hypothesis that global forcing, such as sea temperature increase or ocean acidification, altered the foraminiferal community found little support."

Browne (2012) writes "local stressors erode reef resilience, and therefore increase their vulnerability to global stressors that include ocean warming, [which is] predicted to increase the severity and intensity of coral bleaching events (Hoegh-Guldberg, 1999), ocean acidification, [which is] predicted to reduce calcification rates and reef growth (Kleypas *et al.*, 1999), and increased storm and cyclone activity, [which is] predicted to reduce coral framework complexity and stability (Puotinen, 2004)." In a study designed to assess the overall impact of these several reef stressors, Browne describes how "coral growth rates (linear extension, density, calcification rates) of three fast-growing corals (*Acropora*, *Montipora*, *Turbinaria*) were studied *in situ* on Middle Reef, an inshore reef located on the central Great Barrier Reef (GBR)," in order to "assess the influence of changing environmental conditions on coral condition and reef growth."

Browne found "despite local anthropogenic pressures and global climate change, Middle Reef has a robust and resilient coral community," and "*Acropora* linear extension rates were comparable with rates observed at similar depths and sea surface temperatures on mid to offshore reefs on the GBR, and in the Caribbean." In addition, "*Montipora* and *Turbinaria* are abundant on inshore turbid reefs due to their adaptive capacities and are therefore an important source of carbonate for reef growth and development." Browne writes, "*Montipora* linear extension was greater than current estimates available, and *Turbinaria*, although characterized by slow linear extension, had a dense skeleton and hence may be more resilient to physical damage as ocean pH falls." Although both species "may be more susceptible during the warmer months due to multiple stressors, they were able to rapidly recover during the cooler months," Browne writes. "In summary," Browne concludes, "corals on Middle Reef are robust and resilient to their marginal environmental conditions."

Helmle *et al.* (2011) collected coral cores in May 1997 and June 1998 from seven *Montastraea faveolata* colonies located in the upper Florida Keys (USA), where they "were drilled at the location of maximum vertical growth of the colony." The scientists constructed chronologies from the annual density bands found in the cores and determined all of them had a 60-year common period from 1937 to 1996. For these cores the scientists obtained and

analyzed annual extension, density, and calcification rates, to see how they varied over this period of intensifying warming and acidification of the global ocean.

The five U.S. scientists report their data show "no evidence of significant age effects" over the 1937–1996 period for extension, density, or calcification. Helmle *et al.* say their findings demonstrate "the measured corals have historically been able to maintain rates of extension and calcification over the 60-year period from 1937 to 1996 under the combination of local environmental and climatic changes." They also note calcification rates were positively related to sea surface temperature, "similar to results for *Porites* corals from Tahiti (Bessat and Buigues, 2001) and the Great Barrier Reef (Lough and Barnes, 1997)," but they say the Florida results explained only about 7% of the annual calcification variability as opposed to ~30% at the Pacific locations.

As for why the Florida Keys corals have fared so well, Helmle *et al.* suggest the answer could be "massive reef-building corals are not as susceptible to declines in Ω_{arag} [aragonite saturation state] as demonstrated by laboratory experiments; local processes, such as high seasonal variation in Ω_{arag} in the Florida Keys, may be temporarily enabling these corals to maintain their historical rates of calcification; the role of Ω_{arag} in controlling calcification is masked amidst considerable natural inter-annual variability; or the actual *in situ* reef-site carbonate chemistry is decoupled from the oceanic values, which could occur as a result of shifts in benthic community metabolism, mineral buffering and/or coastal biogeochemical processes."

Shi *et al.* (2012) state "rising atmospheric CO_2 and global warming are regarded as fatal threats to coral reefs," noting "IPCC has reported that by the end of this century, coral reefs will be the first ecological system that will become extinct," citing Wilkinson (2004). They write, "others contend that rising seawater temperature is conducive to enhanced coral calcification, and increased calcification will be higher than the decline caused by rising CO_2," so "coral calcification will increase by about 35% beyond pre-industrial levels by 2100, and no extinction of coral reefs will occur in the future," citing McNeil *et al.* (2004).

In late May of 2004 and 2007 Shi *et al.* extracted core samples of coral skeletons from several massive live and dead *Porites lutea* colonies comprising part of the Meiji Reef in the southern South China Sea, after which they analyzed their skeletal calcification

rates by means of X-ray photography, which enabled them to construct a nearly three-century-long history of coral calcification rate for the period 1716–2005. The results of the six scientists' efforts are depicted in Figure 6.5.2.1.3.1.

As best as can be determined from the Chinese scientists' graph, over the period of time depicted—when IPCC claims the world warmed at a rate unprecedented over the past millennium or two, and when the atmosphere's CO_2 concentration rose to values not seen for millions of years—the two "fatal threats to coral reefs," even acting together, did not prevent coral calcification rates on Meiji Reef from rising by about 11% over the past three centuries.
Figure 6.5.2.1.3.1. The long-term history of coral calcification rate on Meiji Reef. Adapted from Shi *et al.* (2012).

Cooper *et al.* (2012) studied coral reefs spanning an 11° latitudinal range in the southeast Indian Ocean, collecting 27 long cores from massive *Porites* coral colonies at six locations covering a north-south distance of about 1,000 km off the coast of Western Australia. From these cores they developed 1900–2010 histories of "annual extension (linear distance between adjacent density minima, cm/year), skeletal density (g/cm³), and calcification rate (the product of skeletal density and annual extension, g/cm²/year)," based on gamma densitometry data.

Cooper *et al.* report calcification rates at the Houtman Abrolhos Islands, where a relatively large sea surface temperature (SST) increase had occurred (0.10°C/decade), rose by 23.5%, and at Coral Bay and Tantabiddi, SST increases of 0.8 and 0.6°C/decade were associated with 8.7 and 4.9% increases in decadal calcification rates, respectively. They found smaller and non-significant positive trends in

calcification rates at Clerke and Imperieuse Reefs, where the increase in SST was only 0.2°C/decade.

The three Australian researchers say their latter non-significant findings are consistent with those of Helmle *et al.* (2011), who they say "found a similar non-correlation for the massive coral *Montastraea faveolata* in the Florida Keys between 1937 and 1996, when there was no significant SST warming." Regarding the large increases in calcification rates they documented at the rapidly warming Houtman Abrolhos Islands, they write, "Lough and Barnes (2000) documented a similar positive correlation, suggesting that calcification rates may, at least initially, increase with global warming." They conclude "the rate of change in the thermal environment of coral reefs is currently the primary driver of change in coral calcification rates," driving them ever-higher as temperatures continue to rise, and "the large-scale phenomenon of ocean acidification is not currently limiting calcification on coral reefs uniformly at a global scale."

Hughes *et al.* (2012) note, "contemporary research on how climate change affects coral reefs has matured beyond the simplistic 'canary in the coal mine' concept to a more nuanced recognition that climate-related pressures such as bleaching (due to the loss of symbiotic zooxanthellae) and ocean acidification do not affect all species equally." And "in this context," they note, "a critical issue for the future status of reefs will be their ability to maintain functional capacity in the face of the changes in species composition that are already underway due to multiple anthropogenic impacts."

Hughes *et al.* applied a "rigorous quantitative approach to examine large-scale spatial variation in the species composition and abundance of corals on mid-shelf reefs along the length of Australia's Great Barrier Reef, a biogeographic region where species richness is high and relatively homogeneous." They used "a hierarchical, nested sampling design to quantify scale-dependent patterns of coral abundances [for] five regions of the Great Barrier Reef [they] sampled from north to south, each 250–500 km apart." They thus identified and measured a total of 35,428 coral colonies on 33 reefs, categorizing each colony they encountered (including the majority of species that are too rare to analyze individually) into "ecologically relevant groups depending on their physiology, morphology and life history."

The seven scientists report the diverse pool of species they examined along the latitudinal gradient of the Great Barrier Reef "can assemble in markedly different configurations across a wide range of

contemporary environments." Regarding temperature, for example, they indicate "the geographic ranges of 93% of the 416 coral species found on the Great Barrier Reef extend northwards toward the equator (e.g., to Papua New Guinea, the Solomon Islands, and/or the Indonesian archipelago)," whereas "46% are also found in colder conditions further to the south." As for lower ocean pH levels, they write, "globally, ocean surface pH has decreased by 0.1 unit since 1750 due to the uptake of atmospheric CO_2, with a smaller 0.06 decline recorded for the tropics," citing Kleypas *et al*. (2006). In contrast, they report contemporary variation in pH among various reef habitats on the Great Barrier Reef, as well as differences among short-term replicate measurements, span a range of 0.39 unit, from 8.37 to 7.98, citing Gagliano *et al*. (2010). And they note this short-term and habitat-scale variability literally swamps that of latitudinal trends.

Hughes *et al*. say their real-world observations "all point to a surprisingly resilient response by some elements of coral assemblages to spatial and temporal shifts in climatic conditions." They conclude, "the flexibility in community composition that we document along latitudinal environmental gradients indicates that climate change is likely to result in a re-assortment of coral reef taxa rather than wholesale loss of entire reef ecosystems." This clearly deflates the catastrophic prognostications put forth by IPCC with regard to the future of the planet's corals.

6.5.2.2 Echinoderms

This section examines what scientists have learned from studies focusing on the impacts of higher temperatures and lower seawater pH levels on echinoderms. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- The relative growth of juvenile sea stars increased linearly with temperature from 5°C to 21°C, while also responding positively to atmospheric CO_2 enrichment.

- Serpent starfish were able to successfully cope with the physiological changes brought about by a modest temperature increase and/or pH decline.

- The intertidal seastar *Parvulastra exigua* was shown to be resilient to elevated temperature and reduced pH, and "may possess scope for adaptation (evolutionary change) and/or acclimation via phenotypic plasticity" to withstand future changes in temperature and pH.

- The negative effects of a 0.35 to 0.55 CO_2-induced decline in seawater pH on the growth and calcification of the sea urchin *Tripneustes gratilla* can be largely overcome by an accompanying 3°C increase in water temperature.

- No significant effect of ocean warming and lower seawater pH levels on the percentage of egg fertilization in four intertidal and shallow subtidal echinoids was found, possibly reflecting adaptation to the large temperature and pH fluctuations that characterize their shallow water coastal habitats.

- In a combined pH decline/temperature increase study on the sea urchin *Psammechinus miliaris*, it was determined "current ocean pH levels are suboptimal for *P. miliaris* sperm-swimming speed and that reproductive success for certain marine species may benefit from a reduced pH ocean."

- Fertilization and embryonic development of the ecologically important sea urchin *Sterechinus neumayeri* to the blastula stage was "robust to levels of temperature and pH change predicted over coming decades."

- The ecologically important sea urchin *Centrostephanus rodgersii* displays a genetic variation in tolerance affirming its ability to successfully adapt to ocean warming and falling ocean pH levels..

Gooding *et al.* (2009) measured growth and feeding rates of juvenile sea stars (*Pisaster ochraceus*) maintained in 246-liter aquaria filled with recirculating natural seawater maintained at temperatures ranging from 5 to 21°C and constantly bubbled with ambient air of 380 ppm CO_2 or CO_2-enriched air of 780 ppm CO_2. They found "the relative growth (change in wet mass/initial wet mass) of juvenile *P. ochraceus* increased linearly with temperature from

5°C to 21°C," and it also responded positively to atmospheric CO_2 enrichment. The authors state "relative to control treatments, high CO_2 alone increased relative growth by ~67% over 10 weeks, while a 3°C increase in temperature alone increased relative growth by 110%." They also state increased CO_2 "had a positive but non-significant effect on sea star feeding rates, suggesting CO_2 may be acting directly at the physiological level to increase growth rates." Their data show the percentage of calcified mass in the sea stars dropped from approximately 12% to 11% in response to atmospheric CO_2 enrichment at 12°C, but it did not decline further in response to a subsequent 3°C warming at either ambient or elevated CO_2. The three Canadian researchers say their findings demonstrate "increased CO_2 will not have direct negative effects on all marine invertebrates, suggesting that predictions of biotic responses to climate should consider how different types of organisms will respond to changing climatic variables." They state, "responses to anthropogenic climate change, including ocean acidification, will not always be negative."

Wood *et al*. (2010) studied the serpent starfish (*Ophiura ophiura*), collecting 96 individuals with a disc diameter between 10 and 15 mm from Cawsand Bay, Plymouth Sound (50°09.77' N, 4°11.50' W). They exposed the brittlestars to three pH treatments (pH of 8.0, 7.7, or 7.3) and two temperature treatments (10.5°C or 15°C) for 40 days. They measured metabolism, calcification, mortality, motility, arm structure, and arm regeneration; the latter parameter was studied by removing either 10, 20, 30, or 40 mm of arm length on one of the animals' arms.

The researchers found survival was "100% at both temperatures and across all pH treatments"; metabolic rate increased as pH decreased in the low temperature treatment, but there was no significant difference across the different pH treatments in the high temperature regime; muscle appearance and density did not change over either the temperature or pH treatment ranges in established or regenerated arms; and a faster response time in movement (motility) was observed at low temperature and low pH. They also found brittlestars across "all treatments had the same net calcification throughout the experiment"; arm regeneration rate within the low temperature treatment was "unaffected by the length of arm lost and the rate was similar between all pH treatments"; and arm regeneration rate was significantly faster at higher temperatures than lower temperatures. Taken as a whole, the findings indicate the serpent starfish should be able to cope

successfully with the physiological changes brought about by any modest temperature increase and/or pH decline likely to occur in the future.

McElroy *et al*. (2012) measured the metabolic rates of adult specimens of the intertidal seastar *Parvulastra exigua* collected from Little Bay, Sydney (Australia) at conditions characteristic of high tide (ca. 18°C and pH 8.2), as well as at 3 and 6°C warmer conditions and at additional pH values of 7.8 and 7.6 "in all combinations." The measurements revealed "the metabolic response of *P. exigua* to increased temperature (+3°C and +6°C) at control pH [8.2] indicates that this species is resilient to periods of warming as probably often currently experienced by this species in the field." They also report they "did not observe a negative effect of acidification on rate of oxygen consumption at control temperature, a combination of stressors that this species currently experiences at night time low tide."

Although the metabolic response of *P. exigua* is resilient to current levels of extreme temperature and pH stress—which are equivalent to mean conditions predicted for the end of the twenty-first century—it is possible the extreme seawater temperatures and pH levels at that future time (if IPCC predictions prove true) will be greater than the extreme levels of today, which could prove to be a real challenge for the seastars. McElroy *et al*. point out, in the concluding paragraph of their report, "species such as *P. exigua* with a broad distribution from warm to cold temperate latitudes may possess scope for adaptation (evolutionary change) and/or acclimation via phenotypic plasticity (Visser, 2008), as suggested for sympatric echinoid and ophiuroid species (Byrne *et al*., 2011; Christensen *et al*., 2011)."

Brennand *et al*. (2010) reared embryos of the sea urchin *Tripneustes gratilla* in flow-through chambers filled with filtered seawater maintained at all combinations of three temperatures (24, 27, and 30°C) and three pH values (8.15, 7.8, and 7.6), where the 24°C/pH 8.15 combination represented normal control conditions. After five days of such exposure, they assessed the growth and development of the larvae.

Brennand *et al*. found "larvae reared at pH 7.6 and pH 7.8 had smaller post oral arms when compared with those reared at control pH." However, they report, "a +3°C warming diminished the negative effects of low pH/high CO_2," as was "seen in the similar post oral arm length of larvae treated at 27°C/pH 7.6 and 27°C/pH 7.8 and those reared in control temperature and pH." In addition, "as total length of calcite rods is largely comprised of the post

oral arms, this measure [of calcification] followed a similar pattern."

The results of this study suggest the negative effects of a 0.35 to 0.55 CO_2-induced decline in seawater pH on the growth and calcification of the sea urchin *Tripneustes gratilla* can be largely overcome by a 3°C increase in water temperature. And since the projected maximum decline in seawater pH is somewhere in the range of 0.1 to 0.18 in the vicinity of AD 2100, there is little reason for concern about any negative impact of rising atmospheric CO_2 concentrations on this particular species of sea urchin, which is widely distributed throughout the Indo-Pacific region and well suited for production by aquaculture (Lawrence and Agatsuma, 2007; Juinio-Menez *et al*., 1998; Dworjanyn *et al*. 2007).

Byrne *et al*. (2009) investigated the effects of lower ocean pH levels (pH values of 8.2–7.6, corresponding to atmospheric CO_2 concentrations of 230–690 ppm) and seawater temperature (20–26°C, where 20°C represents the recent thermal history of indigenous adults) on the fertilization of sea urchin (*Heliocidaris erythrogramma*) eggs and their subsequent development in what they call "the eastern Australia climate change hot spot," located near Sydney.

According to the authors, over the ranges of seawater pH and temperature they studied, there was "no effect of pH" and "no interaction between temperature and pH" on sea urchin egg fertilization. Seawater pH also had no effect on the longer-term development of fertilized sea urchin eggs; but the six scientists say warming led to "developmental failure at the upper warming (+4 to +6°C) level, regardless of pH." Even here, however, they appear quite hopeful, stating "it is not known whether gametes from *H. erythrogramma* adults acclimated to 24°C would have successful development in a +4°C treatment," noting their study "highlights the potentiality that adaptive phenotypic plasticity may help buffer the negative effects of warming, as suggested for corals." They write, "single stressor studies of thermotolerance in a diverse suite of tropical and temperate sea urchins show that fertilization and early development are robust to temperature well above ambient and the increases expected from climate change," citing Farmanfarmaian and Giese (1963), Chen and Chen (1992), and Roller and Stickle (1993).

Byrne *et al*. (2010a) examined the interactive effects of near-future (ca. AD 2070–2100) ocean warming (temperature increases of 2–6°C) and lower ocean pH levels (pH reductions of 0.2–0.6) on fertilization in four intertidal and shallow subtidal echinoids (*Heliocidaris erythrogramma, Heliocidaris Tuberculata, Tripneustes gratilla, Centrostephanus rodgersii*), an asteroid (*Patiriella regularis*), and an abalone (*Haliotis coccoradiata*), working with batches of eggs they collected from multiple females fertilized by sperm obtained from multiple males, all of which species were maintained in all combinations of three temperature and three pH treatments.

The eight researchers found "no significant effect of warming and acidification on the percentage of fertilization." Byrne *et al*. say their results indicate "fertilization in these species is robust to temperature and pH/PCO_2 fluctuation," and their findings "may reflect adaptation to the marked fluctuation in temperature and pH that characterizes their shallow water coastal habitats."

Byrne *et al*. (2010b) investigated the effects of projected near-future oceanic warming and acidification of the sea urchin *Heliocidaris erythrogramma* for conditions predicted for southeast Australia within the timeframe of 2070–2100: an increase in sea surface temperature of 2 to 4°C and a decline in pH of 0.2 to 0.4. Byrne *et al.* conducted multifactorial experiments that incorporated a titration of sperm density ($10–10^3$ sperm per ml) across a range of sperm-to-egg ratios (10:1–1500:1). They found "across all treatments there was a highly significant effect of sperm density, but no significant effect of temperature or interaction between factors." They state "low pH did not reduce the percentage of fertilization even at the lowest sperm densities used, and increased temperature did not enhance fertilization at any sperm density." They write, "a number of ecotoxicology and climate change studies, where pH was manipulated with CO_2 gas, show that sea urchin fertilization is robust to a broad pH range with impairment only at extreme levels well below projections for ocean acidification by 2100 (pH 7.1–7.4, 2,000–10,000 ppm CO_2)," citing Bay *et al*. (1993), Carr *et al*. (2006), and Kurihara and Shirayama (2004). Because neither seawater warming nor seawater acidification (caused by contact with CO_2-enriched air) had either a positive or a negative effect on sea urchin fertilization, the five scientists conclude "sea urchin fertilization is robust to climate change stressors."

According to Caldwell *et al*. (2011), "the reproductive processes and early life-stages of both calcifying and non-calcifying animals are believed to be particularly vulnerable to a reduced pH environment," but "there is as yet no clear and reliable predictor for the impacts of ocean acidification on marine animal reproduction." Caldwell *et al*. "investigated the combined effect of

pH (8.06–7.67) and temperature (14–20°C) on percent sperm motility and swimming speed in the sea urchin *Psammechinus miliaris* using computer assisted sperm analysis (CASA)," working with specimens they collected from the Isle of Cumbrae (Scotland). "Surprisingly," the six scientists write, "sperm swimming performance benefited greatly from a reduced pH environment," as "both percent motility and swimming speeds were significantly enhanced at pHs below current levels." In light of the additional fact that sperm-activating peptides—which are believed to have evolved some 70 million years ago during a period of high atmospheric CO_2 concentration—are fully functional from pH 6.6 to 8.0 (Hirohashi and Vacquier, 2002), they state "the combined data on motility, swimming speed and SAP function at reduced pH indicates that sperm are sufficiently robust to allow functionality at pHs that would have been experienced in the paleo-ocean (*ca* pH 7.4–7.6) and which are within projections for near-future climate change scenarios." The UK researchers conclude "current ocean pH levels are suboptimal for *P. miliaris* sperm-swimming speed and … reproductive success for certain marine species may benefit from a reduced pH ocean."

Ericson *et al*. (2012) "examined the interactive effects of warming and acidification on fertilization and embryonic development of the ecologically important sea urchin *Sterechinus neumayeri* reared from fertilization in elevated temperature (+1.5°C and 3°C) and decreased pH (–0.3 and –0.5 pH units)." They found "fertilization using gametes from multiple males and females, to represent populations of spawners, was resilient to acidification at ambient temperature (0°C)," and development to the blastula stage was "robust to levels of temperature and pH change predicted over coming decades." The sea urchins the seven scientists studied thus appear well-equipped to deal with IPCC-predicted near-future increases in seawater temperature and acidification.

Ho *et al*. (2013) report, "the impact of increased temperature (2–4°C above ambient) and decreased pH (0.2–0.4 pH units below ambient) on fertilization in the Antarctic echinoid *Sterechinus neumayeri* across a range of sperm concentrations was investigated in cross-factorial experiments," where "gametes from multiple males and females in replicate experiments were used to reflect the multiple spawner scenario in nature." They examined this species because "polar marine organisms are among the most stenothermal in the world due to the stability of their environment over evolutionary time (Clarke, 1983)," which suggests they may be "sensitive to the slightest of environmental perturbations, particularly [in] early life history stages (Barnes and Peck, 2008)."

The five researchers' work confirmed "the importance of considering both ocean warming and acidification," and they note "decreased pH did not affect fertilization." Warming, however, "enhanced fertilization ... likely through stimulation of sperm motility and reduced water viscosity." In the concluding sentence of their paper's abstract, Ho *et al*. state their results indicate "fertilization in *S. neumayeri*, even at low sperm levels potentially found in nature, is resilient to near-future ocean warming and acidification."

Foo *et al*. (2012) write, "selection by stressful conditions will only result in adaptation if [1] variation in stress tolerance exists within a population, if [2] tolerance of stressors is heritable, and if [3] changes in tolerance traits are not constrained by negative genetic correlations with other fitness traits," citing references both old and recent: Darwin (1859) and Blows and Hoffmann (2005).

Foo *et al*. "quantified genetic variation in tolerance of early development of the ecologically important sea urchin *Centrostephanus rodgersii* to near-future (2100) ocean conditions projected for the southeast Australian global change hot spot," in which "multiple dam-sire crosses were used to quantify the interactive effects of warming (+2–4°C) and acidification (–0.3–0.5 pH units) across twenty-seven family lines" of the species. The four Australian researchers report, "significant genotype by environment interactions for both stressors [warming and acidification] at gastrulation indicated the presence of heritable variation in thermal tolerance and the ability of embryos to respond to changing environments." They say "positive genetic correlations for gastrulation indicated that genotypes that did well at lower pH also did well in higher temperatures." Thus, Foo *et al*. conclude "the presence of tolerant genotypes, and the lack of a trade-off between tolerance to pH and tolerance to warming contribute to the potential of *C. rodgersii* to adapt to concurrent ocean warming and acidification, adding to the resilience of this ecologically important species in a changing ocean."

6.5.2.3 Other Marine Species

This section examines what scientists have learned in studies , focusing on the impacts of changing seawater temperature and pH levels on marine species not discussed in prior sections. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- A high tolerance to pH decline and rising temperature was observed during the larval growth stage of the Portuguese oyster.

- The often complex and severe spatial and temporal variability of environmental conditions in coastal ecosystems suggests organisms living there are preconditioned to be tolerant of lower ocean pH levels and warming.

- There is no evidence that predator-prey interactions among green crabs and periwinkles will change in the future under lower ocean pH levels and warming.

- Analyses of tube mineralogy, ultrastructure, and mechanical properties of the serpulid tubeworm *Hydroides elegans* reveal "predicted coastal warming may not hinder *H. elegans* ability to build normal tubes even in the face of projected near-future decreases in pH or salinity."

- Norway lobster (*Nephrops norvegicus*) "would benefit from global warming and be able to

withstand the predicted decrease in ocean pH in the next century during their earliest life stages."

- Baltic cod (*Gadus morhua*), which live in sea waters naturally high in pCO_2 "may be adapted to conditions predicted in ocean acidification scenarios for centuries to come," as "no effect on hatching, survival, development, and otolith size was found at any stage in the development of Baltic cod" under projected future ocean pH levels and temperature scenarios.

- Polyps of the moon jellyfish have been shown to be tolerant of low pH and warmer temperatures, surviving and reproducing asexually. Yet analyses of "all available long-term datasets on changes in jellyfish abundance across multiple coastal stations" reveal there is no compelling evidence to support the view that the global abundance of jellyfish is increasing as a result of lower ocean pH levels and warming.

- Lower ocean pH levels and temperature increases were found to negatively impact the growth and survival of juvenile anemone fish. The negative effects were absent or reversed when the parents of the juveniles also experienced lower ocean pH levels and warming, revealing "conditions experienced by adults can have significant carry-over effects on the performance of their offspring … leading to improved capacity to cope with environmental stress."

- In a study of copepods, "higher production temperature induced a positive maternal effect resulting in faster hatching and indicating that the mothers can invest more in their eggs, and therefore produce better quality eggs."

Thiyagarajan and Ko (2012) conducted a number of laboratory studies designed to see how the larval growth stage of the Portuguese oyster responds to various "climate change stressors," investigating the effects of low pH (7.9, 7.6, 7.4) at ambient salinity (34 ppt) and low salinity (27 ppt), while "the combined effect of pH (8.1, 7.6), salinity (24 and 34 ppt) and temperature (24°C and 30°C) was examined using factorial experimental design." The two researchers write, "surprisingly, the early growth phase from hatching to 5-day-old veliger stage showed high tolerance to pH 7.9 and pH 7.6 at both 34 ppt and 27 ppt," and "larval shell area was significantly smaller at pH 7.4 only in low-salinity."

In the three-factor experiment (see Figure 6.5.2.3.1), they observed "shell area was affected by salinity and the interaction between salinity and temperature but not by other combinations." They also discovered "larvae produced the largest shell at the elevated temperature in low-salinity, regardless of pH."
Figure 6.5.2.3.1. Mean shell area of the Portuguese oyster larvae exposed to a low-pH or elevated carbon dioxide treatment for five days at two levels of salinity (ambient and low-salinity) and temperature (ambient and elevated). Each bar represents the mean ± S.D. of four replicate cultures. Adapted from Thiyagarajan and Ko (2012).

Thiyagarajan and Ko conclude "the growth of the Portuguese oyster larvae appears to be robust to near-future pH level (>7.6) when combined with projected elevated temperature and low-salinity in the coastal aquaculture zones of [the] South China Sea."

Pansch *et al*. (2012) note to date "most studies have focused on ocean acidification (OA) effects in fully marine environments, while little attention has been devoted to more variable coastal ecosystems, such as the Western Baltic Sea." Since "natural spatial and temporal variability of environmental conditions such as salinity, temperature or CO_2 impose more complex stresses upon organisms inhabiting these habitats, species [living there] can be expected to be more tolerant to OA (or warming) than fully marine taxa."

Pansch *et al*. acquired data on the variability of temperature and pH within the inner Kiel Fjord of Schleswig-Holstein, Germany, and on "the responses of the barnacle *Amphibalanus improvisus* from this habitat to simulated warming and OA during its early development." They exposed *A. improvisus* nauplii

(the first larval stage of many crustaceans) and cyprids (the second larval stage of barnacles) to different temperatures (12, 20, and 27°C) and CO_2 (nominally 400, 1,250, and 3,250 ppm) treatments for eight and four weeks, respectively," while "survival, larval duration and settlement success were monitored."

The four researchers found a prolongation of the nauplius phase, which they acknowledge could "lead to a mismatch of the larvae with their phytoplankton prey." However, they note the predicted increase in seawater temperature would likely "accelerate nauplii development and, thus, may buffer OA effects." Such results, they write, have been observed "in sea urchin larvae and oysters, where higher temperatures mitigated negative effects of OA," citing Brennand *et al*. (2010) and Waldbusser *et al*. (2011). In their own study, however, they found just the opposite, saying "warming negatively impacted cyprid survival" but "OA counteracted these negative effects."

"It should also be stressed," they continue, "that only the most severe OA level applied herein (3,250 ppm CO_2) had occasional effects, whereas the OA conditions as predicted by the end of this century (1,250 ppm CO_2) in most cases did not affect *A. improvisus* larvae." In addition, and "interestingly," they report, "the major release of larvae and thus, development, settlement and first intense calcification in *A. improvisus* occurs during early summer when pH is lowest." They add, "*A. improvisus* is also found in stands of the brown macroalga *Fucus* spp. where 2,500 ppm CO_2 (pH 7.4) can be measured," and they note "another barnacle species, *Chthamalus stellatus*, was shown to survive and grow at extremely low mean pH of 6.6 in the vicinity of volcanic CO_2 vents in Ischia, Italy (Hall-Spencer *et al*., 2008)."

Pansch *et al*. write, "given their present wide tolerance and the possibility to adapt to shifting environmental conditions over many generations, barnacles (*A. improvisus*) from the Western Baltic Sea might be able to overcome OA as predicted by the end of this century." And, "supporting this," they note Parker *et al*. (2011) have shown "selectively bred lines of the estuarine oyster *Saccostrea glomerata* to be more resilient to OA than wild populations."

Pansch *et al*. (2013) again collected juvenile barnacles (*Amphibalanus improvisus*) from Kiel Fjord in the western Baltic Sea and distributed them to different temperature and pH treatment combinations in a laboratory setting: seawater of two temperatures (20 and 24°C) and three pH levels (mean pCO_2 values of 700, 1,000, and 2,140 µatm). They fed the barnacles a mix of two marine diatoms every other

day until day 24, after which they added specified amounts of brine shrimp until the end of the experiment, on day 62. The four German scientists observed "reduced growth rates as well as weakening of barnacle shells only under very high pCO_2 (>1930 µatm)." They state "even under these highly acidified conditions, and corroborating other recent investigations on barnacles (e.g., McDonald *et al*., 2009; Findlay *et al*., 2010a,b), these impacts were subtle and sub-lethal." And "furthermore," they write, "ocean warming as expected to occur in the future (IPCC, 2007) has the potential to mitigate the negative effects of ocean acidification (Brennand *et al*., 2010; Waldbusser, 2011; present study)." The findings of Pansch *et al*., as well as those of the other researchers they cite, indicate juvenile barnacles of the species they studied are already equipped to meet the challenges of a significantly warmed and acidified ocean should such challenges occur.

Landes and Zimmer (2012) state, "both ocean warming and acidification have been demonstrated to affect the growth, performance and reproductive success of calcifying invertebrates." However, they write, "relatively little is known regarding how such environmental change may affect interspecific interactions." They separately treated green crabs (*Carcinus maenas*, the predators) and periwinkles (*Littorina littorea*, their prey) under conditions that mimicked either ambient conditions (control) or warming and acidification (both separately and in combination), for five months, after which they assessed the predators, their prey, and the predator-prey interaction for CO_2- and warming-induced changes in response to the environmental perturbations imposed on them.

They found "acidification negatively affected the closer-muscle length of the crusher chela and correspondingly the claw-strength increment in *C. maenas*," and "the effects of warming and/or acidification on *L. littorea* were less consistent but indicated weaker shells in response to acidification." As might have been expected on the basis of these individual species responses to lower ocean pH levels and warming (weaker claw strength in the predator, but weaker shells in the prey), Landes and Zimmer say "on the community level," they "found no evidence that predator-prey interactions will change in the future."

Chan *et al*. (2013) write, "the majority of marine benthic invertebrates protect themselves from predators by producing calcareous tubes or shells that have remarkable mechanical strength," but "an elevation of CO_2 or a decrease in pH in the environment can reduce intracellular pH at the site of calcification and thus interfere with the animal's ability to accrete $CaCO_3$," which "may result in the animal producing severely damaged and mechanically weak tubes." They investigated how the interaction of environmental drivers affects the production of calcareous tubes by the serpulid tubeworm, *Hydroides elegans*, in a factorial manipulative experiment in which they analyzed the effects of pH (8.1 and 7.8), salinity (34 and 27%), and temperature (23 and 29°C) on the biomineral composition, ultrastructure, and mechanical properties of the tubeworm's tubes.

The five researchers report, "at an elevated temperature of 29°C, the tube calcite/aragonite ratio and Mg/Ca ratio were both increased, the Sr/Ca ratio was decreased, and the amorphous $CaCO_3$ content was reduced." And "notably," they emphasize, at elevated temperature with decreased pH and reduced salinity, "the constructed tubes had a more compact ultrastructure with enhanced hardness and elasticity compared to decreased pH at ambient temperature." Chan *et al*. conclude their "results from the analyses of tube mineralogy, ultrastructure and mechanical properties showed that predicted coastal warming may not hinder *H. elegans* ability to build normal tubes even in the face of projected near-future decreases in pH or salinity."

The Norway lobster (*Nephrops norvegicus*) is a decapod crustacean found on the continental shelf and slope throughout the northeastern Atlantic Ocean and the Mediterranean Sea. Styf *et al*. (2013) exposed berried Norway lobsters (females carrying fertilized eggs on the undersides of their abdomens) to four months of "the combination of six ecologically relevant temperatures (5–18°C) and reduced pH (by 0.4 units)," studying embryonic development of the species "by quantifying proxies for development rate and fitness including: % yolk consumption, mean heart rate, rate of oxygen consumption, and oxidative stress." The three Swedish scientists report "the rate of yolk consumption per day, as a measure of embryonic development rate, significantly increased with temperature," and lower pH "had no effect on development rate." They also found "pH had no effect on heart rate" and "there was no interaction between pH and temperature." Further, "there was no significant effect of temperature on oxidative stress when analyzed independent of embryonic age," but "there was a significantly higher level of oxidative stress in the control embryos compared with the embryos developed in low pH." They "observed no mortality nor abnormalities."

The three researchers conclude "this species

would benefit from global warming and be able to withstand the predicted decrease in ocean pH in the next century during their earliest life stages," a significant expression of optimism regarding a species considered the most important crustacean in all Europe (Nofima, 2012).

Winans and Purcell (2010) tested the ability of jellyfish to respond to changes in water temperature and pH during the early life stages. Polyps produced by medusae collected from the moon jellyfish (*Aurelia labiata*) in Dyes Inlet, Washington (USA) were arbitrarily assigned (18 each) to one of six treatments comprised of all combinations of two water temperatures (9 and 15°C) and three pH levels (7.2, 7.5 and 7.9), where they were allowed to develop under controlled conditions for 122 days. The researchers found "polyp survival was 100% after 122 days in seawater in all six temperature and pH combinations;" and because few polyps strobilated at 9°C and "temperature effects on budding were consistent with published results," they "did not analyze data from those three treatments further." At 15°C, there were also no significant effects of pH on the numbers of ephyrae or buds produced per polyp or on the numbers of statoliths per statocyst." However, they write, "statolith size was significantly smaller in ephyrae released from polyps reared at low pH."

Winans and Purcell conclude "*A. labiata* polyps are quite tolerant of low pH, surviving and reproducing asexually even at the lowest tested pH." Nevertheless, the authors note "the effects of small statoliths on ephyra fitness are unknown," which means the phenomenon could bode poorly for jellyfish. Winans and Purcell acknowledge many organisms "may be able to acclimate or adapt to slowly changing pH conditions." They report in Puget Sound "pH fluctuates from 7.2 to 9.6 in 2.4-meter deep water over the span of a couple of days," and "with such large pH fluctuations due to plant photosynthesis during the day and respiration at night, many organisms may be exposed to low pH conditions routinely."

That the findings of Winans and Purcell should not be considered as evidence of future jellyfish blooms is made clear by the study of Condon *et al*. (2013), who note there is "concern about the deterioration of the world's oceans," and that one line of evidence for this concern is "an increasing incidence of jellyfish blooms." They say this "perception," as they describe it, is "largely based on reports of increases in a few disparate regions (Condon *et al*., 2012)" and on "an analysis of media reports and perceptions of scientific experts and

fishers (Brotz *et al*., 2012)."

Condon *et al*. set out to analyze "all available long-term datasets on changes in jellyfish abundance across multiple coastal stations, using linear and logistic mixed models and effect-size analysis," in order "to test the null hypothesis that jellyfish population sizes and the occurrence of blooms have not significantly increased in the world's oceans."

The 22 researchers, from Argentina, Australia, Canada, Japan, Norway, Peru, Slovenia, Spain, the United Kingdom, and the United States, found "no robust evidence for a global increase in jellyfish." Although they acknowledge "there has been a small linear increase in jellyfish since the 1970s," they say "this trend was unsubstantiated by effect-size analysis that showed no difference in the proportion of increasing vs. decreasing jellyfish populations over all time periods examined." Instead, they report, "the strongest non-random trend indicated jellyfish populations undergo larger, worldwide oscillations with an approximate 20-year periodicity, including a rising phase during the 1990s that contributed to the perception of a global increase in jellyfish abundance." They conclude their research points normal "recurrent phases of rise and fall in jellyfish populations that society should be prepared to face."

Miller *et al*. (2012) note "a major limitation to predicting the effects of increasing [atmospheric] CO_2 concentrations on marine species and ecosystems is the lack of information on acclimation or adaptation to increased CO_2 over timescales relevant to climate change predictions," and "there is increasing evidence that the capacity for acclimation to environmental stress may depend on the history of previous life stages (Marshall and Morgan, 2011; Parker *et al*., 2012)."

Miller *et al*. conditioned adult anemone fish, *Amphiprion melanopus*, to present-day (430 ppm), moderate (581 ppm), and high (1,032 ppm) CO_2 treatments—"consistent with projections for CO_2 concentrations in the atmosphere and ocean over the next 50–100 years." They allowed the fish to spawn naturally, after which juvenile fish from control parents were reared at either the control CO_2 or transferred to high CO_2 at each of three temperatures (28.5, 30.0, and 31.5°C), while "juveniles from parents in the moderate- and high-CO_2 treatments were reared in similar CO_2 conditions as their parents at each of the three temperatures."

They found "ocean conditions projected for the end of the century (approximately 1,000 ppm CO_2 and a temperature rise of 1.5–3.0°C) cause an increase in metabolic rate and decreases in length,

weight, condition and survival of juvenile fish." But the five Australian researchers found "these effects are absent or reversed when parents also experience high CO_2 concentrations," indicating "conditions experienced by adults can have significant carry-over effects on the performance of their offspring (Bonduriansky and Day, 2009; Marshall and Morgan, 2011; Donelson *et al*., 2012), often leading to improved capacity to cope with environmental stress (Bernardo, 1996; Donelson *et al*., 2009)." Miller *et al*. conclude "parental effects prepare juveniles for similar conditions to those experienced in the parental generation," and, therefore, they suggest "non-genetic parental effects can dramatically alter the response of marine organisms to increasing CO_2 and demonstrate that some species have more capacity to acclimate to ocean acidification than previously thought."

Vehmaa *et al*. (2012) state "maternal effects are defined as cross-generation phenotypic plasticity, implying the capability of a mother to adjust the phenotype of her offspring [in] response to environmental cues that her offspring will encounter, in a manner that enhances offspring fitness (Parker and Begon, 1986; Lacey, 1998)," stating as an example, "Sydney rock oyster larvae are larger and develop faster in higher CO_2 conditions, if the adults also have been incubated in high CO_2 conditions (Parker *et al*., 2012)."

Vehmaa *et al*. "tested the reproductive response of *Acartia* sp. calanoid copepods and the importance of maternal effects in determining the offspring quality in a changing environment according to a 2100 climate scenario of a pH decline by 0.4 unit and a temperature elevation of 3°C." They monitored the egg production of copepods incubated in four pH and temperature conditions for five consecutive days, and on days one, three, and five they divided the eggs and allowed them to hatch in conditions either the same as or different from those in which they were produced.

The three Finnish researchers report, "higher production temperature induced a positive maternal effect resulting in faster hatching and indicating that the mothers can invest more in their eggs, and therefore produce better quality eggs." They note the similar studies of Karell *et al*. (2008) and Jonasdottir *et al*. (2009) showed how "the egg quality in terms of maternal immunological or nutritional provisioning improved," and they suggest this phenomenon may explain "the declining effect of pH difference on egg hatching." Vehmaa *et al*. conclude maternal effects "are an important mechanism in the face of environmental change."

Frommel *et al*. (2013) provide evidence for the adaptive capacity of fish to overcome the potential threat of lower ocean pH levels as well. In spite of its predicted detrimental effects on calcifying organisms, studies of possible impacts of ocean acidification [OA] on fish "remain scarce," the research team found. And although "adults will most likely remain relatively unaffected by changes in seawater pH," they state the "early life-history stages are potentially more sensitive, due to the lack of gills with specialized ion-regulatory mechanisms." They studied the egg and early larval stages of Baltic cod (*Gadus morhua*), which they describe as "the commercially most important fish stock in the Baltic Sea." They examined the effects of lower ocean pH levels on a number of egg and larval properties of *G. morhua* "over the range of CO_2 concentrations predicted in future scenarios for the Baltic Sea (from current values of 380 µatm up to 3,200 µatm CO_2 water)," both "with and without the combination of increasing temperature."

They report "no effect on hatching, survival, development, and otolith size was found at any stage in the development of Baltic cod," where "in situ levels of pCO_2 are already at levels of 1,100 µatm with a pH of 7.2." Their data showed "the eggs and early larval stages of Baltic cod seem to be robust to even higher levels of OA (3,200 µatm), indicating an adaptational response to CO_2." Frommel *et al*. conclude, "since the Baltic Sea is naturally high in pCO_2, its fish stocks may be adapted to conditions predicted in ocean acidification scenarios for centuries to come."

Human Health

Key Findings

The following bulleted points summarize the main findings of this chapter:

- Warmer temperatures lead to a net decrease in temperature-related mortality, including deaths associated with cardiovascular disease, respiratory disease, and strokes. The evidence of this benefit comes from research conducted in every major country of the world.

- In the United States the average person who died because of cold temperature exposure lost in excess of 10 years of potential life, whereas the average person who died because of hot temperature exposure likely lost no more than a few days or weeks of life.

- Some 4,600 deaths are delayed each year as people in the U.S. move from cold northeastern states to warm southwestern states. Between 3 and 7% of the gains in longevity experienced by the U.S. population over the past three decades is due simply to people moving to warmer states.

- Cold-related deaths are far more numerous than heat-related deaths in the United States, Europe, and almost all countries outside the tropics. Coronary and cerebral thrombosis account for about half of all cold-related mortality.

- Global warming is reducing the incidence of cardiovascular diseases related to low temperatures and wintry weather by a much greater degree than it increases the incidence of cardiovascular diseases associated with high temperatures and summer heat waves.

- The adverse health impacts of cold temperatures, especially with respect to respiratory health, are more significant than those of high temperatures in many parts of the world, including Spain, Canada, Shanghai, and Taiwan. In the subtropical island of Taiwan, for example, researchers found low minimum temperatures were the strongest risk

factor associated with outpatient visits for respiratory diseases.

- A vast body of scientific examination and research contradict the claim that malaria will expand across the globe and intensify as a result of CO_2-induced warming.

- Concerns over large increases in vector-borne diseases such as dengue as a result of rising temperatures are unfounded and unsupported by the scientific literature, as climatic indices are poor predictors for dengue disease.

- While climatic factors largely determine the geographical distribution of ticks, temperature and climate change are not among the significant factors determining the incidence of tick-borne diseases.

- The ongoing rise in the air's CO_2 content is not only raising the productivity of Earth's common food plants but also significantly increasing the quantity and potency of the many health-promoting substances found in their tissues, which are the ultimate sources of sustenance for essentially all animals and humans.

- Atmospheric CO_2 enrichment positively impacts the production of numerous health-promoting substances found in medicinal or "health food" plants, and this phenomenon may have contributed to the increase in human life span that has occurred over the past century or so.

- There appears to be little reason to expect any significant CO_2-induced increases in human-health-harming substances produced by plants as the atmosphere's CO_2 concentration continues to rise.

Introduction

Carbon dioxide (CO_2) does not seriously affect human health until the CO_2 content of the air reaches approximately 15,000 ppm (Luft *et al.*, 1974; Schaefer, 1982), more than 37 times greater than the current concentration of atmospheric CO_2. There is no reason to be concerned about any direct adverse human health consequences of the ongoing rise in the air's CO_2 content now or in the future, as even extreme model projections do not indicate anthro-

pogenic activities will raise the air's CO_2 concentration above 1,000 to 2,000 ppm.

Nevertheless, IPCC contends rising CO_2 concentrations are causing several *indirect* threats to human health, which they project will worsen as the air's CO_2 concentration rises in the future. According to a draft from the Working Group II contribution to IPCC's *Fifth Assessment Report,*

The most important effect of climate change is that it will exacerbate current risks to health *[very high confidence].* In recent decades, climate change has contributed to levels of ill-health (*likely*). If climate change continues as projected in scenarios in the next few decades, the major increases of ill-health compared to no climate change will occur through:

Greater incidence of injury, disease, and death due to more intense heat waves, storms, floods, and fires. [*very high confidence*]

Increased risk of under-nutrition resulting from diminished food production in poor regions. [*high confidence*]

Increased risks of food- and water-borne diseases and vector-borne infections. [*high confidence*]

… positive effects will be out-weighed, world-wide, by the magnitude and severity of the negative effects of climate change. [*high confidence*] ((IPCC-II, 2013a, Chapter 11, Human Health, p. 3; italics in original, bold removed and formatting changed).

We should note before going on that IPCC's assignment of "confidence" levels to each of these claims is purely a rhetorical device and not based on any statistical tests. (Idso *et al.*, 2013) Placing these expressions of opinion in italics and brackets doesn't make any of these dubious or untrue statements any more credible or true.

In a draft Technical Summary of the same document, Working Group II claims, "The health of human populations is sensitive to shifts in weather patterns and other aspects of climate change [*very high confidence*] and "There is emerging evidence of non-linearities in response (such as greater-than-expected mortality due to heat waves) as climates become more extreme" (IPCC-II, 2013b, Technical Summary, p. 16; italics in original, bold removed).

As shown in the material presented in this chapter, however, IPCC's view of the impacts of rising temperatures and atmospheric CO_2 on human

health is simply wrong. Numerous peer-reviewed studies demonstrate a warmer planet is beneficial to humanity, as warmer temperatures in all parts of the world lead to decreases in temperature-related mortality. The medical literature shows warmer temperatures and a smaller difference between daily high and low temperatures, as occurred during the twentieth and early twenty-first centuries, reduce mortality rates due to cardiovascular and respiratory disease and stroke occurrence.

Similarly, the research is quite clear that climate has exerted only a minimal influence on recent trends in vector-borne diseases such as malaria, dengue fever, and tick-borne diseases. Other factors, many of them related to economic and technological setbacks or progress and not to weather, are far more important factors determining the transmission and prevalence of such diseases.

Finally, IPCC entirely overlooks several positive effects of rising levels of atmospheric CO_2 on human health. Carbon dioxide fertilization, for example, has been shown to enhance certain health-promoting substances in plants, such as antioxidants, vitamin C, and fatty acids, and promote the growth of plants such as St. John's wort used for the treatment of a variety of illnesses. In this way, global warming portends great health benefits for humans. IPCC makes no mention of these benefits.

7.1 Hot vs. Cold Weather

- Warmer temperatures lead to a net decrease in temperature-related mortality, including deaths associated with cardiovascular disease, respiratory disease, and strokes. The evidence of this benefit comes from research conducted in every major country of the world.

According to IPCC, rising atmospheric carbon dioxide concentrations cause global warming, and this temperature increase will lead to greater human mortality. However, examination of pertinent real-world data reveals warmer temperatures lead to a decrease in temperature-related deaths, and this phenomenon represents one of the many indirect benefits of atmospheric CO_2 enrichment that IPCC has long downplayed and ignored.

As illustrated in the research described below, it is abundantly clear unseasonable cold temperatures cause far more health-related maladies and deaths than do unseasonable warm temperatures.

7.1.1 Asia

Behar (2000) studied sudden cardiac death (SCD) and acute myocardial infarction (AMI) in Israel, concentrating on the role temperature may play in the incidence of these health problems. Behar notes "most of the recent papers on this topic have concluded that a peak of SCD, AMI and other cardiovascular conditions is usually observed in low temperature weather during winter." He cites an Israeli study by Green *et al.* (1994), which reported between 1976 and 1985 "mortality from cardiovascular disease was higher by 50% in mid-winter than in mid-summer, both in men and women and in different age groups," even though summer temperatures in the Negev, where much of the work was conducted, often exceed 30°C and winter temperatures typically do not drop below 10°C. Behar concludes these results "are reassuring for populations living in hot countries."

Several researchers have examined the relationship between temperature and human health in Shanghai, China. Kan *et al.* (2003), for example, investigated the association between temperature and daily mortality from 1 June 2000 to 31 December 2001, finding a V-like relationship between total mortality and temperature that had a minimum mortality risk at 26.7°C. Above this optimum temperature, they observe, "total mortality increased

by 0.73% for each degree Celsius increase; while for temperatures below the optimum value, total mortality decreased by 1.21% for each degree Celsius increase." The net effect of a warming in Shanghai, China, therefore, would likely be reduced mortality on the order of 0.5% per degree Celsius increase in temperature, or perhaps more, since the warming of the past few decades has been primarily manifested in increases in daily minimum temperatures, with much smaller increases at the high end of the temperature spectrum. Hence, the recovery of Earth from the global chill of the Little Ice Age has had a positive effect on the health of the people of Shanghai that should continue into the foreseeable future if the planet continues to warm.

Tan *et al*. (2007) used a multivariate analysis "to investigate the relationships between mortality and heat wave intensity, duration, and timing within the summer season, along with levels of air pollution," for the exceptional heat waves of 1998 and 2003. "For heat waves in both summers," the researchers write, "mortality was strongly associated with the duration of the heat wave." Whereas the heat wave of 2003 was of much greater duration than the heat wave of 1998 (19 days in 2003 vs. 11 days in 1998), the mortality experienced in 2003 was much less than that experienced in 1998 (6.3 deaths/heat day in 2003 vs. 13.3 deaths/heat day in 1998). Tan *et al*. write, "since the meteorological conditions and pollution levels for the two heat waves were alike, we conclude that improvements in living conditions in Shanghai, such as increased use of air conditioning [1.35/household in 2003 vs. 0.69/household in 1998], larger living areas [13.8 m^2/person in 2003 vs. 9.7 m^2/person in 1998], and increased urban green space, along with higher levels of heat awareness and the implementation of a heat warning system, were responsible for the lower levels of human mortality in 2003 compared to 1998."

Kan *et al*. (2007) examined the association between Diurnal Temperature Range (DTR, defined as daily maximum temperature minus daily minimum temperature) and human mortality, using daily weather and mortality data from Shanghai over the period 1 January 2001 to 31 December 2004 via a semi-parametric generalized additive model after controlling for covariates including time trend, day of week, temperature, humidity, and outdoor air pollution levels. For cold days (below 23°C), "a 1°C increase of the 3-day moving average of DTR corresponded to 1.41%, 1.76% and 1.47% increases in total non-accidental, cardiovascular and respiratory mortality," respectively, whereas for warm days

(above 23°C), "an increase of 1°C DTR corresponded to 1.13%, 1.91% and 0.54% increases in total non-accidental, cardiovascular and respiratory mortality."

Kan *et al*. say their data suggest "even a slight increase in DTR is associated with a substantial increase in mortality." In addition, they note over the past century global warming has been characterized by "the daily minimum temperature increasing at a faster rate ... than the daily maximum, resulting in a decrease in the DTR for many parts of the world." Their results suggest that in addition to the reduction in human mortality typically provided by the increase in daily mean temperature, the accompanying decrease in DTR also should have been tending to reduce human mortality.

Ma *et al*. (2011) analyzed weather data from the Shanghai Meteorological Bureau to investigate the impact of heat waves and cold spells on hospital admissions in Shanghai, China. They defined a heat wave as a period of at least seven consecutive days with daily maximum temperature above 35.0°C and daily average temperatures above the 97th percentile during the study period. They defined a cold spell as a period of at least seven consecutive days with daily maximum temperature and daily average temperatures below the 3rd percentile during the study period. For one heat wave (24 July to 2 August, 2007) and one cold spell (28 January to 3 February, 2008), they obtained daily hospital admission data for these periods from the Shanghai Health Insurance Bureau.

The four researchers report the number of excess (above normal) hospital admissions during the eight-day heat wave was 352—driven by a 2% increase in all-cause admissions, an 8% increase in admissions due to cardiovascular problems, and a 6% increase in admissions related to respiratory problems. During the 10-day cold spell there were 3,725 excess admissions, driven by 38%, 33%, and 32% increases in admissions due to all-cause, cardiovascular, and respiratory problems, respectively. Ma *et al*. conclude "the cold spell seemed to have a larger impact on hospital admission than the heat wave in Shanghai."

Cheng and Kan (2012) employed a generalized additive model with penalized splines to analyze mortality, air pollution, temperature, and covariate data over the period 1 January 2001 through 31 December 2004 in Shanghai, focusing on particulate matter of diameter 10 μm or less (commonly referred to as PM_{10}) and ozone (O_3). Cheng and Kan report they "did not find a significant interaction between air pollution and higher temperature [>85th percentile days]," but "the interaction between PM_{10} and extreme low

temperature [<15th percentile days] was statistically significant for both total and cause-specific mortality." Compared to normal temperature days (15th-85th percentile), they found a 10-µg/m^3 increase in PM_{10} on extreme low temperature days led to all-cause mortality rising from 0.17% to 0.40%. They add, "the interaction pattern of O_3 with low temperature was similar," noting their finding of "a stronger association between air pollution and daily mortality on extremely cold days confirms those of three earlier seasonal analyses in Hong Kong, Shanghai and Athens," citing Touloumi et al. (1996), Wong et al. (1999, 2001), and Zhang et al. (2006).

Wang et al. (2013) write, "a large change in temperature within one day may cause a sudden change in the heart rate and circulation of elderly people, which all may act to increase the risk of cardiopulmonary and other diseases, even leading to fatal consequences." They further note, "it has been shown that a rise of the minimum temperature has occurred at a rate three times that of the maximum temperature during the twentieth century over most parts of the world, which has led to a decrease of the diurnal temperature range (Karl et al., 1984, 1991)."

Wang et al. evaluated the short-term effect of diurnal temperature range (DTR) on emergency room (ER) admissions among elderly adults in Beijing. As they describe it, "after controlling the long-time and seasonal trend, weather, air pollution and other confounding factors, a semi-parametric generalized additive model (GAM) was used to analyze the exposure-effect relationship between DTR and ER admissions among elderly adults with different lag structures from 2009 to 2011 in Beijing," where they "stratified groups by age and gender."

The nine researchers report "significant associations were found between DTR and four major causes of daily ER admissions among elderly adults in Beijing." They state "a 1°C increase in the 8-day moving average of DTR (lag 07) corresponded to an increase of 2.08% in respiratory ER admissions and 2.14% in digestive ER admissions," and "a 1°C increase in the 3-day and 6-day moving average of DTR (lag 02 and lag 05) corresponded to a 0.76% increase in cardiovascular ER admissions, and a 1.81% increase in genitourinary ER admissions, respectively." They add, "people aged 75 years and older were associated more strongly with DTR than the 65–74 age group."

Guo et al. (2012) note knowledge of the health effects of extreme temperatures on mortality comes mainly from developed countries, particularly from regions with temperate climates, and they say "few studies have been conducted in developing countries, particularly in tropical regions." They used a Poisson regression model combined with a distributed lag non-linear model to examine the nonlinear and delayed effects of temperature on cause-specific and age-specific mortality, employing data from 1999 to 2008 for Chiang Mai, Thailand (18°47'N, 98°59'E), with a population of 1.6 million people. Controlling for season, humidity, ozone, and particulate matter (PM_{10}) pollution, the three researchers found "both hot and cold temperatures resulted in immediate increase in all mortality types and age groups," but "the hot effects on all mortality types and age groups were short-term, while the cold effects lasted longer." The cold effects were greater, with more people dying from them than from the effects of heat.

Lindeboom et al. (2012) write, "while the association of weather and mortality has been well documented for moderate climate zones, little is known about sub-tropical zones, particularly Bangladesh." They aimed "to assess the short-term relationship of temperature and rainfall on daily mortality after controlling for seasonality and time-trends." Working with daily mortality and weather data for the period 1983–2009 pertaining to Matlab, Bangladesh, where a rigorous health and demographic surveillance system (HDSS) has been operational since 1966, Lindeboom et al. applied time series Poisson regression with cubic spline functions that allowed for lagged effects of weather on mortality, controlling for time trends and seasonal patterns.

The four researchers report "mortality in the Matlab surveillance area shows overall weak associations with rainfall, and stronger negative association with temperature." They determined there was "a 1.4% increase in mortality with every 1°C decrease in mean temperature at temperatures below 29.2°C," but only "a 0.2% increase in mortality with every 1°C increase in mean temperature." In addition, they note the "elderly, aged 60 years and above, seem to be most affected at lower temperatures, with a 5.4% increase in mortality with every 1°C decrease in temperature below 23°C." Lindeboom et al. further report the Bangladesh Meteorological Department data on minimum and maximum temperatures observed in 1950–2010 "showed an increasing trend," but they note the increase was faster for minimum temperature, as opposed to maximum temperature.

Wu et al. (2013) note "numerous studies have reported the association between ambient temperature and mortality," but "few multi-city studies have been conducted in subtropical regions in developing countries." They first assessed the health effects of

temperature on mortality in four subtropical cities of China (Changsha, Kunming, Guangzhou, and Zhuhai) by means of a "double threshold-natural cubic spline" distributed lag non-linear model at different temporal lags. They used the combined results to conduct a meta-analysis to estimate the overall cold and hot effects on mortality at different lag days. The 11 researchers report a U-shaped relationship between temperature and mortality was found in the four cities, indicating "mortality is usually lowest around a certain temperature and higher at lower or higher temperatures," as they say also was found by Alberdi *et al.* (1998), Huynen *et al.* (2001), Curriero *et al.* (2002), O'Neill *et al.* (2003), Armstrong (2006), Laaidi *et al.* (2006), and Kan *et al.* (2007). In addition, "the hot effect peaked at the current day, and then diminished with lag days; whereas "the cumulative cold effect increased gradually with lag days, with the highest effect at lag 0–27."

Although "both low and high temperatures were associated with increased mortality in the four subtropical Chinese cities," Wu *et al.* state the "cold effect was more durable and pronounced than the hot effect."

Yang *et al.* (2013) examined the effects of Diurnal Temperature Range (DTR) on human mortality rates, as well as whether the effects were different for different individual characteristics, such as gender, age, and education level. This was accomplished using daily meteorological data for the period 1 January 2003 through 31 December 2010 obtained from the China Meteorological Data Sharing System, which included daily mean temperature plus minimum and maximum temperatures collected from a single station located in the heart of the urban area of Guangzhou City (the largest metropolis in Southern China), along with individual data for all 189,379 registered deaths that occurred over the same time period, which they obtained from the Guangzhou Center for Disease Control and Prevention.

They found "a linear DTR-mortality relationship, with evidence of increasing mortality with DTR increase," where "the effect of DTR occurred immediately and lasted for four days," such that over that time period, a 1°C increase in DTR was associated with a 0.47% increase in non-accidental mortality. They also found "the elderly, females and residents with less education have been identified as more vulnerable to rapid temperature change within a single day." In addition, they report there was a joint adverse effect with temperature "when mean temperature was below 22°C, indicating that high DTR enhanced cold-related mortality."

In light of their findings, the eight researchers speculate the expected "decrease in DTR in future climate scenarios might lead to two benefits: one from decreasing the adverse effects of DTR [which is reduced due to greater warming at night than during the day], and the other from decreasing the interaction effect with temperature [which is expected to rise with greenhouse warming]."

7.1.2 Europe

The early studies of Bull (1973) and Bull and Morton (1975a, b) in England and Wales demonstrate even normal changes in temperature are typically associated with inverse changes in death rates, especially in older people. That is, when temperatures rise, death rates fall, whereas when temperatures fall, death rates rise. In addition, at the lower end of the temperature range, Bull and Morton (1978) report, "there are more deaths the longer the 'run of days,'" while at the higher end of the temperature range the reverse is true"; i.e., "the longer the 'run' the fewer the deaths," suggesting people adapt more readily to extreme heat than to extreme cold. Such findings have been echoed in many studies across Europe.

Keatinge and Donaldson (2001) analyzed the effects of temperature, wind, rain, humidity, and sunshine during high pollution days in the greater London area over the period 1976–1995 to determine which weather and/or pollution factors have the biggest influence on human mortality. They observed simple plots of mortality rate versus daily air temperature revealed a linear increase as temperatures fell from 15°C to near 0°C. Mortality rates at temperatures above 15°C, however, were "grossly alinear," as they describe it, showing no trend. Days with high SO_2, CO, or PM_{10} (particulate matter of diameter less than 10μm) concentrations were colder than average, but a multiple regression analysis revealed none of these pollutants was associated with a significant increase in mortality among people 50 years of age or older. Only low temperatures were found to have a significant effect on immediate mortality (one day after a temperature perturbation) and long-term mortality (up to 24 days after a temperature perturbation), with the net increase in

mortality over the 24 days following a one-day fall in temperature amounting to 2.77 daily deaths per million people per degree Celsius temperature drop. Keatinge and Donaldson conclude "the large, delayed increase in mortality after low temperature is specifically associated with cold and is not due to associated patterns of wind, rain, humidity, sunshine, SO_2, CO, or smoke."

How does cold kill? The two scientists say "cold causes mortality mainly from arterial thrombosis and respiratory disease, attributable in turn to cold-induced hemoconcentration and hypertension [in the first case] and respiratory infections [in the second case]." McGregor (2005) notes "anomalous cold stress can increase blood viscosity and blood pressure due to the activation of the sympathetic nervous system which accelerates the heart rate and increases vascular resistance (Collins *et al.*, 1985; Jehn *et al.*, 2002; Healy, 2003; Keatinge *et al.*, 1984; Mercer, 2003; Woodhouse *et al.*, 1993)," adding, "anomalously cold winters may also increase other risk factors for heart disease such as blood clotting or fibrinogen concentration, red blood cell count per volume and plasma cholesterol." Keatinge and Donaldson conclude although "increases in mortality due to cold weather are large in many temperate regions ... effective protection against personal cold exposure virtually prevents excess winter mortality," even in places as cold as Siberia.

In a study explicitly considering personal cold exposure, Gemmell (2001) analyzed the answers of 858 respondents to pertinent health and housing questions put to them in the second sweep of the "West of Scotland Twenty-07 Study" conducted in 1991. This effort indicated "over and above socioeconomic factors and house conditions, inadequate home heating is associated with poor health in those aged 55–60." Gemmell notes, for example, "respondents who reported feeling cold in winter 'most of the time' were over three times more likely to suffer from a limiting condition and almost five times as likely to report 'fair' or 'poor' self assessed health," leading him to conclude "living in a cold house will almost certainly exacerbate existing conditions and may lead to early mortality." Gemmell suggests "affordable efficient methods of home heating could help reduce the number of people living in homes that are detrimental to their health."

Carson *et al.* (2006) analyzed London mortality and meteorological data for four periods of the twentieth century they "selected to avoid times of war and influenza pandemics: 1900–1910, 1927–1937, 1954–1964, and 1986–1996." They found "an increase in risk at low temperatures in each period, but the strength of association gradually declined over the century ... from a 2.5% increase in mortality for each degree-C fall in temperature below 15°C in 1900–1910 to approximately a 1.2% increase in mortality per degree-C fall in temperature in 1986–1996." At the other end of the temperature spectrum, their analyses "also provided some indication of heat-related mortality in the earlier periods of analysis, but not in 1954–1964 or 1986–1996."

These results suggest cold is a more effective killer than heat. In addition, they suggest the deadly effects of both extreme cold and extreme heat have been muted with the passage of time, "despite the aging of the population and a progressive increase in the prevalence of cardiorespiratory disease, as Carson *et al.* add, "which would otherwise tend to increase susceptibility" to temperature-induced death.

Another implication of their study results, Carson *et al.* write, is "the decline in vulnerability to cold and heat is most readily explained by beneficial changes relating to increasing wealth." Some of the items they mention are improvements in health care, nutrition, and housing; increased car ownership; climate-controlled transportation and shopping facilities; and improved clothing fabrics, although they say, "we cannot quantify or even identify all of the modifying factors that have contributed to this reduced susceptibility." Finally, they say "it is reasonable to conclude that a similar modification of risk will occur among populations in other settings, particularly in low- and middle-income countries, as they grow richer."

According to Christidis *et al.* (2010), "the IPCC AR4 states with very high confidence that climate change contributes to the global burden of disease and to increased mortality," citing the contribution of Confalonieri *et al.* (2007) to that document. In an effort to evaluate this *very-high-confidence* contention of IPCC, Christidis *et al.* extracted the numbers of daily deaths from all causes from death registration data supplied by the UK Office of National Statistics for men and women 50 years of age or older in England and Wales for the period 1976–2005, which they divided by daily estimates of population "obtained by fitting a fifth order polynomial to mid-year population estimates, to give mortality as deaths per million people." They then compared the death results with surface air temperature data that showed a warming trend during the same three-decade period of 0.47°C per decade. In addition, they employed a technique called optimal detection, which they describe as "a formal statistical methodology" that

can be used to estimate the role played by human adaptation in the temperature-related changes in mortality they observed.

As expected, during the hottest portion of the year, warming led to increases in death rates, whereas during the coldest portion of the year warming led to decreases in death rates. The three scientists report if no adaptation had taken place, there would have been 1.6 additional deaths per million people per year due to warming in the hottest part of the year over the period 1976–2005, but there would have been 47 fewer deaths per million people per year due to warming in the coldest part of the year, for a lives-saved to life-lost ratio of 29.4, representing a huge net benefit of the warming experienced in England and Wales over the three-decade period of warming. When adaptation was included in the analysis, as was the case in the data they analyzed, they found there were only 0.7 death per million people per year due to warming in the hottest part of the year, but a decrease of fully 85 deaths per million people per year due to warming in the coldest part of the year, for a phenomenal lives-saved to live-lost ratio of 121.4. Such observations indicate IPCC's "very-high-confidence" conclusion is woefully wrong. Warming is highly beneficial to human health, even without any overt adaptation to it. And when adaptations are made, warming is incredibly beneficial in terms of lengthening the human lifespan.

In France, Laaidi *et al*. (2006) conducted an observational population study in six regions between 1991 and 1995 to assess the relationship between temperature and mortality in areas of widely varying climatic conditions and lifestyles, including urban (Paris), oceanic (Finistere), semi-continental (Cote-d'Or), or mountain (the Hautes-Alpes) climates and two types of Mediterranean climate, one relatively mild and sheltered (the Alpes-Maritimes) and the other more extreme and windy (the Herault). Daily death and cause-of-death data were provided by the Epidemiological Centre on the Medical Causes of Death, part of the country's National Institute for Health and Medical Research.

Laaidi *et al*. report "mean daily counts of deaths showed an asymmetrical V-like or U-like pattern with higher mortality rates at the time of the lowest temperatures experienced in the area than at the time of the highest temperatures," noting "between these two peaks, there is a critical temperature threshold, referred to as the thermal optimum, where mortality rates are minimal." This relationship varied somewhat between the two sexes and among different age groups and causes of death. In all cases, however,

they found "more evidence was collected showing that cold weather was more deadly than hot weather." These findings, the researchers say, are "broadly consistent with those found in earlier studies conducted elsewhere in Europe (Kunst *et al*., 1993; Ballester *et al*., 1997; Eurowinter Group, 1997; Keatinge *et al*., 2000a,b; Beniston, 2002; Muggeo and Vigotti, 2002), the United States (Curriero *et al*., 2002) and South America (Gouveia *et al*., 2003)." They also say their findings "give grounds for confidence in the near future," stating even a 2°C warming over the next half century "would not increase annual mortality rates."

Diaz *et al*. (2005) examined the effect of extreme winter temperature on mortality in Madrid, Spain for people older than 65, using data from 1,815 winter days over the period 1986–1997, during which time 133,000 deaths occurred. They found daily T_{max} was more closely correlated with mortality than was daily T_{min}, because, as they describe it, "very low Tmin occur mostly during stagnation episodes, characterized by very cold nights and sunny days, with a typical temperature range of between 15°C and 20°C," while "most of the days with very low Tmax occur under cloudy conditions, with very limited temperature ranges of around 5°C," so "human exposure to low temperatures during these days is longer than that occurring during the stagnation days associated with a very low Tmin." In addition, they note, "Tmin is usually recorded around 7 a.m., when very little human activity occurs outdoors, while Tmax is usually recorded at around 4 p.m."

Diaz *et al*. determined that as Tmax dropped below 6°C, which they describe as an unusually cold day (UCD), "the impact on mortality also increased significantly." They also found the impact of UCDs increased as the winter progressed, with the first UCD of the season producing an average of 102 deaths/day at a lag of eight days and the sixth UCD producing an average of 123 deaths/day at a lag of eight days. This behavior suggests, in their words, "acclimatisation does not occur, with every cold spell enhancing the pathologies produced in previous spells." Consequently, whereas they report "the impact of heat waves is reduced as they occur during a certain season, suggesting an acclimatisation to heat," just the opposite occurs in the case of recurring cold, which becomes ever more deadly with each new occurrence.

Fernandez-Raga *et al*. (2010) obtained from Spain's National Meteorological Institute data from weather stations situated in eight of the provincial capitals in the Castile-Leon region—a plateau in the northwestern part of the country that includes nine

provinces "with a low population density that can be considered as ageing." The data covered the period 1980–1998, and they obtained contemporary mortality data from the country's National Institute for Statistics for deaths associated with cardio-vascular, respiratory, and digestive system diseases.

Analyses of the monthly averaged data revealed a number of interesting results. First, for all three of the disease types studied, Fernandez-Raga *et al.* found "the death rate is about 15% higher on a winter's day than on a summer's day," which they describe as "a result often found in previous studies,"

Figure 7.1.2.1. Monthly deaths in the Castile-Leon region of Spain attributable to cardiovascular disease. Adapted from Fernandez-Raga *et al.* (2010).

citing Fleming *et al.* (2000), Verlato *et al.* (2002), Grech *et al.* (2002), Law *et al.* (2002), and Eccles (2002). Second, in a finding that helps explain the first, the three researchers discovered when monthly averaged human death rates were plotted against monthly averages of daily mean, maximum, and minimum air temperature, the results nearly always took the form of a U-shaped concave parabola. And for all three disease types, they found all three temperatures (daily mean, maximum, and minimum) at which minimum death rates occurred—which they refer to as ideal or comfort temperatures—were within about 1–7°C of the maximum values typically reached by those three types of temperature, and they were anywhere from 14–24°C away from their minimum values. Consequently, the ideal or comfort temperatures always were very close to (and sometimes nearly identical to) the maximum values reached by the mean, maximum, and minimum temperatures experienced in the region, and they were much more removed from the minimum values of those three temperature parameters, as illustrated in Figure 7.1.2.1, which relates death rates due to cardiovascular diseases to mean air temperature.

The data of Figure 7.1.2.1 clearly demonstrate the people of the Castile-Leon region of Spain are much more likely to die from a cardiovascular disease in the extreme cold of winter than in the extreme heat of summer. The same holds true with respect to dying from respiratory and digestive system diseases.

Referencing the *Fourth Assessment Report* of

IPCC, Wichmann *et al.* (2011) write "temperature, a key climate change indicator, is expected to increase substantially in the Northern Hemisphere, with potentially grave implications for human health." Concerned about what that might mean for their homeland, the five Danish researchers investigated the association between the daily three-hour maximum apparent temperature (which reflects the physiological experience of combined exposure to humidity and temperature) and deaths due to cardiovascular disease (CVD), cerebrovascular disease (CBD), and respiratory disease (RD) in the nation's capital, Copenhagen, over the period 1999–2006.

During the warm half of the year (April–September), Wichmann *et al.* found a rise in temperature had an inverse or protective effect with respect to CVD mortality (a 1% decrease in death in response to a 1°C increase in apparent temperature). This finding is unusual but also has been observed in Dublin, Ireland, as reported by Baccini *et al.* (2008, 2011). Wichmann *et al.* found no association with RD and CBD mortality. At the other end of the thermal spectrum, during the cold half of the year, all three associations were inverse or protective. This finding, according to the researchers, is "consistent with other studies (Eurowinter Group, 1997; Nafstad *et al.*, 2001; Braga *et al.*, 2002; O'Neill *et al.*, 2003; Analitis *et al.*, 2008)."

Whereas many observers (including IPCC) continue to emphasize the primarily negative impact

of summer heat waves on human death rates in low- and mid-latitude regions of Earth, essentially neglecting to report what happens there during winter cold spells, Wichmann *et al*.'s summer results tell a dramatically different story that is likely typical of higher latitudes. They also portray what tends to happen nearly everywhere in winter, noting during that cold part of the year "only protective effects [of warming] were observed."

Matzarakis *et al*. (2011) developed a relationship between heat stress and all-cause mortality in the densely populated city of Vienna (Austria), using a human biometeorological index known as the physiologically equivalent temperature or PET, which "describes the thermal situation by the air temperature of a reference environment, in which the core and the skin temperature is the same as in the complex outdoor environment." This reference environment is defined as "a room with a wind velocity < 0.1 m/sec, a vapor pressure of 12 hPa and a mean radiation temperature that equals the air temperature," as described in more detail by Mayer and Hoppe (1987).

Based on data from 1970–2007, and after adjusting the long-term mortality rate to account for temporal variations in the size of the population of Vienna, temporal changes in life expectancy, and the changing age structure of Vienna's population, the three researchers found a significant relationship between heat stress and mortality. Over this 38-year period, "some significant decreases of the sensitivity were found, especially in the medium heat stress levels," they report.

With respect to the cause of this decrease in heat stress sensitivity, Matzarakis *et al*. state in the final sentence of their abstract, these decreases in sensitivity "could indicate active processes of long-term adaptation to the increasing heat stress." In the discussion section of their paper, they write such sensitivity changes "were also found for other regions," citing Davis *et al*. (2003), Koppe (2005), Tan *et al*. (2007), and Donaldson and Keatinge (2008). In the conclusion of their paper, they refer to these changes as "positive developments."

Vocks *et al*. (2001) statistically evaluated the influence of various meteorological variables on the intensity of clinical symptoms (itching) caused by the skin disease atopic eczema in the high-mountain area of Davos, Switzerland for the period 1983–1989. Itching intensity was found to be inversely correlated with air temperature, air pressure, and water vapor pressure, such that an increase in any of these variables decreased the severity of itching. Examination of the three variables during periods of

abrupt and/or prolonged change, on the order of several weeks to months, substantially improved the correlations. Such findings suggest future warming, whether local, regional, or global, will bring a measure of relief from itching to sufferers of atopic eczema.

In Germany, Laschewski and Jendritzky (2002) analyzed daily mortality rates in Baden-Wurttemberg (10.5 million inhabitants) over the 30-year period 1958–1997 to determine the sensitivity of the population of this moderate climatic zone to long- and short-term episodes of heat and cold. Their research indicates mortality shows "a marked seasonal pattern with a minimum in summer and a maximum in winter." With respect to short-term exposure to heat and cold, they found "cold spells lead to excess mortality to a relatively small degree, which lasts for weeks," and "the mortality increase during heat waves is more pronounced, but is followed by lower than average values in subsequent weeks." The authors say the latter observation suggests people who died from short-term exposure to heat possibly "would have died in the short term anyway."

With respect to this short-term mortality displacement in the case of heat-related deaths, it is worth noting Laschewski and Jendritzky's data demonstrate it is merely a displacement of deaths and not an overall increase. They found, for example, the mean duration of above-normal mortality for the 51 heat episodes that occurred from 1968 to 1997 was 10 days, with a mean increase in mortality of 3.9%, after which there was a mean decrease in mortality of 2.3% for 19 days. Hence, the net effect of the two perturbations was an overall decrease in mortality of 0.2% over the full 29-day period. This is additional evidence cold spells are more deadly than heat waves. Hence, global warming should be expected to confer significant benefits upon mankind in both the short- and long-term, for in both situations, cold kills but heat heals, especially in the long term, which is what global warming projections are all about.

Focusing on the Czech Republic, Kysely and Huth (2004) calculated deviations of the observed number of deaths from the expected number of deaths for each day of the year for the period 1992–2000. They found "the distribution of days with the highest excess mortality in a year is clearly bimodal, showing a main peak in late winter and a secondary one in summer." Regarding the smaller number of summer heat-wave-induced deaths, they also found "a large portion of the mortality increase is associated with the harvesting effect, which consists in short-term shifts in mortality and leads to a decline in the number of

deaths after hot periods (e.g. Rooney *et al.*, 1998; Braga *et al.*, 2002; Laschewski and Jendritzky, 2002)." For the Czech Republic, they report, "the mortality displacement effect in the severe 1994 heat waves can be estimated to account for about 50% of the total number of victims." As they describe it, "people who would have died in the short term even in the absence of oppressive weather conditions made up about half of the total number of deaths." Hence, not only is the overall number of deaths typically smaller in the warmest part of the year than in the coldest time of the year in the Czech Republic, approximately half of the heat-related excess deaths associated with the severe 1994 heat waves likely would have occurred even without the unseasonable heat, as they were merely normal deaths simply hastened by unseasonably warm temperatures.

Kysely and Plavcova (2012) write, "there is much concern that climate change may be associated with large increases in heat-related mortality," but "growing evidence has been emerging that the relationships between temperature extremes and mortality impacts are nonstationary," and "most of these studies point to declining heat-related mortality in developed countries, including the US, Australia, the UK, the Netherlands and France (Davis *et al.*, 2002, 2003a, 2003b; Bi and Walker, 2001; Donaldson *et al.*, 2003; Garssen *et al.*, 2005; Carson *et al.*, 2006; Fouillet *et al.*, 2008; Sheridan *et al.*, 2009)." This is true, they note, despite "aging populations and prevailing rising trends in temperature extremes."

Most of the studies cited above were conducted in developed countries; the two Czech researchers note "much less is understood about temporal changes in the impacts of temperature extremes in developing (low- and middle-income) countries and in regions that have undergone (or are undergoing) a transition from the developing to the developed world," They note "post-communist Central and Eastern Europe is one such region, where pronounced changes have occurred over the past 20 years." They examined "temporal changes in mortality associated with spells of large positive temperature anomalies (hot spells) in extended summer season in the population of the Czech Republic (Central Europe) during 1986–2009."

Kysely and Plavcova found declining mortality trends in spite of rising temperature trends, just the opposite of what IPCC claims will occur in response to global warming. The Czech scientists add, "the finding on reduced vulnerability of the population remains unchanged if possible confounding effects of within-season acclimatization and mortality displacement are taken into account," and "neither

does it depend on the changing age structure of the population, since similar (and slightly more pronounced) declines in the mortality impacts are found in the elderly (age group 70+ years) when examined separately."

Kysely and Plavcova write, "recent positive socioeconomic development following the collapse of communism in 1989 is the likely primary cause of the declining impacts of hot spells," and "other important factors have been enhanced media coverage and better public awareness of heat-related risks." They also note their key result "supports the idea that the adverse health effects of heat are largely preventable (e.g., Matthies and Menne, 2009)," ultimately concluding "climate change may have relatively little influence on heat-related deaths, particularly if the recent warming trend is viewed as an early manifestation of anthropogenic climate change." They continue, "it appears that changes in other factors that influence vulnerability of a population are dominant instead of temperature trends and that the level of adaptability to high ambient temperatures may be large."

Huynen *et al.* (2001) evaluated the impact of heat waves and cold spells on mortality rates of people of all ages throughout the Netherlands for the 19-year period 1 January 1979 through 31 December 1997. During heat waves they found a mean excess mortality of 39.8 deaths per day, whereas during cold spells they found a mean excess mortality of 46.6 deaths per day. These numbers indicate a typical cold-spell day kills at a rate 17% greater than a typical heat-wave day. They also report the heat waves of the period they studied ranged from six to 13 days in length, whereas the cold spells lasted from nine to 17 days, making the average cold spell approximately 37% longer than the average heat wave. Adjusting for this duration differential makes the number of deaths per cold spell in the Netherlands fully 60% greater than the number of deaths per heat wave. Also, excess mortality continued for the entire month after the cold spells, leading to even more deaths, whereas in the case of heat waves, there appeared to be mortality deficits in the following month, suggesting "some of the heat-induced increase in mortality can be attributed to those whose health was already compromised" or "who would have died in the short term anyway." That conclusion also was reached by Kunst *et al.* (1993), Alberdi *et al.* (1998), Eng and Mercer (1998), and others mentioned in this section. It is highly likely, therefore, that the 60% greater death toll calculated for Dutch cold spells compared to Dutch heat waves is a vast underestimate of the

true differential killing power of these two temperature extremes.

In a letter to the editor of *Epidemiology*, the senior and second authors of the Huynen *et al.* paper discussed whether global climate change reduces thermal stress in the Netherlands (Martens and Huynen, 2001). Based on the predictions of nine GCMs for an atmospheric CO_2 concentration of 550 ppm in the year 2050—taken to imply a 50% increase in Dutch heat waves and a 67% drop in Dutch cold spells—they calculated a total mortality decrease of approximately 1,100 people per year for the country at that point in time.

In a multiregional study, Keatinge *et al.* (2000a) examined heat- and cold-related mortality in north Finland, south Finland, southwest Germany, the Netherlands, Greater London, north Italy, and Athens, Greece, in people aged 65–74. For each of these regions, they determined the 3°C temperature interval of lowest mortality and then evaluated mortality deviations from that base level as temperatures rose and fell by increments of 0.1°C. As they describe their findings, "all regions showed more annual cold related mortality than heat related mortality." Over the seven regions studied, annual cold-related deaths were nearly 10 times greater than annual heat-related deaths. Moreover, Keatinge *et al.* note the very successful adjustment of the populations in their study to widely different summer temperatures "gives grounds for confidence that they would adjust successfully, with little increase in heat related mortality, to the global warming of around 2°C predicted to occur in the next half century." They say their data suggest "any increases in mortality due to increased temperatures would be outweighed by much larger short term declines in cold related mortalities." For the entire population of Europe, therefore, even a 2°C increase in temperature, if it were to occur, would be a climate change for the better.

In a major assessment of cold-weather effects on mortality in Europe, Analitis *et al.* (2008) state, "in recent years, the effects of meteorologic factors on health have attracted renewed interest because of the observed and predicted climate change, which is expected to result in a general rise in temperature." This development, they write, has led to a "recent focus on heat-wave episodes," which may have fostered the perception cold-related mortality is not as important a public health concern as heat-related mortality.

Analitis *et al.* analyzed short-term effects of cold weather on mortality in 15 European cities: Athens,

Greece; Barcelona, Spain; Budapest, Hungary; Dublin, Ireland; Helsinki, Finland; Ljubljana, Slovenia; London, United Kingdom; Milan, Italy; Paris, France; Prague, Czech Republic; Rome, Italy; Stockholm, Sweden; Turin, Italy; Valencia, Spain; and Zurich, Switzerland. They assessed the effects of minimum apparent temperature on cause- and age-specific daily mortality over the cold half of the year (October–March), using data from 1990–2000 they analyzed via "Poisson regression and distributed lag models, controlling for potential confounders."

The international team of scientists—from Finland, Greece, Ireland, Italy, Slovenia, Spain, and Sweden—found "a 1°C decrease in temperature was associated with a 1.35% increase in the daily number of total natural deaths and a 1.72%, 3.30% and 1.25% increase in cardiovascular, respiratory, and cerebro-vascular deaths, respectively." In addition, they report "the increase was greater for the older age groups," and the cold effect "persisted up to 23 days, with no evidence of mortality displacement." Analitis *et al.* conclude their results "add evidence that cold-related mortality is an important public health problem across Europe and should not be overlooked by public health authorities because of the recent focus on heat-wave episodes."

7.1.3 North America

Goklany and Straja (2000) examined trends in United States death rates over the period 1979–1997 due to excessive hot and cold weather. They report there were no trends in deaths due to either extreme heat or cold in the entire population or, "more remarkably," as they say, in the older, more-susceptible age groups, those aged 65 and over, 75 and over, and 85 and over. Deaths due to extreme cold in these older age groups exceeded those due to extreme heat by as much as 80% to 125%. With respect to the absence of trends in death rates attributable to either extreme heat or cold, Goklany and Straja say this "suggests that adaptation and technological change may be just as important determinants of such trends as more obvious meteorological and demographic factors."

Davis *et al*. (2002) studied changes in the impact of high temperatures on daily mortality rates over a period of four decades in six major metropolitan areas along a north-south transect in the eastern United States. They found few significant weather-mortality relationships for any decade or demographic group in the three southernmost cities examined, where warmer weather is commonplace. In the three northernmost cities, however, there were statistically significant decreases in population-adjusted mortality rates during hot and humid weather between 1964 and 1994. The authors write, "these statistically significant reductions in hot-weather mortality rates suggest that the populace in cities that were weather-sensitive in the 1960s and 1970s have become less impacted by extreme conditions over time because of improved medical care, increased access to air conditioning, and biophysical and infrastructural adaptations." They further note, "this analysis counters the paradigm of increased heat-related mortality rates in the eastern US predicted to result from future climate warming."

Davis *et al*. (2003) evaluated "annual excess mortality on days when apparent temperatures—an index that combines air temperature and humidity—exceeded a threshold value for 28 major metropolitan areas in the United States from 1964 through 1998." They found "for the 28-city average, there were 41.0 ± 4.8 excess heat-related deaths per year (per standard million) in the 1960s and 1970s, 17.3 ± 2.7 in the 1980s, and 10.5 ± 2.0 in the 1990s." Analyzing these results together with various types of ancillary data, they conclude, "this systematic desensitization of the metropolitan populace to high heat and humidity over time can be attributed to a suite of technologic, infrastructural, and biophysical adaptations, including increased availability of air conditioning." Consequently, because "all-causes mortality during heat stress events has declined despite increasingly stressful weather conditions in many urban and suburban areas ... heat-related mortality in the United States seems to be largely preventable at present." The technology and infrastructure advancements made possible by the economic progress of the past few decades have more than compensated for the increasing heat stress during this period of what IPCC describes as "unprecedented" global warming.

Davis *et al*. (2004) examined the seasonality of mortality due to all causes, using monthly data for 28 major U.S. cities from 1964 to 1998, then calculated the consequences of a future 1°C warming of the conglomerate of those cities. At all locations studied, they report "warmer months have significantly lower

mortality rates than colder months." They calculate "a uniform 1°C warming results in a net mortality decline of 2.65 deaths (per standard million) per metropolitan statistical area." Since the annual death rate of about 9,500 deaths (per standard million) is so much larger, however, the "death benefits" of the warming are extremely small—a reduction in the annual number of deaths of less than 0.03%, which also pales in comparison to the nearly 20% reduction in annual mortality that has occurred as a consequence of technological advancements experienced between the 1960s–1970s and the 1990s.

The primary implication of Davis *et al.*'s findings, in their words, "is that the seasonal mortality pattern in US cities is largely independent of the climate and thus insensitive to climate fluctuations, including changes related to increasing greenhouse gases."

O'Neill *et al.* (2005) assessed the influence of air pollution and respiratory epidemics on empirical associations between apparent temperature, which "represents an individual's perceived air temperature," and daily mortality in Mexico's largest and third-largest cities: Mexico City and Monterrey, respectively. They report, "the effects of cold weather on all-age mortality were similar in Monterrey and Mexico City." When considering the entire temperature spectrum, they found "in Mexico City, the 7-day temperature mortality association has a hockey stick shape with essentially no effect of higher temperatures," whereas in Monterrey the function they fit to the data "shows a U-shape," with "a higher mortality risk at both ends of the distribution," although the effect is much weaker at the high-temperature end of the plot than at the low-temperature end, and the absolute value of the slope of the mortality vs. temperature relationship is smaller across the high-temperature range of the data.

Most interesting, perhaps, was the researchers' finding that "failure to control for respiratory epidemics and air pollution resulted in an overestimate of the impact of hot days by 50%," whereas "control for these factors had little impact on the estimates of effect of cold days." They note "most previous assessments of effects of heat waves on hot days have not controlled for air pollution or epidemics." In other words, the death-dealing effects of heat waves typically are not adjusted for concurrent effects of air pollution and respiratory epidemics, which often account for as much as half of the deaths attributed to hot temperatures; these two confounding factors do not appear to impact assessments of the effect of cold temperatures on

deaths.

A prime example of the failure to account for concurrent air pollution effects on mortality occurred in the aftermath of the European heat wave of 2003. In analyzing the impact of air pollutants present during that episode in the United Kingdom, Stedman (2004) found 21–38% of the total excess deaths claimed to be due to high temperatures were actually the result of elevated concentrations of ozone and PM_{10} (particulate matter of diameter less than 10µm). Likewise, Fischer *et al.* (2004) determined 33–50% of the deaths attributed to the same heat wave in the Netherlands were caused by concurrent high ozone and PM_{10} concentrations. This factor is often unaccounted for in mortality-related studies of heat waves.

Deschenes and Moretti (2009) analyzed the relationship between weather and mortality, based on "data that include the universe of deaths in the United States over the period 1972–1988," in which they "match each death to weather conditions on the day of death and in the county of occurrence." This "high-frequency data and the fine geographical detail," they write, allow them "to estimate with precision the effect of cold and hot temperature shocks on mortality, as well as the dynamics of such effects." Most notably, the data allowed them to detect the existence or absence of a "harvesting effect," whereby the temperature-induced deaths are or are not subsequently followed by a drop in the normal death rate, which could compensate for the prior extreme temperature-induced deaths.

The two researchers say their results "point to widely different impacts of cold and hot temperatures on mortality." They discovered "hot temperature shocks are indeed associated with a large and immediate spike in mortality in the days of the heat wave," but "almost all of this excess mortality is explained by near-term displacement." As a result, "in the weeks that follow a heat wave, we find a marked decline in mortality hazard, which completely offsets the increase during the days of the heat wave," so "there is virtually no lasting impact of heat waves on mortality."

In the case of cold temperature days, they also found "an immediate spike in mortality in the days of the cold wave," but "there is no offsetting decline in the weeks that follow," so "the cumulative effect of one day of extreme cold temperature during a thirty-day window is an increase in daily mortality by as much as 10%." In addition, they write, "this impact of cold weather on mortality is significantly larger for females than for males," but "for both genders, the

effect is mostly attributable to increased mortality due to cardiovascular and respiratory diseases."

Deschenes and Moretti state "the aggregate magnitude of the impact of extreme cold on mortality in the United States is large," noting it "roughly corresponds to 0.8% of average annual deaths in the United States during the sample period." They estimate "the average person who died because of cold temperature exposure lost in excess of ten years of potential life," whereas the average person who died because of hot temperature exposure likely lost no more than a few days or weeks of life.

Interestingly, Deschenes and Moretti report many people in the United States have taken advantage of these evident facts by moving "from cold northeastern states to warm southwestern states." Based on their findings, for example, they calculate "each year 4,600 deaths are delayed by the changing exposure to cold temperature due to mobility," and "3% to 7% of the gains in longevity experienced by the U.S. population over the past three decades are due to the secular movement toward warmer states in the West and the South, away from the colder states in the North."

7.1.4 Other Regions

In Brazil, Gouveia *et al*. (2003) extracted daily counts of deaths from all causes except violent deaths and neonatal deaths up to one month of age, from Sao Paulo's mortality information system for the period 1991–1994. They analyzed this data for the effects of temperature on the age groups of less than 15 years (children), 15–64 years (adults), and 65 years or older (elderly), determining "change points" at which heat and cold effects started.

Interestingly, the authors found the change points for both heat- and cold-induced deaths were identical: 20°C. For each 1°C increase above this value for a given and prior day's mean temperature, they observed a 2.6% increase in deaths from all causes in children, a 1.5% increase in deaths from all causes in adults, and a 2.5% increase in deaths from all causes in the elderly. For each 1°C decrease below the 20°C change point, the effect was greater, with increases in deaths from all causes in children, adults, and the elderly registering 4.0%, 2.6%, and 5.5%, respectively. These cooling-induced death rates were 54%, 73%, and 120% greater than those attributable to warming.

Bi *et al*. (2008) used correlation and auto-regressive integrated moving average regression analyses to derive relationships between various aspects of weather and mortality in the general population and elderly (65 years of age and older) of Brisbane, Australia, which they describe as having a subtropical climate, over the period 1986–1995. They found "death rates were around 50–80 per 100,000 in June, July, and August [winter], while they were around 30–50 per 100,000 in the rest of the year, including the summer," and "this finding applied both to the general population and to the elderly population, and to deaths from various causes."

In discussing their finding that "more deaths occurred in the winter than during other seasons of the year, although winter in Brisbane is very mild," the researchers note "it is understandable that more deaths would occur in winters in cold or temperate regions, but even in a subtropical region, as indicated in this study, a decrease in temperatures (in winters) may increase human mortality." The evidence continues to grow for extremes of cold leading to the deaths of many more people than extremes of heat, in

both cold and warm climates.

Xu *et al*. (2013) preface their work by stating, "previous studies have found that high and cold temperatures increase the risk of childhood diarrhea," but much less is known about whether the within-day variation of temperature (i.e., the daily maximum minus minimum, or diurnal temperature range, DTR) has any effect on it. They write, "a Poisson generalized linear regression model combined with a distributed lag non-linear model was used to examine the relationship between diurnal temperature range and emergency department admissions for diarrhea among children under five years in Brisbane [Australia] from 1st January 2003 to 31st December 2009."

The six scientists found "a statistically significant relationship between diurnal temperature range and childhood diarrhea," such that "a 1°C increase in diurnal temperature range was associated with a 3% increase of Emergency Department Admissions for childhood diarrhea." They conclude, "as climate change continues, DTRs are likely to become more variable," and as a result, "the incidence of childhood diarrhea may increase." Other research suggests this is likely *not* to be the case: Karl *et al*. (1984, 1991) have shown during most of twentieth century global warming, daily minimum temperatures rose at a rate fully three times greater than daily maximum temperature over most of the world. DTRs actually declined over this period and must have led to significant decreases in emergency department admissions for diarrhea among children under five years of age, representing yet another positive health benefit of global warming.

Mrema *et al*. (2012) state "weather and climate changes are associated with a number of immediate and long-term impacts on human health that occur directly or indirectly, through mediating variables," but "few studies to date have established the empirical relationship between monthly weather and mortality in sub-Saharan Africa." Working with mortality data obtained from the Rufiji (Tanzania) Health and Demographic Surveillance System (RHDSS) for the period 1999 to 2010, Mrema *et al*. employed time-series Poisson regression models to estimate the association between monthly temperature—which ranges from 27.9 to 34.4°C in this tropical region—and mortality, adjusted for long-term trends, in three age groups (0–4, 5–59, 60+).

The four Tanzanian researchers report "mortality in all age groups peaked up at the mid of the year," which is "the time when the temperature is relatively lower compared to other periods of the year in Rufiji." If the monthly average temperature drops to a value of 24°C from the threshold, they state, "mortality will increase by 80.7%, 65.7% and 74% in age groups 0–4, 5–59 and over 60, respectively." Mrema *et al*. note "Rufiji's population is accustomed to a tropical climate and, like any other population, is exposed to cold temperatures relative to its average climate." Hence even in a warm, tropical region, relative cold kills far more people than relative heat.

Egondi *et al*. (2012) state, "many studies have established a link between weather (primarily temperature) and daily mortality in developed countries," but "little is known about this relationship in urban populations in sub-Saharan Africa." They employed mortality data from the Nairobi Urban Health and Demographic Surveillance System (NUHDSS) along with time-series models "to study the relationship between daily weather and mortality for a population of approximately 60,000 during the period 2003–2008."

"Overall," the six scientists report, "there are seasonal fluctuations in mortality, with the highest rates of death occurring during periods of relative cold." They also note "mortality risk over the year rises from the lowest mortality risk by about 40% in the 0–4 age group and by about 20% for all ages" in response to a drop in temperature. In addition, "the effects of low temperatures on mortality can last for days," and therefore, "although the world will get warmer in the future, the low temperature-related mortality is likely to remain an important concern." Such findings further demonstrate a change in the weather or shifting of the seasons to cooler conditions, rather than an equivalent increase in warmth, is typically the more deadly of the two types of temperature evolution, even in relatively warm places.

7.1.5 Multiple Regions

Studying North Carolina (USA); South Finland, comprising all of Finland except the northern provinces of Oulu and Lapland; and Southeast England, comprising Greater London, Essex, Kent, Sussex, Hampshire, Surrey, Berkshire, Oxfordshire, Buckinghamshire, and Bedfordshire, Donaldson *et al*. (2003) determined the mean daily May–August 3°C temperature band in which deaths of people aged 55 and above were at a minimum. They compared the numbers of heat- and cold-related deaths at temperatures above and below this optimum temperature interval for each region and determined how heat-related deaths in the three areas changed between 1971 and 1997 in response to the 1.0°C temperature rise experienced in North Carolina over this period, starting from an initial temperature of 23.5°C; the 2.1°C temperature rise experienced in Southeast England, starting from an initial temperature of 14.9°C; and the unchanging 13.5°C temperature of South Finland.

Donaldson *et al*. report the 3°C temperature band at which mortality was at its local minimum was lowest for the coldest region (South Finland), highest for the warmest region (North Carolina), and in between for the "in between" region (Southeast England), indicating the populations of these three regions are somewhat acclimated to their respective thermal climates. They also found cold-related mortality was greater than heat-related mortality in each region. With respect to changes in heat-related

mortality from 1971 to 1997, they determined for the coldest of the three regions (South Finland, where there was no change in temperature over the study period), heat-related deaths per million inhabitants in the 55-and-above age group declined from 382 to 99. In somewhat warmer Southeast England, where it warmed by 2.1°C over the study period, heat-related deaths per million of the at-risk age cohort declined, but only from 111 to 108. And in the warmest of the three regions (North Carolina, where mean daily May–August temperature rose by 1.0°C over the study period), corresponding heat-related deaths also fell from 228 to a mere 16 per million.

Such findings imply first that people can adapt to both warmer and cooler climates to some degree. Beyond that, local cooling tends to produce many more deaths than does local warming in all three of the areas studied. As for the dramatic decline in the number of heat-related deaths over a period of warming in the hottest area of the study (North Carolina), Donaldson *et al*. attribute this phenomenon to "the increase of air conditioning in the South Atlantic region of the U.S.A.," where they note "the percentage of households with some form of air conditioning in that region rose from 57% in 1978 to 72% in 1997." With respect to the declining heat-related deaths in the other two regions, they say, "the explanation is likely to lie in the fact that both regions shared with North Carolina an increase in prosperity, which could be expected to increase opportunities for avoiding heat stress."

In a review article touching on multiple aspects of temperature-related deaths, Keatinge and Donaldson (2004) report "cold-related deaths are far more numerous than heat-related deaths in the United States, Europe, and almost all countries outside the tropics," noting coronary and cerebral thrombosis account for about half of all cold-related mortality. In describing the mechanisms behind this cold temperature-death connection, they say cold stress causes an increase in arterial thrombosis "because the blood becomes more concentrated, and so more liable to clot during exposure to cold." The sequence of events, as they describe it, is as follows: "the body's first adjustment to cold stress is to shut down blood flow to the skin to conserve body heat," which "produces an excess of blood in central parts of the body," and to correct for this effect, "salt and water are moved out from the blood into tissue spaces," leaving behind "increased levels of red cells, white cells, platelets and fibrinogen" that lead to increased viscosity of the blood and a greater risk of clotting. In addition, cold stress "tends to suppress immune

responses to infections," and respiratory infections typically "increase the plasma level of fibrinogen," which also "contributes to the rise in arterial thrombosis in winter."

Keatinge and Donaldson note "cold spells are closely associated with sharp increases in mortality rates," and "deaths continue for many days after a cold spell ends." On the other hand, "increased deaths during a few days of hot weather are followed by a lower than normal mortality rate," because "many of those dying in the heat are already seriously ill and even without heat stress would have died within the next 2 or 3 weeks."

Keatinge and Donaldson state, "since heat-related deaths are generally much fewer than cold-related deaths, the overall effect of global warming on health can be expected to be a beneficial one." As an example, and even including the heat-harvesting of naturally expected deaths, they report "the rise in temperature of 3.6°F expected over the next 50 years would increase heat-related deaths in Britain by about 2,000 but reduce cold-related deaths by about 20,000." Keatinge and Donaldson conclude, "the overall effect of global warming on health can be expected to be a beneficial one."

Hajat *et al*. (2005) analyzed the history of heat-wave-related deaths in three cities of contrasting wealth (defined as gross national income per capita)—Delhi (India), Sao Paulo (Brazil), and London (England)—based on daily numbers of nonviolent deaths derived from mortality registries for the four-year period January 1991 to December 1994, examining "time-series of daily mortality data in relation to daily ambient temperature using Poisson models and adjusting for season, relative humidity, rainfall, particulate air pollution, day of the week and public holidays," and using "unconstrained distributed lag models to identify the extent to which heat-related [death] excesses were followed by deficits." The latter phenomenon (mortality displacement) arises when people who die during heat waves would have died shortly thereafter even in the absence of the elevated warmth.

For each city, an increase in all-cause mortality was observed for same- and previous-day temperatures greater than 20°C, with excess deaths being greatest in Delhi and smallest in London. In Delhi, the excess of deaths persisted for three weeks, whereas in London it prevailed for only two days and was followed by deficits that led to the sum of the two effects being zero by day 11. In Sao Paulo, as might have been expected, the pattern of deaths was intermediate between these two extremes. Summed

over the course of 28 days, the risk of death associated with heat stress was 2.4% per degree greater than 20°C in Delhi, 0.8% in Sao Paulo, and negative 1.6% in London. These findings led Hajat *et al*. to conclude, "populations in low-income countries where life-threatening infections are still common may have the greatest vulnerability to the effects of heat," and "those most susceptible to heat are likely to remain susceptible if there is not due attention paid to infectious disease, diarrheal illness, and other major causes of early mortality in these poor populations."

Byremo *et al*. (2006) studied the effects of temperature on atopic eczema, "a chronic inflammatory skin disease characterized by itching, lesions and lichenification," especially at "the flexure sites of the major joints of the upper and lower extremities." The pain and itching associated with the disease, as they describe it, "may cause depressive symptoms, social isolation and reduced self-perception," lowering the quality of life in children and their caretakers. They report epidemiological studies suggest climate influences the disease's prevalence, noting "atopic eczema has been reported worldwide to be positively associated with latitude and negatively with temperature (Weiland *et al*., 2004)."

Byremo *et al*. transported 30 children, 4 to 13 years of age with severe atopic eczema, from their homes in Norway to the Canary Islands, where they stayed for four weeks before returning, and 26 similarly infected children of the same age group stayed at home in Norway the entire time. All were evaluated for various disease characteristics at the start of the study, at the conclusion of the group-of-30's four-week period of stay in the Canary Islands, and three months after the 30 children left the islands to return home to Norway. The specific disease parameters employed in the evaluation were the Scoring of Atopic Dermatitis, the Children's Dermatology Life Quality Index, skin colonization by *Staphylococcus aureus*, and pharmacological skin treatment.

Noting temperatures during the children's stay in the Canary Islands were much higher than those in Norway, Byremo *et al*. report the children's time in the warmer climate significantly reduced the severity of atopic eczema, and the youths improved in severity of eczema, quality of life, and bacterial skin culture, which was reflected in a reduction in the use of topical steroids, antihistamines, and topical antibiotics. These positive changes were observed at the conclusion of the four-week stay in the Canary Islands as well as back home in Norway three months later. The researchers state the four weeks spent in the

975

Canary Islands "led to a lasting improvement for the children," whereas "the control group did not show similar improvement."

Although greater exposure to sunlight and the effect of regularly bathing in seawater, such as the children did at the Canary Islands, likely played positive roles in reducing the severity of their atopic eczema, the results of this study are harmonious with the worldwide negative correlation that prevails between eczema and temperature, suggesting global warming may prove beneficial to people unfortunate enough to suffer from it.

According to Young and Kakinen (2010), "Arctic populations, especially indigenous people, could be considered as 'vulnerable,' because their health status generally shows disparities when compared to the national or more southern populations," and "it is not known if the harsh climate, and especially cold temperatures, could be a contributing or causative factor of the observed health inequalities." To shed some light on this subject, they determined "mean January and July temperatures ... for 27 Arctic regions based on weather station data for the period 1961–1990 and their association with a variety of health outcomes assessed by correlation and multiple linear regression analyses."

The two researchers report mean January temperature correlated negatively with several health outcomes, including infant mortality rate, age-standardized mortality rates (all causes, respiratory, cancer, injuries), perinatal mortality rate, and tuberculosis incidence rate, but it correlated positively with life expectancy. That is to say, as mean January temperature rose, life expectancy at birth rose as well, whereas the undesirable health metrics (such as mortality and disease incidence) declined. They report, "for every 10°C increase in mean January temperature, the life expectancy at birth among males increased by about six years," whereas "infant mortality rate decreased by about four deaths per thousand live births." Young and Kakinen conclude the cold climate of the Arctic is "significantly associated with higher mortality" and "should be recognized in public health planning," noting "within a generally cold environment, colder climate results in worse health."

7.2 Cardiovascular Disease

- Global warming is reducing the incidence of cardiovascular diseases related to low temperatures and wintry weather by a much greater degree than it increases the incidence of cardiovascular diseases associated with high temperatures and summer heat waves.

According to IPCC, global warming will pose numerous challenges to human health, including premature death due to heat-induced cardiovascular problems. This section examines the results of studies that dealt with this important subject in the past decade or so.

Enquselassie *et al*. (1993) investigated the effects of extremes of temperature and rainfall, as well as intermediate levels, on the number of coronary events, both fatal and nonfatal, reported in the Hunter Region of New South Wales, Australia, located on the east coast of the country about 150 km north of Sydney, for the five-year period 1 July 1985 to 30 June 1990. "Daily temperature and rainfall," they write, "were taken as indicators of acute effects of weather and the month when an event occurred was used to indicate longer-term or seasonal effects."

Regarding seasonal effects, Enquselassie *et al*. report "fatal coronary events and non-fatal definite myocardial infarction were 20–40% more common in winter and spring than at other times of year." As to daily temperature effects, they found "rate ratios for deaths were significantly higher for low tem-

peratures," noting "on cold days coronary deaths were up to 40% more likely to occur than at moderate temperatures." Effects of humidity and rainfall were negligible. The authors conclude their data "support the theory of increased risk of coronary mortality when temperatures are unusually low," and "avoiding temperature extremes could contribute to reduction in annual peaks in coronary events," which occur during the colder part of the year.

Thanks to Norwegian law, which requires all deaths be examined by a physician who diagnoses cause and reports it on the death certificate, Nafstad *et al.* (2001) were able to examine the effects of temperature on mortality due to all forms of cardiovascular disease for citizens of the country's capital over the period 1990 to 1995. Their analysis showed the average daily number of cardiovascular-related deaths was 15% higher in the winter months (October–March) than in the summer months (April–September), leading them to conclude "a milder climate would lead to a substantial reduction in average daily number of deaths."

Research in Israel conducted by Green *et al.* (1994) revealed that between 1976 and 1985, mortality from cardiovascular disease was higher by 50% in mid-winter than in mid-summer, both in men and in women, as well as in different age groups. Summer temperatures in the Negev, where much of the work was conducted, often exceeded 30°C, whereas winter temperatures typically did not drop below 10°C. These findings have been substantiated by several other Israeli studies, including those reviewed by Behar (2000), who wrote "most of the recent papers on this topic have concluded that a peak of sudden cardiac death, acute myocardial infarction and other cardiovascular conditions is usually observed in low temperature weather during winter."

Evidence of a seasonal variation in cardiac-related mortality also has been noted in the relatively mild climate of southern California in the United States. In a study of all 222,265 death certificates issued by Los Angeles County for deaths caused by coronary artery disease from 1985 through 1996, Kloner *et al.* (1999) found death rates in December and January were 33% higher than those observed in June through September. Likewise, based on a study of the Hunter region of New South Wales, Australia, which covered 1 July 1985 to 30 June 1990, Enquselassie *et al.* (1993) determined "fatal coronary events and non-fatal definite myocardial infarction were 20–40% more common in winter and spring than at other times of year." With respect to daily temperature effects, they found "rate ratios for deaths

were significantly higher for low temperatures," noting "on cold days coronary deaths were up to 40% more likely to occur than at moderate temperatures."

Hajat and Haines (2002) set out to determine whether the number of cardiovascular-related doctor visits by the elderly bore a similar relationship to cold temperatures. Based on data obtained between January 1992 and September 1995 for registered patients aged 65 and older from several practices in London, England, they found the number of general practitioner consultations was higher in the cool-season months (October–March) than in the warm-season months (April–September) for all cardio-vascular diseases.

In a study of both "hot" and "cold" cities in the United States—where Atlanta, Georgia; Birmingham, Alabama; and Houston, Texas comprised the "hot" group, and Canton, Ohio; Chicago, Illinois; Colorado Springs, Colorado; Detroit, Michigan; Minneapolis-St. Paul, Minnesota; New Haven, Connecticut; Pittsburgh, Pennsylvania; and Seattle and Spokane, Washington comprised the "cold" group—Braga *et al.* (2002) determined both the acute effects and lagged influence of temperature on cardiovascular-related deaths. They found in the hot cities neither hot nor cold temperatures had much impact on mortality related to cardiovascular disease (CVD). In the cold cities, on the other hand, both high and low temperatures were associated with increased CVD deaths. The effect of cold temperatures persisted for days, whereas the effect of high temperatures was restricted to the day of the death or the day before. For all CVD deaths, the hot-day effect was five times smaller than the cold-day effect. In addition, the hot-day effect included some "harvesting," where Braga *et al.* observed a deficit of deaths a few days later, which they did not observe for the cold-day effect.

Gouveia *et al.* (2003) determined the number of cardiovascular-related deaths in adults aged 15–64 years of age in Sao Paulo, Brazil over the period 1991–1994 increased by 2.6% for each 1°C decrease in temperature below 20°C, while they found no evidence for heat-induced deaths due to temperatures rising above 20°C. In the elderly (65 years of age and above), a 1°C warming above 20°C led to a 2% increase in deaths, but a 1°C cooling below 20°C led to a 6.3% increase in deaths, more than three times as many cardiovascular-related deaths due to cooling than to warming in the elderly.

For the period 1974–1999, McGregor *et al.* (2004) obtained data on ischaemic heart disease (IHD) and temperature for five English counties aligned on a north-south transect (Tyne and Wear,

West Yorkshire, Greater Manchester, West Midlands, and Hampshire) and analyzed them for relationships between the two parameters. They determined "the seasonal cycles of temperature and mortality are inversely related," and "the first harmonic accounts for at least 85% (significant at the 0.01 level) of the variance of temperature and mortality at both the climatological and yearly time scales." They also report "years with an exaggerated mortality peak are associated with years characterized by strong temperature seasonality," and "the timing of the annual mortality peak is positively associated with the timing of the lowest temperatures." McGregor *et al.* explain, "frequent exposure to cold causes a rise in IHD risk factors (Lloyd, 1991) through increasing blood pressure and viscosity, vasoconstriction, heart rate and angina (Morgan and Moran, 1997)."

Chang *et al.* (2004) analyzed data from the World Health Organization (WHO) Collaborative Study of Cardiovascular Disease and Steroid Hormone Contraception (WHO, 1995) to determine the effects of monthly mean temperature on rates of hospitalization for arterial stroke and acute myo-cardial infarction (AMI) among young women aged 15–49 from 17 countries in Africa, Asia, Europe, Latin America, and the Caribbean. These efforts revealed "among young women from 17 countries, the rate of hospitalized AMI, and to a lesser extent stroke, was higher with lower mean environmental air temperature." They report, "on average, a 5°C reduction in mean air temperature was associated with a 7 and 12% increase in the expected hospitalization rates of stroke and AMI, respectively." They also note "the findings of an inverse association between mean air temperature and hospitalization rate of AMI in this study are in agreement with several other studies," citing Douglas *et al.* (1990), Douglas *et al.* (1991), Mackenbach *et al.* (1992), Douglas *et al.* (1995), Seto *et al.* (1998), Danet *et al.* (1999), and Crawford *et al.* (2003). Finally, they note, "lagging the effects of temperature suggested that these effects were relatively acute, within a period of a month."

Bartzokas *et al.* (2004) "examined the relationship between hospital admissions for cardiovascular (cardiac in general including heart attacks) and/or respiratory diseases (asthma etc.) in a major hospital in Athens [Greece] and meteorological parameters for an 8-year period." Over the year, "there was a dependence of admissions on temperature" and low temperatures were "responsible for a higher number of admissions," they found. Specifically, "there was a decrease of cardiovascular or/and respiratory events from low to high values [of

temperature], except for the highest temperature class in which a slight increase was recorded."

Nakaji *et al.* (2004) evaluated seasonal trends in deaths in Japan due to various diseases, using nationwide vital statistics from 1970 to 1999 and recorded weather data, specifically, mean monthly temperature. The nine researchers note Japan has "bitterly cold winters," and their analysis indicates the numbers of deaths due to infectious and parasitic diseases including tuberculosis, respiratory diseases including pneumonia and influenza, diabetes, digestive diseases, and cerebrovascular and heart diseases rise to a maximum during that cold time of year. Of the latter two categories, they found peak mortality rates due to heart disease and stroke were one-and-a-half to two times greater in winter (January) than at the time of their yearly minimums (August and September). They conclude, in order "to reduce the overall mortality rate and to prolong life expectancy in Japan, measures must be taken to reduce those mortality rates associated with seasonal differences." They also note, "it has long been recognized that cold temperature acts as a trigger for coronary events," and "major infectious diseases are epidemic in winter."

Hence, to achieve the scientists' stated objectives, it is necessary to bring about a "reduction in exposure to cold environments," as they put it, which is precisely what global warming does, and what it does best by warming more in winter than in summer, as Nakaji *et al.* demonstrate to be the case in Japan, where winter warming over the past 30 years was twice as great as it was during the rest of the year.

In Sao Paulo, Brazil, where 12,007 deaths were observed from 1996 to 1998, Sharovsky *et al.* (2004) investigated "associations between weather (temperature, humidity and barometric pressure), air pollution (sulfur dioxide, carbon monoxide, and inhalable particulates), and the daily death counts attributed to myocardial infarction." Their efforts revealed "a significant association of daily temperature with deaths due to myocardial infarction ($p<0.001$), with the lowest mortality being observed at temperatures between 21.6 and 22.6°C." For all practical purposes, however, their data showed little variation in death rates from 18°C to just over 25°C, with the latter representing the typical upper limit of observed temperature in Sao Paulo, which is located on the Tropic of Capricorn at an altitude of 800 m. As mean daily temperature dropped below 18°C, however, death rates rose in essentially linear fashion to attain a value at 12°C (the typical lower limit of observed temperature in Sao Paulo) more than 35%

greater than the minimum baseline value registered between 21.6 and 22.6°C.

Sharovsky *et al.* say their findings "demonstrated a strong association between daily temperature and myocardial infarction in Sao Paulo, Brazil," which suggests "an acclimatization of the population to the local climate occurs and that myocardial infarction deaths peak in winter not only because of absolute low temperature but possibly secondary to a decrease relative to the average annual temperature." This indeed must be true, for deaths due to heart attacks are consistently greater in winter than in summer, as they write, "across many regions of the world (Marshall *et al.*, 1998; Douglas *et al.*, 1991; Seto *et al.*, 1998; Sheth *et al.*, 1999)."

Kovats *et al.* (2004) analyzed patterns of temperature-related hospital admissions and deaths in Greater London during the mid-1990s. For the three-year period 1994–1996, cardiovascular-related deaths were approximately 50% greater during the coldest part of the winter than during the peak warmth of summer, whereas respiratory-related deaths were nearly 150% greater in the depths of winter cold than at the height of summer warmth. Also, with respect to heat waves, the mortality impact of the notable heat wave of 29 July to 3 August 1995 was so tiny it could not be discerned among the random scatter of plots of three-year-average daily deaths from cardiovascular and respiratory problems versus day of year.

In a review article published in the *Southern Medical Journal*, Keatinge and Donaldson (2004) begin with a clear declaration of the relative dangers of heat and cold for human mortality, writing, "cold-related deaths are far more numerous than heat-related deaths in the United States, Europe, and almost all countries outside the tropics, and almost all of them are due to common illnesses that are increased by cold."

Keatinge and Donaldson report coronary and cerebral thrombosis account for about half of all cold-related deaths, and respiratory diseases account for approximately half of the rest. They say cold stress causes an increase in arterial thrombosis "because the blood becomes more concentrated, and so more liable to clot during exposure to cold." As they describe it, "the body's first adjustment to cold stress is to shut down blood flow to the skin to conserve body heat," which "produces an excess of blood in central parts of the body," and to correct for this effect, "salt and water are moved out from the blood into tissue spaces," leaving behind "increased levels of red cells, white cells, platelets and fibrinogen" that lead to increased viscosity of the blood and a greater risk of clotting.

As to respiratory-related deaths, the British scientists report the infections that cause them spread more readily in cold weather because people "crowd together in poorly ventilated spaces when it is cold." In addition, they say "breathing of cold air stimulates coughing and running of the nose, and this helps to spread respiratory viruses and bacteria." The "train of events leading to respiratory deaths," they continue, "often starts with a cold or some other minor infection of the upper airways," which "spreads to the bronchi and to the lungs," whereupon "secondary infection often follows and can lead to pneumonia." They also note cold stress "tends to suppress immune responses to infections," and respiratory infections typically "increase the plasma level of fibrinogen, and this contributes to the rise in arterial thrombosis in winter."

Keatinge and Donaldson also note "cold spells are closely associated with sharp increases in mortality rates," and "deaths continue for many days after a cold spell ends." On the other hand, they report, "increased deaths during a few days of hot weather are followed by a lower than normal mortality rate," because "many of those dying in the heat are already seriously ill and even without heat stress would have died within the next 2 or 3 weeks."

With respect to the implications of global warming for human mortality, Keatinge and Donaldson state "since heat-related deaths are generally much fewer than cold-related deaths"—and, it should be noted, consist primarily of deaths that typically would have occurred shortly even without excess heat—"the overall effect of global warming on health can be expected to be a beneficial one." They report, "the rise in temperature of 3.6°F expected over the next 50 years would increase heat-related deaths in Britain by about 2,000 but reduce cold-related deaths by about 20,000."

Keatinge and Donaldson concluded, "even in climates as warm as southern Europe or North Carolina [USA], cold weather causes more deaths than hot weather." They report "global warming will reduce this at first," but "the improvement is not likely to continue without action to promote defenses against cold." They report "people in regions with mild winters become careless about cold stress, protect themselves less effectively against cold, and generally have more winter deaths than people in colder regions," noting "climatic warming therefore calls for action to control cold stress as well as heat stress," and stating if appropriate precautions are taken, "rising temperatures could reduce overall

mortality rates." Consequently, they conclude, "the overall effect of global warming on health can be expected to be a beneficial one."

McGregor (2005) noted "anomalous cold stress can increase blood viscosity and blood pressure due to the activation of the sympathetic nervous system which accelerates the heart rate and increases vascular resistance (Collins *et al.*, 1985; Jehn *et al.*, 2002; Healy, 2003; Keatinge *et al.*, 1984; Mercer, 2003; Woodhouse *et al.*, 1993)," while further noting "anomalously cold winters may also increase other risk factors for heart disease such as blood clotting or fibrinogen concentration, red blood cell count per volume and plasma cholesterol." He conducted an analysis to determine whether there was any association between the level of IHD mortality in three English counties (Hampshire, West Midlands, and West Yorkshire) and the winter-season North Atlantic Oscillation (NAO), which exerts a fundamental control on the nature of winter climate in Western Europe, focusing on the winters of 1974–1975 through 1998–1999.

McGregor found "generally below average monthly and all-winter IHD mortality is associated with strong positive values of the monthly or winter climate index which indicates the predominance of anomalously warm moist westerly flows of air over England associated with a positive phase of the NAO." At the other extreme, he found "winters with elevated mortality levels ... have been shown to be clearly associated with a negative NAO phase and anomalously low temperatures," adding "the occurrence of influenza ... helps elevate winter mortality above that of summer."

Carder *et al.* (2005) used generalized linear Poisson regression models to investigate the relationship between outside air temperature and deaths due to all non-accident causes in the three largest cities of Scotland (Glasgow, Edinburgh, and Aberdeen) between January 1981 and December 2001. They observed "an overall increase in mortality as temperature decreases," which "appears to be steeper at lower temperatures than at warmer temperatures," while "there is little evidence of an increase in mortality at the hot end of the temperature range." They also report "the observed relation between cold temperature and mortality was typically stronger among the elderly," and "cold temperature effects on mortality persist with lag periods of beyond two weeks." The seven scientists found, for temperatures below 11°C, a 1°C drop in the daytime mean temperature on any one day was associated with an increase in cardiovascular-caused mortality of

3.4% over the following month. At any season of the year a decline in air temperature in the major cities of Scotland leads to increases in deaths due to cardiovascular causes, whereas there is little or no such increase in mortality associated with heat waves.

Cagle and Hubbard (2005) examined the relationship between temperature and cardiac-related deaths in King County, Washington (USA) over the period 1980–2000 using Poisson regression analysis, based on information provided by the Washington State Department of Health on out-of-hospital deaths of all adults over the age of 54, plus historical meteorological data obtained from the National Climate Data Center for the Seattle-Tacoma International Airport. They determined there was an average of 2.86 cardiac-related deaths per day for all days when the maximum temperature fell within the broad range of 5–30°C. For days with maximum temperatures less than 5°C, the death rate rose by 15% to a mean value of 3.30, whereas on days with maximum temperatures greater than 30°C, death rates did not rise at all, actually dropping by 3% to a mean value of 2.78. In addition, "the observed association between temperature and death rate is not due to confounding by other meteorological variables," and "temperature continues to be statistically significantly associated with death rate even at a 5-day time lag."

Cagle and Hubbard describe a number of human haematological changes that occur upon exposure to cold, including a decrease in blood plasma volume (Bass and Henschel, 1956; Chen and Chien, 1977; Fregley, 1982; Collins *et al.*, 1985) that is accompanied by "a sympathetic nervous system reflex response to cold-induced stress (LeBlanc *et al.*, 1978; Collins *et al.*, 1985; LeBlanc, 1992)" and "an increase in packed cell volume due to increased numbers of red cells per unit volume (Keatinge *et al.*, 1984), increased platelet counts and platelet volume (Finkel and Cumming, 1965; Keatinge *et al.*, 1984), increased whole blood viscosity (Keatinge *et al.*, 1984), increased serum lipid levels (Keatinge *et al.*, 1984; Woodhouse *et al.*, 1993; Neild *et al.*, 1994), and increased plasma fibrinogen and factor VII clotting activity values (Keatinge *et al.*, 1984; Woodhouse *et al.*, 1994)." These haemodynamic and vasoconstrictive factors combine "to produce what Muller *et al.* (1994) refer to as 'acute risk factors' that may trigger a cardiac event." Vasoconstriction and concomitant increases in central blood volume and systolic blood pressure, for example, "put additional workload on the heart which may lead to increased arrhythmias (Amsterdam *et al.*, 1987), decreased thresholds for angina and abnormal myocardial

contractions (De Lorenzo *et al.*, 1999), as well as increasing the risk of dislodging a vulnerable plaque which could lead to thrombosis (Muller *et al.*, 1994)," which "may occur through increased cardiac filling pressure and stroke volume which in turn increases cardiac oxygen requirements while lessening cardiac access to oxygen (Muza *et al.*, 1988; De Lorenzo *et al.*, 1999)." In addition, the Washington researchers report "greater blood viscosity also works to increase the load on the heart through greater resistance to flow (Frisancho, 1993) and increasing blood pressure (Keatinge *et al.*, 1984)."

Tam *et al.* (2009) employed daily mortality data for the years 1997 to 2002, obtained from the Hong Kong Census and Statistics Department, to examine the association between diurnal temperature range (DTR = daily maximum temperature minus daily minimum temperature) and cardiovascular disease among the elderly (people aged 65 and older). They report "a 1.7% increase in mortality for an increase of 1°C in DTR at lag days 0–3" and describe these results as being "similar to those reported in Shanghai." The four researchers state "a large fluctuation in the daily temperature—even in a tropical city like Hong Kong—has a significant impact on cardiovascular mortality among the elderly population." In addition, the DTR has declined significantly over many parts of the world as mean global temperature has risen over the past several decades (Easterling *et al.*, 1997), perhaps another reason why colder temperatures are a much greater risk to human life than are warmer temperatures.

Working in the nine urban districts of Shanghai, China, Cao *et al.* (2009) used time-series and case-crossover approaches to assess the relationship between DTR and coronary heart disease (CHD) deaths that occurred between 1 January 2001 and 31 December 2004, based on mortality data for elderly (66 years of age or older) people, obtained from the Shanghai Municipal Center of Disease Control and Prevention, and temperature data they obtained from a fixed-site station in the Xuhui District of Shanghai. They adjusted the data to account for the mortality impacts of long-term and seasonal trends in CHD mortality, day of week, temperature, relative humidity, and concomitant atmospheric concentrations of PM_{10}, SO_2, NO_2, and O_3, which they obtained from the Shanghai Environmental Monitoring Center. They found "a 1°C increase in DTR (lag = 2) corresponded to a 2.46% increase in CHD mortality on time-series analysis, a 3.21% increase on unidirectional case-crossover analysis, and a 2.13% increase on bidirectional case-crossover

analysis," and "the estimated effects of DTR on CHD mortality were similar in the warm and cool seasons." The seven scientists conclude their "data suggest that even a small increase in DTR is associated with a substantial increase in deaths due to CHD."

Employing a generalized additive statistical model that blends the properties of generalized linear models with additive models, Bayentin *et al.* (2010) analyzed the standardized daily hospitalization rates for ischemic heart disease (IHD) and their relationship with climatic conditions up to two weeks prior to the day of admission—controlling for time trends, day of the season, and gender—to determine the short-term effects of climate conditions on the incidence of IHD over the 1989–2006 time period for 18 health regions of Quebec. The authors report, "a decline in the effects of meteorological variables on IHD daily admission rates was observed over the period of 1989–2006." This observation, they write, "can partly be explained by the changes in surface air temperature," which they describe as warming "over the last few decades," as is further described by Bonsal *et al.* (2001) and Zhang *et al.* (2000) for the twentieth century portion of the study's duration. In addition, they note, "winters have been steadily warmer" while "summers have yet to become hotter for most regions," another beneficial characteristic of the warming experienced over most of the planet throughout the latter part of the twentieth century (Easterling *et al.*, 1997). The six scientists also report what they call their "counter-intuitive finding," that "cold temperatures resulted in a protective effect for women except for most Northern regions."

Toro *et al.* (2010) note "several studies have demonstrated that cardiovascular mortality has a seasonal distribution (Arntz *et al.*, 2000; Weerasinghe *et al.* 2002; Nakaji *et al.*, 2004; Kloner, 2006)" and "the relationship between cold weather and ischemic heart disease mortality is well established (Vuori, 1987; Gyllerup *et al.*, 1993; Gyllerup, 2000)." They state "cold temperature may be an important factor in bringing on the onset of life-threatening cardiac events, even in regions with relatively mild winters," citing Cagle and Hubbard (2005).

Working with data on 7,450 cardiovascular-related deaths that occurred in Budapest, Hungary between 1995 and 2004, where the deceased were "medico-legally autopsied," Toro *et al.* sought potential relationships between daily maximum, minimum, and mean temperature, air humidity, air pressure, wind speed, global radiation, and daily numbers of the heart-related deaths.

The six Hungarian scientists report and restate

their primary finding numerous times throughout their paper, writing, "both the maximum and the minimum daily temperatures tend to be lower when more death cases occur in a day," "on the days with four or more death cases, the daily maximum and minimum temperatures tend to be lower than on days without any cardiovascular death events," "the largest frequency of cardiovascular death cases was detected in cold and cooling weather conditions," "we found a significant negative relationship between temperature and cardiovascular mortality," "the analysis of 6-hour change of air pressure suggests that more acute or chronic vascular death cases occur during increasing air pressure conditions (implying cold weather fronts)," "we found a high frequency of cardiovascular death in cold weather," "a significant negative relationship was detected between daily maximum [and] minimum temperature[s] and the number of sudden cardiovascular death cases," and "a significant negative correlation was detected between daily mean temperature and cardiovascular mor-tality." In a summary statement regarding their work, Toro *et al.* write, "with these analyses, we confirmed the results of other studies (Donaldson *et al.*, 1998; Gyllerup, 2000; Mercer, 2003) that mortality was in inverse relation to air temperature."

Bhaskaran *et al.* (2010) explored the short-term relationship between ambient temperature and risk of heart attacks (myocardial infarction) in England and Wales by analyzing daily time series data from 15 metropolitan areas. The data covered 84,010 hospital admissions from 2003–2006. They found a broadly linear relationship between temperature and heart attacks that was well characterized by log-linear models without a temperature threshold, such that each 1°C reduction in daily mean temperature was associated with a 2.0% cumulative increase in risk of myocardial infarction over the current and following 28 days. They also report heat had no detrimental effect, as an increased risk of myocardial infarction at higher temperatures was not detected. They found adults aged 75–84 and those with previous coronary heart disease seemed more vulnerable to the effects of cold than other age groups (P for interaction 0.001 or less in each case), whereas those taking aspirin were less vulnerable (P for interaction 0.007).

Kysely *et al.* (2011) write, "in the Czech Republic, mortality associated with heat waves (Kysely, 2004; Kysely and Kriz, 2008) and cold spells (Kysely *et al.*, 2009) has been examined," but they note, "previous studies were based on different definitions and approaches which did not allow for a comparative analysis.

Working with a nationwide database of daily mortality records that cover the 21-year period 1986–2006—which, in their words, "encompasses seasons with the hottest summers on record (1992, 1994, 2003) as well as several very cold winters (1986/87, 1995/96, 2005/06)"—Kysely *et al.* compared the effects of hot and cold periods on cardiovascular mortality using analogous definitions for heat waves and cold spells based on quantiles of daily average temperature anomalies and did not incorporate any location-specific threshold, while excluding periods characterized by epidemics of influenza and acute respiratory infections that occur primarily in winter and are also responsible for many deaths. The four Czech scientists report "both hot and cold spells are associated with significant excess cardiovascular mortality," but "the effects of hot spells are more direct (unlagged) and typically concentrated in a few days of a hot spell, while cold spells are associated with indirect (lagged) mortality impacts persisting after a cold spell ends." Although they report "the mortality peak is less pronounced for cold spells," they determined "the cumulative magnitude of excess mortality is larger for cold than hot spells."

With respect to gender differences, the researchers found a "much larger excess mortality of females in hot spells and more lagged effects in females than males associated with cold spells." With respect to age, they report "effects of hot spells have a similar temporal pattern in all age groups but much larger magnitude in the elderly," whereas in the case of cold spells, "relative excess mortality is largest in the middle-aged population (25–59 years)."

Kysely *et al.* (2011) conclude, "in the context of climate change, substantial reductions in cold-related mortality are very likely in mid-latitudinal regions, particularly if the increasing adaptability of societies to weather is taken into account (cf. Christidis *et al.*, 2010)," and "it is probable that reductions in cold-related mortality will be more important than possible increases in heat-related mortality."

Lim *et al.* (2012) state, "with the increasing concern directed at climate change, temperature-related environment variables have been studied as risk factors for cardiovascular and respiratory diseases, especially in European, Australian, and US cities," noting "in addition to heat or cold waves, diurnal temperature range (DTR) has been suggested as a predictor of mortality (Curriero *et al.*, 2002) and was, in fact, found to be a risk factor for human health." Focusing on the four largest cities of Korea—the populations of which ranged from 2.5 to 9.8 million (Seoul, Incheon, Daegu, and Busan)—

Lim *et al*. obtained daily hospital admission information pertaining from the countrywide database of the Korea National Health Insurance Corporation, which covers 97% of Korea's population. They assessed the effects of increasing DTR on hospital admissions for the most common cardiovascular and respiratory diseases in those four cities for the period 2003–2006, employing two statistical approaches: "a Poisson generalized linear model (GLM) and a temperature-matched case-crossover (CC) design (Basu *et al*., 2005)."

According to the three South Korean researchers, the data showed "the area-combined effects of DTR on cardiac failure and asthma were statistically significant," and the DTR effects on asthma admissions were greater for the elderly (75 years or older) than for the non-elderly group. "In particular," they write, "the effects on cardiac failure and asthma were significant with the percentage change of hospital admissions per 1°C increment of DTR at 3.0% and 1.1%, respectively."

Because the global warming of the past several decades has been associated with a decrease in DTR (global warming is predominantly caused by an increase in daily minimum temperature), it likely has helped to significantly reduce hospital admissions for cardiac failure and asthma in the larger cities of Korea and around the world. Lim *et al*. note DTR effects on nonaccidental, cardiovascular, and respiratory mortality or emergency admissions have been studied in a number of Asian countries, citing Cao *et al*. (2009), Chen *et al*. (2007), Kan *et al*. (2007), Liang *et al*. (2008), Liang *et al*. (2009), Lim *et al*. (2012), Shinkawa *et al*. (1990), Song *et al*. (2008), and Tam *et al*. (2009). Each of these studies, Lim *et al*. note, "reported a 1 to 2% increase in mortality risk per 1°C increase of DTR."

Wanitschek *et al*. (2013) note "previous studies reported an association of cold weather conditions with an excess incidence of acute coronary syndromes (ACS) according to hospital discharge reports (Eurowinter Group, 1997; Spencer *et al*., 1998; Danet *et al*., 1999; Kloner *et al*., 1999; Dilaveris *et al*., 2006)." However, they write, "whether these epidemiologic facts also translate into a significantly different rate of acute coronary angiographies between two consecutive winters characterized by a dramatic temperature increase is less clear."

Noting the 2005/2006 winter was very cold, whereas the 2006/2007 winter was extraordinarily warm, Wanitschek *et al*. studied the cases of patients who were suffering acute myocardial infarctions and had been referred to the University Clinic of Internal

Medicine III (Cardiology) at Innsbruck Medical University, Tyrol, Austria, for coronary angiography (CA). They compared the patients' risk factors and in-hospital mortality rates between these two consecutive winters, the latter of which was 7.5°C warmer than the former. The two winters saw nearly identical CA cases (987 vs. 983). According to the six Austrian researchers, 12.9% of the CA cases in the colder winter were acute, while 10.4% of the cases in the warmer winter were acute. Diagnoses of STEMI (ST Elevation Myocardial Infarction) as an indication of acute CA were 74.in the colder winter 0 vs. 62.7% in the warmer. Wanitschek *et al*. conclude, "the average temperature increase of 7.5°C from the cold to the warm winter was associated with a decrease in acute coronary angiographies, in particular due to a lower incidence of STEMI referred for primary percutaneous intervention."

Vasconcelos *et al*. (2013) studied the health-related effects of a daily human-biometeorological index known as the Physiologically Equivalent Temperature or PET, which is based on the input parameters of air temperature, humidity, mean radiant temperature, and wind speed, as employed by Burkart *et al*. (2011), Grigorieva and Matzarakis (2011), and Cohen *et al*. (2012), focusing their attention on Lisbon and Oporto Counties in Portugal over the period 2003–2007. The five Portuguese researchers report there was "a linear relationship between daily mean PET, during winter, and the risk of myocardial infarction, after adjustment for confounding factors," thus confirming "the thermal environment, during winter, is inversely associated with acute myocardial infarction morbidity in Portugal." They observed "an increase of 2.2% of daily hospitalizations per degree fall of PET, during winter, for all ages." In Portugal and many other countries where low winter temperatures "are generally under-rated compared to high temperatures during summer periods," Vasconcelos *et al*. conclude cold weather is "an important environmental hazard" that is much more deadly than the heat of summer.

These several studies clearly demonstrate global warming is beneficial to humanity, reducing the incidence of cardiovascular diseases related to low temperatures and wintry weather by a much greater degree than it increases the incidence of cardiovascular diseases associated with high temperatures and summer heat waves.

7.3 Respiratory Disease

- The adverse health impacts of cold temperatures, especially with respect to respiratory health, are more significant than those of high temperatures in many parts of the world, including Spain, Canada, Shanghai, and Taiwan. In the subtropical island of Taiwan, for example, researchers found low minimum temperatures were the strongest risk factor associated with outpatient visits for respiratory diseases.

According to IPCC, global warming will pose numerous challenges to human health, including the potential for an excess of deaths. This section examines the results of a number of studies conducted over the past decade or so that deal with this important subject as it applies to respiratory diseases. The studies show the excess death hypothesis from respiratory causes is 180 degrees out of phase with reality.

Hajat and Haines (2002) set out to determine whether the well-documented relationship between cold temperatures and respiratory mortality in the elderly extends to the number of visits by the elderly to general practitioners. They employed additive models to regress time-series of daily numbers of general practitioner consultations by the elderly against temperature. The consultation data they employed included visits to the doctor for asthma, lower respiratory diseases other than asthma, and upper respiratory diseases other than allergic rhinitis as obtained for registered patients aged 65 and older from several London practices between January 1992 and September 1995.

Hajat and Haines found the mean number of consultations was higher in cool-season months (October–March) than in warm-season months (April–September) for all respiratory diseases. At mean temperatures below 5°C, the relationship between respiratory disease consultations and temperature was linear, and stronger at a time lag of six to 15 days—a 1°C decrease in mean temperature below 5°C was associated with a 10.5% increase in all respiratory disease consultations.

Keatinge and Donaldson (2001) obtained similar results in their study of the effects of temperature on mortality in people over 50 years of age in the greater London area over the period 1976–1995. Simple plots of mortality rate versus daily air temperature revealed a linear increase in mortality as the air temperature fell from 15°C to near 0°C. Mortality rates at temperatures above 15°C, on the other hand, were, in their words, "grossly alinear," showing no trend. Low temperatures were shown to have a significant effect on both immediate (one day after the temperature perturbation) and long-term (up to 24 days after the temperature perturbation) mortality rates. Why are cold temperatures so deadly? Keatinge and

Donaldson say it is because "cold causes mortality mainly from arterial thrombosis and respiratory disease, attributable in turn to cold-induced hemo-concentration and hypertension and respiratory infections."

Nafstad *et al*. (2001) studied the association between temperature and daily mortality in citizens of Oslo, Norway over the period 1990 to 1995. Because Norwegian law requires all deaths be examined by a physician, who diagnoses the cause of death and reports it on the death certificate, the authors were able to categorize and examine the effects of temperature on mortality specifically associated with respiratory diseases. The results showed the mean daily number of respiratory-related deaths was considerably higher in winter (October–March) than in summer (April–September). Winter deaths associated with respiratory diseases were 47% more numerous than summer deaths. Nafstad *et al*. conclude, "a milder climate would lead to a substantial reduction in average daily number of deaths."

Braga *et al*. (2002) conducted a time-series analysis of both the acute and lagged influence of temperature and humidity on mortality rates in 12 U.S. cities, finding no clear evidence for a link between humidity and respiratory-related deaths. With respect to temperature, they found respiratory-related mortality increased in cities with more variable temperature. This phenomenon, they write, "suggests that increased temperature variability is the most relevant change in climate for the direct effects of weather on respiratory mortality." This finding bodes well for a potentially warmer world, for Robeson (2002) has clearly demonstrated, based on a 50-year study of daily temperatures at more than 1,000 U.S. weather stations, that temperature variability declines with warming, and at a very substantial rate, so this aspect of a warmer world also would lead to a reduction in respiratory-related deaths.

Gouveia *et al*. (2003) extracted daily counts of deaths from all causes, except violent deaths and neonatal deaths (up to one month of age), from Sao Paulo, Brazil's mortality information system for the period 1991–1994 and analyzed them for effects of temperature within three age groups: less than 15 years of age (children), 15–64 years old (adults), and more than 64 years old (elderly). This exercise revealed the change points (the temperatures above and below which temperature begins to impact mortality) for both heat- and cold-induced deaths were identical, at 20°C. For each 1°C increase above

this value for a given and prior day's mean temperature, Gouveia *et al*. observed a 2.6% increase in deaths from all causes in children, a 1.5% increase in deaths from all causes in adults, and a 2.5% increase in deaths from all causes in the elderly. For each 1°C decrease below the 20°C change point, the cold effect was greater, with increases in deaths from all causes in children, adults, and the elderly registering 4.0%, 2.6%, and 5.5%, respectively. These cooling-induced death rates are 54%, 73%, and 120% greater than those due to warming.

Findings with respect to respiratory-induced deaths were similar. Death rates due to a 1°C cooling were twice as great as death rates due to a 1°C warming in adults, and 2.8 times greater in the elderly.

Nakaji *et al*. (2004) evaluated seasonal trends in deaths due to various diseases in Japan, using nationwide vital statistics from 1970 to 1999 and concurrent mean monthly air temperature data. They found the numbers of deaths due to diabetes, digestive diseases, cerebrovascular and heart diseases, infectious and parasitic diseases including tuberculosis, and respiratory diseases including pneumonia and influenza all rise to a maximum during the coldest time of the year. Hence, the team of nine scientists concludes, "to reduce the overall mortality rate and to prolong life expectancy in Japan, measures must be taken to reduce those mortality rates associated with seasonal differences." Consequently, to achieve the scientists' stated objectives, it is necessary to bring about a "reduction in exposure to cold environments," as they put it.

Bartzokas *et al*. (2004) "examined the relationship between hospital admissions for cardio-vascular (cardiac in general including heart attacks) and/or respiratory diseases (asthma etc.) in a major hospital in Athens [Greece] and meteorological parameters for an 8-year period." Over the whole year, they found, "there was a dependence of admissions on temperature," and low temperatures were "responsible for a higher number of admissions." Specifically, "there was a decrease of cardiovascular or/and respiratory events from low to high values [of temperature], except for the highest temperature class in which a slight increase was recorded."

Kovats *et al*. (2004) studied patterns of temperature-related hospital admissions and deaths in Greater London during the mid-1990s. For the three-year period 1994–1996, they found respiratory-related deaths were nearly 150% greater in the depth of winter cold than at the height of summer

warmth. They also found the mortality impact of the heat wave of 29 July to 3 August 1995 (which boosted daily mortality by just over 10%) was so tiny it could not be discerned among the random scatter of plots of three-year-average daily deaths from cardiovascular and respiratory problems versus day of year. Similarly, in a study of temperature effects on mortality in three English counties (Hampshire, West Midlands, and West Yorkshire), McGregor (2005) found "the occurrence of influenza ... helps elevate winter mortality above that of summer."

Carder *et al*. (2005) used generalized linear Poisson regression models to investigate the relationship between outside air temperature and deaths due to all non-accident causes in the three largest cities of Scotland (Glasgow, Edinburgh, and Aberdeen) between January 1981 and December 2001. The authors observed "an overall increase in mortality as temperature decreases," which "appears to be steeper at lower temperatures than at warmer temperatures," and "there is little evidence of an increase in mortality at the hot end of the temperature range." They also state "the observed relation between cold temperature and mortality was typically stronger among the elderly," and "cold temperature effects on mortality persist with lag periods of beyond two weeks." Specifically, "for temperatures below 11°C, a 1°C drop in the daytime mean temperature on any one day was associated with an increase in respiratory mortality of 4.8% over the following month."

Noting "in temperate regions, respiratory disease adds greatly to the workload in general practice facilities and hospitals during the winter," partly because of increases in cases of "bronchiolitis in young children caused by infection with respiratory syncytial virus (RSV)," Donaldson (2006) studied the effect of annual mean daily air temperature on the length of the yearly RSV season. He used weekly data on laboratory reports of RSV isolation by the Health Protection Agency and National Health Service hospital laboratories in England and Wales for 1981–2004, along with meteorological data from four surface stations (Ringway, Squires Gate, Malvern, and Rothamsted) that "are representative of a roughly triangular area of the United Kingdom enclosed by Preston, London, and Bristol."

Reporting "climate change may be shortening the RSV season," Donaldson found "the seasons associated with laboratory isolation of respiratory syncytial virus (for 1981–2004) and RSV-related emergency department admissions (for 1990–2004) ended 3.1 and 2.5 weeks earlier, respectively, per 1°C

increase in annual central England temperature (P = 0.002 and 0.043, respectively)." Consequently, since "no relationship was observed between the start of each season and temperature," he reports, "the RSV season has become shorter." He concludes, "these findings imply a health benefit of global warming in England and Wales associated with a reduction in the duration of the RSV season and its consequent impact on the health service."

According to Frei and Gassner (2008), from 1926 to 1991, hay fever prevalence in Switzerland rose from just under 1% of the country's population to just over 14%, but from 1991 to 2000 it simply fluctuated about a mean value on the order of 15%. In addition, the authors write, "several studies show that no further increase in asthma, hay fever and atopic sensitization in adolescents and adults has been observed during the 1990s and the beginning of the new century," citing Braun-Fahrlander *et al*. (2004) and Grize *et al*. (2006). To see what effect changes in pollen production might have had on this trend in respiratory ailments, Frei and Gassner analyzed daily average concentrations of birch and grass pollen monitored by the country's National Pollen Network at Basel for the period 1969–2007, at Locarno for 1989–2007, and at Zurich for 1982–2007.

The two researchers report "the pollen exposure has been decreasing in Basel since the beginning of the 1990s," and "in Locarno, most of the pollen species also show a decreasing trend," while in Zurich, "most of the pollen types have been increasing," although "some of the pollen counts of this station (grass, stinging nettle, mugwort and ragweed) have been decreasing in the period 1982–2007." In addition, they state the length of the pollen season has recently tended "to get shorter."

Frei and Gassner write, "parallel to the increasing hay fever rate, the pollen amounts of birch and grass were increasing from 1969 to 1990," but "subsequently, the pollen of these plant species decreased from 1991 to 2007." They say this finding "is more or less consistent with the changes of the hay fever rate that no longer increased during this period and even showed a tendency to decrease slightly." Nearly identical findings were presented a year later (Frei, 2009). Although some have claimed rising temperatures and CO_2 concentrations will lead to more pollen and more hay fever (Wayne *et al*., 2002), the analyses of Frei (2009) and Frei and Gassner (2008) suggest that is not true of Switzerland.

Jato *et al*. (2009) collected airborne samples of Poaceae pollen "using Hirst-type volumetric traps" in four cities in Galicia (Northwest Spain)—Lugo,

Santiago, Vigo, and Ourense—noting "the global climate change recorded over recent years may prompt changes in the atmospheric pollen season (APS). The subjected the data "to Spearman's correlation test and regression models, in order to detect possible correlations between different parameters and trends." They calculated the APS "using ten different methods, in order to assess the influence of each on survey results." The Poaceae family (composed chiefly of herbaceous grasses), Jato *et al*. write, "is the most diverse and prolific herbaceous plant family in urban areas," and "its pollen is considered a major aeroallergen, causing symptoms in over 80% of pollen allergy sufferers in Europe (D'Amato *et al*., 2007)."

The four researchers report "all four cities displayed a trend towards lower annual total Poaceae pollen counts, lower peak values and a smaller number of days on which counts exceeded 30, 50 and 100 pollen grains/m^3." The percentage decline in annual pollen grain counts between 1993 and 2007 in Lugo was approximately 75%, and in Santiago the decline was 80%, as best as can be determined from the graphs of the researchers' data. In addition, they write, "the survey noted a trend towards delayed onset and shorter duration of the APS." Thus, even though there was a "significant trend towards increasing temperatures over the months prior to the onset of the pollen season," according the Spanish scientists, Poaceae pollen became far less of a negative respiratory health factor in the four Galician cities over the decade and a half of their study.

Miller *et al*. (2012) say "there is concern that climate change may affect hay fever and other allergic conditions by impacting pollen amount, pollen allergenicity, pollen season, and plant and pollen distribution," because "allergy and atopic disease rates are rising, and global warming has been implicated as a possible cause." They note, "concomitant with climate change over the time course of many of these studies are changes in air pollution levels, economic factors, and lifestyle," and they conducted a study to clarify the situation by separating these potentially confounding factors.

Miller *et al*. extracted annual prevalence data for frequent otitis media (defined as three or more ear infections per year), respiratory allergy, and non-respiratory seizures in children from the U.S. National Health Interview Survey for 1998 to 2006. They also obtained average annual temperatures for the same period from the U.S. Environmental Protection Agency. They performed "complex samples logistic regression analyses" to identify possible correlations

between annual temperature and each of the three disease conditions, while controlling for age and sex.

The three researchers—from the David Geffen School of Medicine at the University of California at Los Angeles, Harvard Medical School, and Brigham and Women's Hospital in Boston—report the regression analysis found "annual temperature did not influence the prevalence of frequent otitis media," "annual temperature did not influence prevalence of respiratory allergy," and "annual temperature and sex did not influence seizure prevalence." Miller *et al*. conclude their findings "may demonstrate that average temperature is not likely to be the dominant cause of the increase in allergy burden or that larger changes in temperatures over a longer period are needed to observe this association." They conclude, "in the absence of more dramatic annual temperature changes, we do not expect prevalence of otitis media to change significantly as global warming may continue to affect our environment."

Xu *et al*. (2013) state "childhood asthma is a major global health issue, affecting more than 300 million people worldwide (Baena-Cagnani and Badellino, 2011)," and it "is regarded as a national health priority in several countries," citing Asher *et al*. (1995, 2006). They studied the relationship between diurnal temperature range (DTR) and the incidence of childhood asthma in Brisbane, Australia. For the study, "a Poisson generalized linear model combined with a distributed lag non-linear model was used to examine the relationship between DTR and emergency department admissions for childhood asthma in Brisbane from January 1st 2003 to December 31st 2009," and daily maximum and minimum temperatures in Brisbane for the same time period were retrieved from the Australian Bureau of Meteorology. Each day's DTR was calculated as the difference between its maximum and minimum temperatures.

The six scientists report "childhood asthma increased above a DTR of 10°C" and "was the greatest for lag 0–9 days, with a 31% increase in [hospital] emergency department admissions per 5°C increment of DTR," further noting, "male children and children aged 5–9 years appeared to be more vulnerable to the DTR effect than others." Since daily minimum temperatures have nearly always risen faster than have daily maximum temperatures in most locations around the globe whenever various regions have warmed, the study's results indicate the decrease in DTR under global warming should lead to a decline in the number of cases of childhood asthma.

Ge *et al*. (2013) also investigated respiratory

health and DTR. They write, "respiratory tract infection (RTI) is among the most common acute diseases worldwide, leading to considerable morbidity, complications, and days lost from work and school," citing Mourtzoukou and Falagas (2007). They report the DTR "has been identified as an independent risk factor for coronary heart disease (Cao *et al.*, 2009; Tam *et al.*, 2009), stroke (Shinkawa *et al.*, 1990; Kyobutungi *et al.*, 2005; Chen *et al.*, 2007), and chronic obstructive pulmonary disease (Song *et al.*, 2008)."

The researchers collected numbers of daily emergency-room visits for RTI at one of the largest medical establishments in Shanghai, China (Huashan Hospital) between 1 January 2008 and 30 June 2009, along with DTR data and data pertaining to possible confounding air pollutants (PM_{10}, SO_2, and NO_2). After making appropriate statistical analyses, the scientists determined increasing DTRs were closely associated with daily emergency-room visits for RTIs, such that "an increase of 1°C in the current-day and in the 2-day moving average DTR corresponded to a 0.94% and 2.08% increase in emergency-room visits for RTI, respectively."

Lin *et al.* (2013) state "high temperatures have garnered considerable attention in Europe and the U.S. because of their short-term adverse health impacts." However, they add, several studies have reported "the adverse health effects of cold temperatures may be more significant than those of high temperatures in Spain, Canada, Shanghai and Taiwan (Gomez-Acebo *et al.*, 2010; Lin *et al.*, 2011; Ma *et al.*, 2011; Martin *et al.*, 2012; Wang *et al.*, 2012)," and "mortality risk associated with low temperatures is likely underestimated when studies fail to address the prolonged effect of low temperature (Martin *et al.*, 2012; Mercer, 2003)." Working with data on daily area-specific deaths from all causes, circulatory diseases, and respiratory diseases, Lin *et al.* developed relationships between each of these cause-of-death categories and a number of cold-temperature related parameters for 2000–2008.

The five researchers discovered "mortality from [1] all causes and [2] circulatory diseases and [3] outpatient visits of respiratory diseases has a strong association with cold temperatures in the subtropical island, Taiwan." In addition, they found "minimum temperature estimated the strongest risk associated with outpatient visits of respiratory diseases."

The several studies described above clearly indicate a warmer world would be a much better world, especially with respect to the respiratory health of the world's citizens.

7.4 Stroke Occurrence

According to IPCC, global warming will pose numerous challenges to human health, including the potential for an excess of deaths. This section examines the results of a number of studies conducted over the past decade or so that deal with this subject as it applies to strokes.

Feigin *et al.* (2000) conducted what they call "the first truly population-based study on the relationship between stroke occurrence and weather parameters in Russia," working within the city of Novosibirsk, Siberia, which has one of the highest stroke incidence rates in the world. Based on analyses of 2,208 patients with sex and age distributions similar to those of Russia as a whole, they found a statistically significant association between stroke occurrence and low ambient temperature over the period 1982–1993. In the case of ischemic stroke (IS), which accounted for 87% of all stroke types, they determined "the risk of IS occurrence on days with low ambient temperature [was] 32% higher than that on days with high ambient temperature." Given what they describe as "the highly significant association observed between low ambient temperature ($< -2.0°C$) and IS occurrence (P = 0.02), together with the proportion of days with such temperature in the region during a calendar year (41.3%)," they conclude the "very high stroke incidence in Novosibirsk, Russia may partially be explained by the highly prevalent cold factor there." They suggest the implementation of "preventive measures in [the] region, such as avoiding low temperature."

Hong *et al.* (2003) investigated the association between the onset of ischemic stroke and prior episodic decreases in temperature in 545 patients who suffered strokes in Incheon, Korea from January 1998 to December 2000. They report "decreased ambient temperature was associated with risk of acute ischemic stroke," with the strongest effect being seen on the day after exposure to cold weather, further noting "even a moderate decrease in temperature can increase the risk of ischemic stroke." They also found "risk estimates associated with decreased temperature were greater in winter than in the summer," which suggests "low temperatures as well as temperature changes are associated with the onset of ischemic stroke." Finally, they explain the reason for the 24- to 48-hour lag between exposure to cold and the onset of stroke "might be that it takes some time for the decreasing temperature to affect blood viscosity or coagulation," which is also suggested by the work of Keatinge *et al.* (1984), who found blood viscosity and the plasma fraction of platelets began to increase one hour after cold exposure and did not reach a peak until sometime beyond six hours later.

Nakaji *et al.* (2004) evaluated seasonal trends in deaths due to various diseases in Japan using nationwide vital statistics from 1970 to 1999 together with mean monthly temperature data. They note Japan has "bitterly cold winters," and their analysis indicates the number of deaths due to cerebrovascular disease rises to a maximum during that cold time of year. They found the peak mortality rate due to stroke was two times greater in winter (January) than at the time of its yearly minimum (August and September). The team of nine scientists say it is necessary to bring about a "reduction in exposure to cold environments," as they put it.

Chang *et al.* (2004) analyzed data from the World Health Organization (WHO) Collaborative Study of Cardiovascular Disease and Steroid Hormone Contraception (WHO, 1995) to determine the effects of monthly mean temperature on rates of hospitalization for arterial stroke and acute myocardial infarction among women aged 15–49 from 17 countries in Africa, Asia, Europe, Latin America, and the Caribbean. Among these women, a 5°C reduction in mean air temperature was associated with a 7% increase in the expected hospitalization rate due to stroke, and this effect was relatively acute, within a period of about a month, the scientists write.

Each spring, Asian dust storm (ADS) events originating in the deserts of Mongolia and China transport great quantities of fine particulate matter of 10µm diameter (PM_{10}) to populated cities of East Asia, including Taipei, Taiwan, where the tiny

particles have the potential to affect people's lives in a very big way. In an attempt to assess one aspect of this phenomenon, Yang *et al.* (2005) identified 54 ADS events that affected Taipei from 1996 to 2001, and they evaluated the impacts of these events on hospital admissions for primary intracerebral hemorrhagic stroke (PIH), ischemic stroke (IS), as well as the conglomerate of strokes of all types. The scientists found associations between dust storms and total stroke admissions and PIH and IS admissions were prominent three days after ADS events, with the relative risk for total stroke admissions being 1.05, that for IS admissions being 1.04, and that for PIH admissions being 1.15, with the latter finding being deemed statistically significant. For this particular stroke category, they additionally determined risk of stroke rose by 2.67% for each 10 $\mu g/m^3$ increase in PM_{10} concentration above the normal mean value of 55.43 $\mu g/m^3$.

With respect to how the ongoing rise in the air's CO_2 content might impact this phenomenon, Chapter 1 of this volume discusses the well-documented increase in plant water use efficiency that results from increases in atmospheric CO_2 concentration. This benefit should allow more plants to grow in the arid source regions of the Asian dust clouds, which will help to stabilize the soil and decrease its susceptibility to wind erosion, thereby reducing the severity of ADS events. Second, the propensity for elevated CO_2 concentrations to increase moisture contents of soils beneath plant canopies as a consequence of CO_2-induced reductions in plant transpiration also should lead to greater ground cover and reduced wind erosion. Third, the ability of extra CO_2 in the atmosphere to enhance the growth of cryptobiotic soil crusts should stabilize the surface of the soil. And fourth, as noted by Zavaleta *et al.* (2003), global warming itself may increase soil moisture contents in water-limited regions by hastening plant senescence and thereby reducing the period of time over which transpiration-driven soil water losses occur.

If the air's CO_2 content continues to rise, even in the face of further warming, there should be a gradual reduction in the number of PM_{10}–induced strokes in the populace of Taipei, Taiwan, as well as in other places affected by Asian and other dust storms.

Gill *et al.* (2012) write, "in the past two decades, several studies reported that meteorologic changes are associated with monthly and seasonal spikes in the incidence of aneurysmal subarachnoid hemorrhage (aSAH)," and "analysis of data from large regional databases in both hemispheres has revealed increased seasonal risk for aSAH in the fall, winter and spring,"

citing Chyatte *et al.* (1994), Lejeune *et al.* (1994), Langmayr *et al.* (1995), Feigin *et al.* (2001), Abe *et al.* (2008), and Beseoglu *et al.* (2008). Gill *et al.* identified the medical records of 1,175 patients at the Johns Hopkins Hospital in Baltimore, Maryland (USA) who were admitted with a radiologically confirmed diagnosis of aSAH between 1 January 1991 and 1 March 2009. The researchers employed Poisson regression "to model the risk of a patient presenting with aSAH based on maximum ambient temperature (MAT), average relative humidity (ARH), and atmospheric pressure, clustering by season of the year to control for the previously reported relationship between season and aSAH presentation."

The six scientists report both "a one-day decrease in temperature and colder daily temperatures were associated with an increased risk of incident aSAH," and "these variables appeared to act synergistically" and were "particularly predominant in the fall, when the transition from warmer to colder temperatures occurred." Gill *et al.* add their study "is the first to report a direct relationship between a temperature decrease and an increased risk of aSAH," and "it also confirms the observations of several reports of an increased risk of aSAH in cold weather or winter," citing Lejeunne *et al.* (1994), Jakovljevic *et al.* (1996), and Nyquist *et al.* (2001).

7.5 Malaria

- A vast body of scientific examination and research contradict the claim that malaria will expand across the globe and intensify as a result of CO_2-induced warming.

According to IPCC, ""If climate change continues as projected in scenarios in the next few decades, the major increases of ill-health compared to no climate change will occur through …increased risks of food- and water-borne diseases and vector-borne infections. *[high confidence]" (IPCC-II, 2013).* Chapter 11, Human Health, Working Group II, *IPCC Fifth Assessment Report,* dated March 28, 2013, p. 3, italics in original, bold removed). This section investigates the reliability of IPCC's claim with respect to malaria.. According to the results of a vast body of scientific examination and research on this topic, there is little support for IPCC's claims. The next two sections will address the related claims regarding dengue fever and tick-borne diseases.

In a research report in *Science*, Rogers and Randolph (2000) note "predictions of global climate change have stimulated forecasts that vector-borne diseases will spread into regions that are at present too cool for their persistence." There are, however, several problems with this scenario.

According to Reiter (2000), claims that malaria resurgence is the product of CO_2-induced global warming ignore other important factors and disregard known facts. A historical analysis of malaria trends, for example, reveals this disease was an important cause of illness and death in England during a period of colder-than-present temperatures throughout the Little Ice Age. Its transmission began to decline only in the nineteenth century, during a warming phase, when, according to Reiter, "temperatures were already much higher than in the Little Ice Age." In short, malaria was prevalent in Europe during some of

the coldest centuries of the past millennium, and it has only recently undergone widespread decline, when temperatures have been warming, Clearly, there are other factors at work that are more important than temperature. Such factors include the quality of public health services, irrigation and agricultural activities, land use practices, civil strife, natural disasters, ecological change, population change, use of insecticides, and the movement of people (Reiter, 2000; Reiter, 2001; Hay *et al.*, 2002).

Nevertheless, concerns have lingered about the possibility of widespread future increases in malaria due to global warming. These concerns are generally rooted in climate models that typically use only one, or at most two, climate variables in making their predictions of the future distribution of the disease over Earth, and they generally do not include any of the non-climatic factors listed in the preceding paragraph. When more variables are included, a less-worrisome future is projected. In one modeling study, for example, Rogers and Randolph (2000) employed five climate variables and obtained very different results. Briefly, they used the present-day distribution of malaria to determine the specific climatic constraints that best define that distribution, after which the multivariate relationship they derived from this exercise was applied to future climate scenarios derived from state-of-the-art climate models, in order to map potential future geographical distributions of the disease.

Their study revealed very little change: a 0.84% increase in potential malaria exposure under the "medium-high" scenario of global warming and a 0.92% decrease under the "high" scenario. Rogers and Randolph explicitly state their quantitative model "contradicts prevailing forecasts of global malaria expansion" and "highlights the use of multivariate rather than univariate constraints in such applications."

Hay *et al.* (2002) investigated long-term trends in meteorological data at four East African highland sites that experienced significant increases in malaria cases over the past couple of decades, reporting "temperature, rainfall, vapour pressure and the number of months suitable for *P. falciparum* transmission have not changed significantly during the past century or during the period of reported malaria resurgence." Thus these factors could not be responsible for the observed increases in malaria cases. Likewise, Shanks *et al.* (2000) examined trends in temperature, precipitation, and malaria rates in western Kenya over the period 1965–1997, finding no linkages among the variables.

Small *et al.* (2003) examined trends in a climate-driven model of malaria transmission between 1911 and 1995, using a spatially and temporally extensive gridded climate dataset to identify locations in Africa where the malaria transmission climate suitability index had changed significantly over this time interval. After determining areas of change, they more closely examined the underlying climate forcing of malaria transmission suitability for those localities. They found malaria transmission suitability did indeed increase because of climate change in specific locations of limited extent, but in Southern Mozambique, the only region for which climatic suitability consistently increased, the cause of the increase was increased precipitation, not temperature. Small *et al.* state, "climate warming, expressed as a systematic temperature increase over the 85-year period, does not appear to be responsible for an increase in malaria suitability over any region in Africa." They conclude "research on the links between climate change and the recent resurgence of malaria across Africa would be best served through refinements in maps and models of precipitation patterns and through closer examination of the role of nonclimatic influences," the great significance of which also has been demonstrated by Reiter *et al.* (2003) for dengue fever, another important mosquito-borne disease.

Zhou *et al.* (2004) employed a nonlinear mixed-regression model study that focused on the numbers of monthly malaria outpatients of the past 10–20 years in seven East African highland sites and their relationships to the numbers of malaria outpatients during the previous time period, seasonality, and climate variability. They state, "for all seven study sites, we found highly significant nonlinear, synergistic effects of the interaction between rainfall and temperature on malaria incidence, indicating that the use of either temperature or rainfall alone is not sensitive enough for the detection of anomalies that are associated with malaria epidemics." Githeko and Ndegwa (2001), Shanks *et al.* (2002), and Hay *et al.* (2002) reached the same conclusion. In addition, climate variability—not just temperature or not just warming—contributed less than 20% of the temporal variance in the number of malaria outpatients, and at only two out of the seven sites studied.

Zhou *et al.* conclude "malaria dynamics are largely driven by autoregression and/or seasonality in these sites," and "the observed large among-site variation in the sensitivity to climate fluctuations may be governed by complex interactions between climate and biological and social factors." The latter include

"land use, topography, *P. falciparum* genotypes, malaria vector species composition, availability of vector control and healthcare programs, drug resistance, and other socioeconomic factors," including "failure to seek treatment or delayed treatment of malaria patients, and HIV infections in the human population," which they say have "become increasingly prevalent."

In a major review of the potential impacts of global warming on vector-borne diseases, Rogers and Randolph (2006) focus on recent upsurges of malaria in Africa, asking, "Has climate change already had an impact?" They demonstrate "evidence for increasing malaria in many parts of Africa is overwhelming, but the more likely causes for most of these changes to date include land-cover and land-use changes and, most importantly, drug resistance rather than any effect of climate," noting "the recrudescence of malaria in the tea estates near Kericho, Kenya, in East Africa, where temperature has not changed significantly, shows all the signs of a disease that has escaped drug control following the evolution of chloroquine resistance by the malarial parasite."

They explain, "malaria waxes and wanes to the beat of two rhythms: an annual one dominated by local, seasonal weather conditions and a *ca*. 3-yearly one dominated by herd immunity," noting "effective drugs suppress both cycles before they can be expressed," but "this produces a population which is mainly or entirely dependent on drug effectiveness, and which suffers the consequence of eventual drug failure, during which the rhythms reestablish themselves, as they appear to have done in Kericho."

Two more review papers on the subject followed two years later. In the first, Zell *et al.* (2008) write, "it is assumed that global warming is forced by the anthropogenic release of 'greenhouse gases,'" and a further "consistent assumption" has been a consequent "increased exposure of humans to tropical pathogens and their vectors." They also note "there is dissent about this hypothesis (Taubes, 1997; Reiter, 2001; Hay *et al*., 2002; Reiter *et al*., 2003; Randolph, 2004; Zell, 2004; Halstead, 2008)," and they explore it in more detail, examining the pertinent literature and describing "those mechanisms that have led to an increase of virus activity in recent years."

Based on their review, the three German researchers report "only very few examples point toward global warming as a cause of excess viral activity." Instead, they determined "coupled ocean/atmosphere circulations and continuous anthropogenic disturbances (increased populations of humans and domestic animals, socioeconomic

instability, armed conflicts, displaced populations, unbalanced ecosystems, dispersal of resistant pathogens etc.) appear to be the major drivers of disease variability," and "global warming at best contributes."

In the second 2008 paper (Reiter, 2008), Paul Reiter—who works with the Insects and Infectious Disease Unit of the Institut Pasteur in Paris, France—writes, "man-made climate change has become a defining moral and political issue of our age," noting "speculations on its potential impact often focus on infectious diseases, and on malaria in particular," and "predictions are common that in the coming decades, tens—even hundreds—of millions more cases will occur in regions where the disease is already present, and that the vectors and the pathogens will move to higher latitudes and altitudes," infecting even more people.

In analyzing these claims, Reiter first discusses the mathematical models employed in this endeavor, after which he discusses common misconceptions and the nature of malaria in temperate regions. In the latter discussions he mentions such items as ecological change, new farm crops, new rearing practices, urbanization and mechanization, human living conditions, and medical care. Then, in a discussion of malaria in the tropics, he considers stable endemic malaria, unstable endemic malaria, birth rate, forest clearance, agriculture, movement of people, urbanization, insecticide resistance, resistance to drugs, degradation of the health infrastructure, and war and civil strife. He then treats three additional topics: Highland malaria in the tropics, Kenya Highlands, and New Guinea Highlands.

Reiter concludes, "simplistic reasoning on the future prevalence of malaria is ill-founded; malaria is not limited by climate in most temperate regions, nor in the tropics, and in nearly all cases, 'new' malaria at high altitudes is well below the maximum altitudinal limits for transmission." He further states, "future changes in climate may alter the prevalence and incidence of the disease, but obsessive emphasis on 'global warming' as a dominant parameter is indefensible; the principal determinants are linked to ecological and societal change, politics and economics." Reiter's conclusions have been borne out in additional studies of the subject.

Jackson *et al*. (2010) say "malaria is one of the most devastating vector-borne parasitic diseases in the tropical and subtropical regions of the world," noting it affects more than 100 countries. According to the World Health Organization, Africa carries the highest infection burden of any continent, with nearly

200 million cases reported in 2006, and the Centers for Disease Control and Prevention estimates between 700,000 and 2.7 million people each year die from the dreaded disease (Suh *et al.*, 2004). In addition, Jackson *et al.* report "the African region bears 90% of these estimated worldwide deaths," and "three-quarters of all malaria related deaths are among African children," citing Breman (2001). They opine, "malaria could be greatly affected by the influence of climate change," such as global warming.

The five U.S. researchers linked reported malaria cases and deaths from the years 1996 to 2006, obtained from the World Malaria Report (2008) for 10 countries in western Africa (Benin, Burkina Faso, Cote d'Ivoire, Gambia, Ghana, Liberia, Mali, Senegal, Sierra Leone, and Togo) with corresponding climate data from the U.S. National Oceanic and Atmospheric Administration's National Climatic Data Center. They searched for transitive relationships between the weather variables and malaria rates via spatial regression analysis and tests for correlation. Jackson *et al.* report their analyses showed "very little correlation exists between rates of malaria prevalence and climate indicators in western Africa." This result, as they describe it, "contradicts the prevailing theory that climate and malaria prevalence are closely linked and also negates the idea that climate change will increase malaria transmission in the region."

Stern *et al.* (2011) examined trends in temperature and malaria for the Highlands of East Africa, which span Rwanda, Burundi, and parts of Kenya, Tanzania, and Uganda, to resolve controversies over whether the area has warmed and malaria has become more prevalent. For temperature, the authors used three time series obtained from the Climatic Research Unit (CRU) for four locations. Temperature data for Kericho extend through 2009, but only through 2006 for the Highlands. For malaria, the researchers used a data set on malaria cases through May 2010 at a hospital in Kericho, Kenya, and data from more than 5,200 surveys on the prevalence of malaria though 2009 in the Highlands. They report temperature has increased significantly in the region, yet "malaria in Kericho and many other areas of East Africa has decreased during periods of unambiguous warming." Their paper does not attempt an explanation for the divergence in these trends.

In a model-based study, Nkurunziza and Pilz (2011) employed Bayesian generalized additive models (GAMs) to assess the impact of an increase in temperature on malaria transmission in Burundi. Overall, the two researchers write, "the results of the GAMs show that an increase in the maximum temperature will cause an increase in minimum temperature," and "the increase in the latter will result in a decreasing maximum humidity, leading to a decrease in rainfall." These results, the writers continue, "suggest that an increased temperature will result in a shortening of the life span of mosquitoes (due to decreasing humidity) and decrease in the capacity of larva production and maturation (due to decreasing rainfall)." Thus, "the increase in temperature will not result in an increased malaria transmission in Burundi," which is "in good agreement with some previous works on the topic," citing as examples WHO, WMO, UNEP (2003), Lieshout *et al.* (2004), and Thomas (2004). In a final statement on the matter, Nkurunziza and Pilz note that in regions with endemic malaria transmission, such as Burundi, "the increase in temperature may lead to unsuitable climate conditions for mosquitoes survival and, hence, probably to a decreasing malaria transmission."

In another model-based study, Béguin *et al.* (2011) quantified the independent effects of climate and socioeconomic factors on the historical and projected future global distribution of malaria. The authors also provide estimates of the factors' separate and combined contributions to the populations at risk of malaria. Specifically, they estimated populations at risk of malaria (PAR) based on climatic variables, population growth, and GDP per capita (GDP$_{pc}$). GDP$_{pc}$ is an approximation for per-capita income ("income" for short) for 1990, 2010, and 2050, based on sensitivity analyses for the following three scenarios: (1) a worst-case scenario, in which income declines to 50% of its 2010 values by 2050; (2) a ''growth reduction'' scenario, in which income declines by 25% in 2030 and 50% in 2050, relative to the A1B scenario; and (3) a scenario in which income stays constant at 2010 values.

The PAR was derived from information on the presence or absence of *P. vivax* malaria in 1990 based on a logistic model for malaria presence that used three parameters: the mean temperature of the coldest month, the mean precipitation of the wettest month during the period 1961–1990, and the square root of income. Accordingly, the PAR does not directly reflect the health impacts of malaria. Secular technological change was ignored in this study. The results are presented in Table 7.5.1.

The authors observe, "under the A1B climate scenario, climate change has much weaker effects than GDP$_{pc}$ increase on the geographic distribution of malaria." This result is consistent with the few studies that have considered the impact of climate change and

Model type	Population at Risk 2030 [billions]	Population at Risk 2050 [billions]
Socioeconomic changes only (no climate change)	3.52	1.74
Socioeconomic and climatic changes (A1B scenario)	3.58 [3.55–3.60]	1.95 [1.93–1.96]
Socioeconomic changes and CC (slower growth scenario)	3.82 [3.39–3.84]	3.42 [3.28–3.45]
No growth scenario , only CC	4.61 [4.54–4.67]	5.20 [5.11–5.25]
Pessimistic growth scenario and CC	5.18 [5.07–5.30]	6.27 [6.19–6.32]

Table 7.5.1. Effects of Climate and Socioeconomic Factors on the Projected Future Global Distribution of Malaria. From Béguin *et al*. (2011).

socioeconomic factors on malaria. (See, e.g., Tol and Dowlatabadi, 2001; Bosello *et al*., 2006). With respect to malaria, therefore, climate change is a relatively minor factor compared to economic development.

Kuhn *et al*. (2003) state, "there has been much recent speculation that global warming may allow the reestablishment of malaria transmission in previously endemic areas such as Europe and the United States." In particular, they note "the British Chief Medical Officer's recent report [*Getting Ahead of the Curve: A Strategy for Combating Infectious Diseases (Including Other Aspects of Health Protection)*, Department of Health (2002), London] asserted that 'by 2050 the climate of the UK may be such that indigenous malaria could become re-established.'" To investigate the robustness of this hypothesis, they analyzed the determinants of temporal trends in malaria deaths within England and Wales in 1840–1910.

With respect to temperature changes over the period of study, Kuhn *et al*. report "a 1°C increase or decrease was responsible for an increase in malaria deaths of 8.3% or a decrease of 6.5%, respectively," which explains "the malaria epidemics in the 'unusually hot summers' of 1848 and 1859." Nevertheless, the long-term near-linear temporal decline in malaria deaths over the period of study, the researchers write, "was probably driven by nonclimatic factors," among which they identify increasing livestock populations (which tend to divert mosquito biting from humans), decreasing acreages of marsh wetlands (where mosquitoes breed), as well as "improved housing, better access to health care and

medication, and improved nutrition, sanitation, and hygiene." They also note the number of secondary cases arising from each primary imported case "is currently minuscule," as demonstrated by the absence of any secondary malaria cases in the UK since 1953.

Although simplistic model simulations may suggest the increase in temperature predicted for Britain by 2050 is likely to cause an 8–14% increase in the potential for malaria transmission, Kuhn *et al*. say "the projected increase in proportional risk is clearly insufficient to lead to the reestablishment of endemicity." They note "the national health system ensures that imported malaria infections are detected and effectively treated and that gametocytes are cleared from the blood in less than a week." For Britain, therefore, they conclude "a 15% rise in risk might have been important in the 19th century, but such a rise is now highly unlikely to lead to the reestablishment of indigenous malaria," because "socioeconomic and agricultural changes" have greatly altered the cause-and-effect relationships of the past.

Hulden and Hulden (2009) analyzed malaria statistics collected in Finland from 1750 to 2008 via correlation analyses between malaria frequency per million people and all variables that have been used in similar studies throughout other parts of Europe, including temperature data, animal husbandry, consolidation of land by redistribution, and household size. They report "malaria was a common endemic disease in Finland in the 18th and 19th centuries and prevalent in the whole country" and "mortality during malaria epidemics usually varied between 0.85 and 3%." Thereafter, however, they found "malaria

declined slowly in Finland without any deliberate counter-measures," such that "the last epidemic in Helsinki occurred in 1902" and "during the 1930s malaria was close to extinction." Over the entire period, "malaria frequency decreased from about 20,000–50,000 per 1,000,000 people to less than 1 per 1,000,000 people," they report.

When malaria was still common in the country, they did find "high peaks in malaria followed high temperatures in June–July," but overriding this within-year temperature response over the long term, "both highs and lows in malaria frequency [were] declining independently of temperature trends." The two Finnish researchers conclude, "indigenous malaria in Finland faded out evenly in the whole country during 200 years with limited or no counter measures or medication," making that situation "one of the very few opportunities where natural malaria dynamics can be studied in detail." Their study indicates "malaria in Finland basically was a sociological disease and that malaria trends were strongly linked to changes in the human household size and housing standard."

Childs *et al.* (2006) present a detailed analysis of malaria incidence in northern Thailand based on a quarter-century monthly time series (January 1977 through January 2002) of total malaria cases in the country's 13 northern provinces. Over this time period, when IPCC claims the world warmed at a rate and to a level unprecedented over the prior one to two millennia, Childs *et al.* report there was an approximately constant rate of decline in total malaria incidence (from a mean monthly incidence in 1977 of 41.5 cases per hundred thousand people to 6.72 cases per hundred thousand people in 2001). This decrease was due primarily to a reduction in cases positive for *Plasmodium falciparum* (mean monthly incidence in 1977 and 2001 of 28.6 and 3.22 cases per 100,000 people, respectively) and secondarily to a reduction in cases positive for *P. vivax* (mean monthly incidence in 1977 and 2001 of 12.8 and 3.5 cases per 100,000 people, respectively). Consequently, noting "there has been a steady reduction through time of total malaria incidence in northern Thailand, with an average decline of 6.45% per year," they say this result "reflects changing agronomic practices and patterns of immigration, as well as the success of interventions such as vector control programs, improved availability of treatment and changing drug policies."

Haque *et al.* (2010) analyzed monthly malaria case data for the malaria endemic district of Chittagong Hill Tracts in Bangladesh from January 1989 to December 2008, looking for potential relationships between malaria incidence and various climatic parameters (rainfall, temperature, humidity, sea surface temperature, and the El Niño-Southern Oscillation), as well as the normalized difference vegetation index (NDVI), a satellite-derived measure of surface vegetation greenness. The six scientists report, "after adjusting for potential mutual confounding between climatic factors there was no evidence for any association between the number of malaria cases and temperature, rainfall and humidity," and "there was no evidence of an association between malaria cases and sea surface temperatures in the Bay of Bengal and NINO3." Instead, they found "the best leading indicator of the number of malaria cases was NDVI at a lag of 0–3 months, and that NDVI was negatively associated with malaria cases," such that "each 0.1 increase in monthly NDVI was associated with a 30.4% decrease in malaria cases." Haque *et al.* write, "it seems counterintuitive that a low NDVI, an indicator of low vegetation greenness, is associated with increases in malaria cases," since the primary vectors of the disease in Bangladesh are associated with forests. In light of this surprising result, they state their study "draws attention again to the complex nature of the relationship between malaria and climate," which in the case of the highlands of Bangladesh appears to be nonexistent.

Paaijmans *et al.* (2012) state "the development rate of parasites and pathogens within vectors typically increases with temperature," and, therefore, "transmission intensity is generally assumed to be higher under warmer conditions." However, they note, "development is only one component of parasite/pathogen life history," adding, "there has been little research exploring the temperature sensitivity of other traits that contribute to transmission intensity."

Paaijmans *et al.* examined prior "standard assumptions" and explored the resulting implications "for our understanding of the effects of temperature on disease transmission" on the rodent malaria *Plasmodium yoelii* and the Asian malaria vector *Anopheles stephensi.* The three U.S. researchers found "vector competence (the maximum proportion of infectious mosquitoes, which implicitly includes parasite survival across the incubation period) tails off at higher temperatures, even though parasite development rate increases." Moreover, "the standard measure of the parasite incubation period (i.e., time until the first mosquitoes within a cohort become infectious following an infected blood-meal) is incomplete because parasite development follows a cumulative distribution, which itself varies with

temperature." Finally, "including these effects in a simple model dramatically alters estimates of transmission intensity and reduces the optimum temperature for transmission." Paaijmans *et al.* conclude their results "challenge current understanding of the effects of temperature on malaria transmission dynamics," and they note their findings imply "control at higher temperatures might be more feasible than currently predicted." Therefore, in regard to "the possible effects of climate warming," they conclude "increases in temperature need not simply lead to increases in transmission."

Russell (2009), a professor in the Department of Medicine of the University of Sydney (Australia) and founding director of its Department of Medical Entomology, reports, "during the past 10 years, there has been increasing concern for health impacts of global warming in Australia, and continuing projections and predictions for increasing mosquito-borne disease as a result of climate change." He writes, these claims "are relatively simplistic, and do not take adequate account of the current or historic situations of the vectors and pathogens, and the complex ecologies that might be involved." Russell reviewed the consequences of these several inadequacies for malaria, dengue fever, the arboviral arthritides (Ross River and Barmah Forest viruses), and the arboviral encephalitides (Murray Valley encephalitis and Kunjin viruses) within the context of predictions of climate change modeled by Australia's Commonwealth Scientific and Industrial Research Organisation (CSIRO) and the Intergovernmental Panel on Climate Change (IPCC).

The abstract of Russell's paper begins with a question: "Will warming climate increase the risk or prevalence of mosquito-borne disease in Australia, as has been projected in a number of scientific publications and governmental reports?" His conclusion provides the answer: "there might be some increases in mosquito-borne disease in Australia with a warming climate, but with which mosquitoes and which pathogens, and where and when, cannot be easily discerned." He concludes, "of itself, climate change as currently projected, is not likely to provide great cause for public health concern with mosquito-borne disease in Australia."

Tuchman *et al.* (2003) took leaf litter from *Populus tremuloides* (Michaux) trees that had been grown out-of-doors in open-bottom root boxes located within open-top aboveground chambers maintained at atmospheric CO_2 concentrations of either 360 or 720 ppm for an entire growing season, incubated the leaf litter for 14 days in a nearby stream, and fed the incubated litter to four species of detritivorous mosquito larvae to assess its effect on their development rates and survivorship. They report larval mortality was 2.2 times higher for *Aedes albopictus* (Skuse) mosquitos that were fed leaf litter that had been produced in the high-CO_2 chambers than it was for those fed litter that had been produced in the ambient-air chambers. In addition, they found larval development rates of *Aedes triseriatus* (Say), *Aedes aegypti* (L.), and *Armigeres subalbatus* (Coquillett) were slowed by 78%, 25%, and 27%, respectively, when fed litter produced in the high-CO_2 as opposed to the ambient-CO_2 chambers, so mosquitoes of these species spent 20, 11, and 9 days longer in their respective larval stages when feeding on litter produced in the CO_2-enriched as compared to the ambient-CO_2 chambers. The researchers suggest "increases in lignin coupled with decreases in leaf nitrogen induced by elevated CO_2 and subsequent lower bacterial productivity [on the leaf litter in the water] were probably responsible for [the] decreases in survivorship and/or development rate of the four species of mosquitoes."

Concerning the significance of these findings, Tuchman *et al.* write, "the indirect impacts of an elevated CO_2 atmosphere on mosquito larval survivorship and development time could potentially be great," because longer larval development times could result in fewer cohorts of mosquitoes surviving to adulthood. With fewer mosquitoes, there should be lower levels of mosquito-borne diseases.

Zell (2004) states many people "assume a correlation between increasing disease incidence and global warming." However, he concludes after studying the issue in considerable depth, "the factors responsible for the emergence/reemergence of vector-borne diseases are complex and mutually influence each other." As an example of this complexity, he notes, "the incidence and spread of parasites and arboviruses are affected by insecticide and drug resistance, deforestation, irrigation systems and dams, changes in public health policy (decreased resources of surveillance, prevention and vector control), demographic changes (population growth, migration, urbanization), and societal changes (inadequate housing conditions, water deterioration, sewage, waste management)." Therefore, he continues, "it may be over-simplistic to attribute emergent/re-emergent diseases to climate change and sketch the menace of devastating epidemics in a warmer world." Zell states, "variations in public health practices and lifestyle can easily outweigh changes in disease biology," especially those that might be caused by

global warming.

Nabi and Qader (2009) considered the climatic conditions that impact the spread of malaria—temperature, rainfall, and humidity—and the host of pertinent nonclimatic factors that play important roles in its epidemiology: the presence or absence of mosquito control programs, the availability or non-availability of malaria-fighting drugs, changing resistances to drugs, the quality of vector control, changes in land use, the availability of good health services, human population growth, human migrations, international travel, and standard of living. The two researchers report "global warming alone will not be of a great significance in the upsurge of malaria unless it is accompanied by a deterioration in other parameters like public health facilities, resistance to anti-malarial drugs, decreased mosquito control measures," etc. They say "no accurate prediction about malaria can truly be made," because "it is very difficult to estimate what the other factors will be like in the future." They do note, however, mosquito-borne diseases were a major public health problem in the United States from the 1600s to the mid-1900s, "with occasional epidemics." By the middle of the twentieth century, however, "malaria disappeared from the country along with the other mosquito borne diseases like Dengue and Yellow fever," and "this decline was attributed to overall improvements in living conditions and better public health measures." These factors have kept these diseases at bay throughout the latter half of the twentieth century as well, even though that period included what climate alarmists describe as "unprecedented global warming."

Nabi and Qader conclude "as public health workers, it would be more justifiable for us to exert our efforts on these other [non-climatic] parameters for the eradication and control of malaria."

Gething *et al.* (2010) observe, based on "model predictions" it is "reported widely in global climate policy debates that climate change is adding to the present-day burden of malaria and will increase both the future range and intensity of the disease," citing IPCC (2007) and the U.S. Environmental Protection Agency (2010). Noting "it has long been known that the range of malaria has contracted through a century of economic development and disease control (Hay *et al.*, 2009)," when "global temperature increases have been unequivocal," Gething *et al.* explore this seeming incongruity by comparing "an evidence-based map of contemporary malaria endemicity (Hay *et al.*, 2009)" with "the most reliable equivalent for the pre-intervention era, around 1900 (Lysenko *et al.*,

1968)," when malaria was "at its assumed historical peak," thereby providing a comparison of "the magnitude of observed changes in range and endemicity to those proposed to occur in response to climate change."

The six scientists—from the Spatial Ecology and Epidemiology Group, the Malaria Public Health and Epidemiology Group, and the Centre for Tropical Medicine of the UK's University of Oxford, plus the Departments of Biology and Geography and the Emerging Pathogens Institute of the United States' University of Florida—report "comparison of the historical and contemporary maps revealed that endemic/stable malaria is likely to have covered 58% of the world's land surface around 1900 but only 30% by 2007." They report, "even more marked has been the decrease in prevalence within this greatly reduced range, with endemicity falling by one or more classes in over two-thirds of the current range of stable transmission." They write, "widespread claims that rising mean temperatures have already led to increases in worldwide malaria morbidity and mortality are largely at odds with observed decreasing global trends in both its endemicity and geographic extent." Rather, "the combined natural and anthropogenic forces acting on the disease throughout the twentieth century have resulted in the great majority of locations undergoing a net reduction in transmission between one and three orders of magnitude larger than the maximum future increases proposed under temperature-based climate change scenarios."

Gething *et al.* conclude there has been "a decoupling of the geographical climate-malaria relationship over the twentieth century, indicating that non-climatic factors have profoundly confounded this relationship over time." They note "non-climatic factors, primarily direct disease control and the indirect effects of a century of urbanization and economic development, although spatially and temporally variable, have exerted a substantially greater influence on the geographic extent and intensity of malaria worldwide during the twentieth century than have climatic factors." As for the future, they conclude climate-induced effects "can be offset by moderate increases in coverage levels of currently available interventions."

The many findings described above make it clear a vast body of scientific examination and research contradict the claim that malaria will expand across the globe and intensify as a result of CO_2-induced warming.

7.6 Dengue Fever

- Concerns over large increases in vector-borne diseases such as dengue as a result of rising temperatures are unfounded and unsupported by the scientific literature, as climatic indices are poor predictors for dengue disease.

According to Ooi and Gubler (2009), "dengue/dengue hemorrhagic fever is the most important vector-borne viral disease globally," with more than half the world's population living in areas deemed to be at risk of infection. Also, they note, "many voices have raised concern that global warming is likely to increase the geographic distribution of the dengue mosquito vectors and the frequency and magnitude of dengue epidemics." Such concerns, as evidenced by the papers discussed below, are ill-founded.

In a major review of mosquito-borne diseases by one of the world's premier authorities on the subject, Reiter (2001) analyzed the history of malaria and dengue fever in an attempt to determine whether the incidence and range of influence of these diseases would indeed increase in response to CO_2-induced global warming. This review indicates the natural history of these vector-borne diseases is highly complex, and the interplay of climate, ecology, vector biology, and a number of other factors defies definition by the simplistic analyses utilized in models that generate predictions of future geographical changes in these diseases under various global warming scenarios.

That there has in fact been a resurgence of these diseases in parts of the world is true; but, as Reiter notes, it is "facile to attribute this resurgence to climate change." This he shows via a number of independent analyses that clearly demonstrate factors associated with politics, economics, and human activity are the principal determinants of the spread of these diseases. He describes these factors as being "much more significant" than climate in promoting

disease expansion.

Two years later, Reiter took up the subject again, this time with 19 other scientists as coauthors (Reiter *et al*., 2003). They began by noting "it has frequently been stated that dengue, malaria, and other mosquito-borne diseases will become common in the United States as a result of global warming (Watson *et al*., 1996; Jetten and Focks, 1997; Patz *et al*., 1998; Watson *et al*., 1998)." The Intergovernmental Panel on Climate Change had played a key role in promoting this claim, but Reiter and his colleagues had acquired solid evidence to prove IPCC was simply wrong on this point.

In the summer of 1999, toward the end of a significant dengue outbreak in "los dos Laredos"—Laredo, Texas, USA (population 200,000) and Nuevo Laredo, Tamaulipas, Mexico (population 290,000)—the team of scientists conducted a seroepidemiologic survey to examine factors affecting dengue trans-mission in the two cities, located adjacent to each other on opposite sides of the Rio Grande and experience, according to the team, "massive cross-border traffic across three multi-lane bridges." They report "the incidence of recent cases, indicated by immunoglobulin M antibody serosurvey, was higher in Nuevo Laredo [16.0% vs. 1.3%], although the vector, *Aedes aegypti*, was more abundant in Laredo [91% vs. 37%]." Reiter *et al*. determined "environmental factors that affect contact with mosquitoes, such as air-conditioning and human behavior, appear to account for this paradox."

They found, for example, "the proportion of dengue infections attributable to lack of air-conditioning in Nuevo Laredo [where only 2% of the homes had central air-conditioning compared to 36% of the homes in Laredo] was 55%," which means 55% of the cases of dengue in Nuevo Laredo would not have occurred if all households there had had air-conditioning. Reiter *et al*. conclude, therefore, "if the current warming trend in world climates continues, air-conditioning may become even more prevalent in the United States, in which case, the probability of dengue transmission [there] will likely decrease." Likewise, if the economy of Mexico continues to grow, the use of air-conditioners likely will increase there as well, which likely would lead to even greater decreases in the occurrence of dengue fever in that country.

In a major review of the general subject of infectious diseases in a warming world, Roland Zell (2004) of the Institute for Virology and Antiviral Therapy at the Fredrich Schiller University in Jena, Germany, reviewed what was known about the putative link some scientists were postulating—and a host of climate alarmists were championing—between global warming and the spread of infectious diseases. Noting many people "assume a correlation between increasing disease incidence and global warming," he states that after studying the issue in considerable depth, he must conclude "the factors responsible for the emergence/reemergence of vector-borne diseases are complex and mutually influence each other." He notes "the incidence and spread of parasites and arboviruses are affected by insecticide and drug resistance, deforestation, irrigation systems and dams, changes in public health policy (decreased resources of surveillance, prevention and vector control), demographic changes (population growth, migration, urbanization), and societal changes (inadequate housing conditions, water deterioration, sewage, waste management)." Therefore, he continues, "it may be over-simplistic to attribute emergent/re-emergent diseases to climate change and sketch the menace of devastating epidemics in a warmer world." He reiterates "variations in public health practices and lifestyle can easily outweigh changes in disease biology."

Kyle and Harris (2008) note "dengue is a spectrum of disease caused by four serotypes of the most prevalent arthropod-borne virus affecting humans today," and "its incidence has increased dramatically in the past 50 years," to where "tens of millions of cases of dengue fever are estimated to occur annually, including up to 500,000 cases of the life-threatening dengue hemorrhagic fever/dengue shock syndrome." In an effort to better understand this increase, they conducted a thorough review of the pertinent scientific literature, exploring "the human, mosquito, and viral factors that contribute to the global spread and persistence of dengue, as well as the interaction between the three spheres, in the context of ecological and climate change."

With respect to the status of dengue fever within the context of global warming, they found "there has been a great deal of debate on the implications of global warming for human health," but "at the moment, there is no consensus." However, "in the case of dengue," they report, "it is important to note that even if global warming does not cause the mosquito vectors to expand their geographic range, there could still be a significant impact on transmission in endemic regions," because "a 2°C increase in temperature would simultaneously lengthen the lifespan of the mosquito and shorten the extrinsic incubation period of the dengue virus, resulting in more infected mosquitoes for a longer

period of time." Nevertheless, they state there are "infrastructure and socioeconomic differences that exist today and already prevent the transmission of vector-borne diseases, including dengue, even in the continued presence of their vectors," citing Reiter (2001). It thus appears whatever advantages rising temperatures may confer upon the dengue virus vector, they can be more than overcome by proper implementation of modern vector control techniques.

In another review of the scientific literature, Wilder-Smith and Gubler (2008) note "the past two decades saw an unprecedented geographic expansion of dengue," reporting "each year an estimated 50 to 100 million dengue infections occur, with several hundred thousand cases of dengue hemorrhagic fever and about twenty thousand deaths." They too state, "global climate change is commonly blamed for the resurgence of dengue," but they add, "there are no good scientific data to support this conclusion." Wilder-Smith and Gubler reviewed what was known about the problem and pieced together a logical conclusion.

With respect to the occurrence of dengue infections, the two researchers report, "climate has rarely been the principal determinant of [their] prevalence or range," and "human activities and their impact on local ecology have generally been much more significant." They cite as contributing factors "urbanization, deforestation, new dams and irrigation systems, poor housing, sewage and waste management systems, and lack of reliable water systems that make it necessary to collect and store water," further noting "disruption of vector control programs, be it for reasons of political and social unrest or scientific reservations about the safety of DDT, has contributed to the resurgence of dengue around the world." In addition, they write "large populations in which viruses circulate may also allow more co-infection of mosquitoes and humans with more than one serotype of virus," which would appear to be borne out by the fact that "the number of dengue lineages has been increasing roughly in parallel with the size of the human population over the last two centuries." Most important, perhaps, is "the impact of international travel," of which they say "humans, whether troops, migrant workers, tourists, business travelers, refugees, or others, carry the virus into new geographic areas," and these movements "can lead to epidemic waves." The two researchers conclude, "population dynamics and viral evolution offer the most parsimonious explanation for the observed epidemic cycles of the disease, far more than climatic factors."

Russell (2009)—a professor in the Department of Medicine of the University of Sydney and founding director of its Department of Medical Entomology—reports, "during the past 10 years, there has been increasing concern for health impacts of global warming in Australia, and continuing projections and predictions for increasing mosquito-borne disease as a result of climate change." He notes these claims "are relatively simplistic, and do not take adequate account of the current or historic situations of the vectors and pathogens, and the complex ecologies that might be involved." He reviewed the consequences of these inadequacies for malaria, dengue fever, the arboviral arthritides (Ross River and Barmah Forest viruses) and the arboviral encephalitides (Murray Valley encephalitis and Kunjin viruses) within the context of predictions of climate changes modeled by Australia's Commonwealth Scientific and Industrial Research Organisation (CSIRO) and the Intergovernmental Panel on Climate Change (IPCC).

The abstract of Russell's paper begins with a question: "Will warming climate increase the risk or prevalence of mosquito-borne disease in Australia, as has been projected in a number of scientific publications and governmental reports?" His conclusion provides the answer: "there might be some increases in mosquito-borne disease in Australia with a warming climate, but with which mosquitoes and which pathogens, and where and when, cannot be easily discerned." He concludes, "of itself, climate change as currently projected, is not likely to provide great cause for public health concern with mosquito-borne disease in Australia."

Russell et al. (2009) report similar findings. The team of scientists note "dengue has emerged as a leading cause of morbidity in many parts of the tropics," and "Australia has had dengue outbreaks in northern Queensland." In addition, they report, "substantial increases in distribution and incidence of the disease in Australia are projected with climate change," or, more specifically, "with increasing temperatures." Russell et al. explored the soundness of these projections by reviewing the history of dengue in Australia.

This work showed the dengue vector (the *Aedes aegypti* mosquito) "was previously common in parts of Queensland, the Northern Territory, Western Australia and New South Wales," and it had, "in the past, covered most of the climatic range theoretically available to it," adding "the distribution of local dengue transmission has [historically] nearly matched the geographic limits of the vector." This being the case, they conclude the vector's current absence from

much of Australia "is not because of a lack of a favorable climate." Thus, they reason "a temperature rise of a few degrees is not alone likely to be responsible for substantial increases in the southern distribution of *A. aegypti* or dengue, as has been recently proposed." Instead, they note, "dengue activity is increasing in many parts of the tropical and subtropical world as a result of rapid urbanization in developing countries and increased international travel, which distributes the viruses between countries." Instead of futile attempts to limit dengue transmission by controlling the world's climate, therefore, the medical researchers recommend "well resourced and functioning surveillance programs, and effective public health intervention capabilities, are essential to counter threats from dengue and other mosquito-borne diseases."

Johansson *et al.* (2009) write, "the mosquito-borne dengue viruses are a major public health problem throughout the tropical and subtropical regions of the world," and "changes in temperature and precipitation have well-defined roles in the transmission cycle and may thus play a role in changing incidence levels." Since "the El Niño Southern Oscillation (ENSO) is a multiyear climate driver of local temperature and precipitation world wide," and "previous studies have reported varying degrees of association between ENSO and dengue incidence," they looked for relationships between ENSO, local weather, and dengue incidence in Puerto Rico (1986–2006), Mexico (1985–2006), and Thailand (1983–2006) using wavelet analysis as a tool to identify time- and frequency-specific associations.

The three researchers report they "did not find evidence of a strong, consistent relationship in any of the study areas," and Rohani (2009), who wrote a Perspective piece on their study, states the three researchers found "no systematic association between multi-annual dengue outbreaks and El Niño Southern Oscillation." Thus, as stated in the "Editors' Summary" of Johansson *et al.*'s paper, their findings "provide little evidence for any relationship between ENSO, climate, and dengue incidence."

Shang *et al.* (2010) used logistic and Poisson regression models to analyze biweekly, laboratory-confirmed dengue cases in Taiwan at their onset dates of illness from 1998 to 2007, in order to "identify correlations between indigenous dengue and imported dengue cases (in the context of local meteorological factors) across different time lags." The researchers write, "the occurrence of indigenous dengue was significantly correlated with temporally-lagged cases

of imported dengue (2–14 weeks), higher temperatures (6–14 weeks), and lower relative humidity (6–20 weeks)," and "imported and indigenous dengue cases had a significant quantitative relationship in the onset of local epidemics." The six Taiwanese researchers conclude, "imported dengue cases are able to initiate indigenous epidemics when appropriate weather conditions are present," or as they state in another place, "imported dengue are able to serve as an initial facilitator, or spark, for domestic epidemics." They suggest "early detection and case management of imported cases through timely surveillance and rapid laboratory-diagnosis may avert large scale epidemics of dengue/dengue hemorrhagic fever," while noting "meteorology alone does not initiate an epidemic." Finally, they state, "an increase in viremic international travelers has caused global dengue hemorrhagic fever case numbers to surge in the past several decades."

Ooi and Gubler (2009a) examined "the history of dengue emergence" in order to determine "the major drivers for the spread of both the viruses and mosquito vectors to new geographic regions." The two researchers note "frequent and cyclical epidemics are reported throughout the tropical world, with regular importation of the virus via viremic travelers into both endemic and non-endemic countries." They state, "there is no good evidence to suggest that the current geographic expansion of the dengue virus and its vectors has been or will be due to global warming." Instead, they conclude, "the magnitude of movement of the human population and trade materials, uncontrolled and poorly planned expansion of urban centers and the lack of effective disease prevention in dengue-endemic regions have served to produce conditions ideal for dengue virus transmission and have been the principal drivers of epidemic dengue for the past three decades," citing Gubler (1998, 2004), Gubler *et al.* (2001), and Ooi and Gubler (2009b).

In another review paper, Dr. Paul Reiter of the Insects and Infectious Disease Unit of the Institut Pasteur in Paris writes, "it is widely stated that the incidence of vector-borne diseases will increase if global temperatures increase" (Reiter, 2010a); and while admitting temperature and rainfall do indeed "play a role" in the transmission of such diseases, he states, "many other factors are involved," citing a paper he wrote at the turn of the century (Reiter, 2001). In revisiting this subject, Reiter (2010a) reviewed the scientific literature, distilling the essence of the then-current state of knowledge pertaining to the potential for yellow fever and dengue trans-

mission throughout modern-day Europe.

The review revealed "the introduction and rapidly expanding range of *Aedes albopictus* in Europe is an iconic example of the growing risk of the globalization of vectors and vector-borne diseases," and "the history of yellow fever and dengue in temperate regions confirms that transmission of both diseases could recur, particularly if *Aedes aegypti*, a more effective vector, were to be re-introduced." He states "conditions are already suitable for transmission."

In light of Reiter's findings, can we expect to face the problem of the two deadly diseases suddenly reappearing and racing across Europe, especially if the climate begins to warm again? Actually, it would not be incredibly surprising if that were to happen even if the climate were to cool, for Reiter concludes, "a more urgent emerging problem is the quantum leap in the mobility of vectors and pathogens that has taken place in the past four decades, a direct result of the revolution of transport technologies and global travel," as described in his recently published article (Reiter, 2010b).

Carbajo *et al.* (2012) report "dengue cases have increased during the last decades, particularly in non-endemic areas, and Argentina was no exception in the southern transmission fringe." Although temperature rise has been blamed for this geographical expansion of the disease, they write, "human population growth, increased travel and inefficient vector control may also be implicated." Thus, they evaluated the relative contributions of geographic, demographic, and climatic variables to the recent spread of the disease.

Carbajo *et al.* divided their study into two halves—a first decade that included the reemergence of the disease, and a second decade that included several epidemics—in which "annual dengue risk was modelled by a temperature-based mechanistic model as annual days of possible transmission," and "the spatial distribution of dengue occurrence was modelled as a function of the output of the mechanistic model, climatic, geographic and demographic variables for both decades."

They found dengue spatial occurrence "was positively associated with days of possible transmission, human population number, population fall and distance to water bodies." When considered separately, the researchers write, "the classification performance of demographic variables was higher than that of climatic and geographic variables." Thus, although useful in estimating annual transmission risk, Carbajo *et al.* conclude temperature "does not fully describe the distribution of dengue occurrence at the country scale," and "when taken separately,

climatic variables performed worse than geographic or demographic variables," while acknowledging "a combination of the three types was best for this task."

These several observations indicate concerns over large increases in vector-borne diseases such as dengue as a result of rising temperatures are unfounded and unsupported by the scientific literature, as climatic indices are poor predictors for dengue disease.

7.7 Tick-Borne Diseases

- While climatic factors largely determine the geographical distribution of ticks, temperature and climate change are not among the significant factors determining the incidence of tick-borne diseases.

Randolph and Rogers (2000) state tick-borne encephalitis (TBE) "is the most significant vector-borne disease in Europe and Eurasia," having "a case morbidity rate of 10–30% and a case mortality rate of typically 1–2% but as high as 24% in the Far East." The disease is caused by a flavivirus (TBEV), which is maintained in natural rodent-tick cycles; humans may be infected with it if bitten by an infected tick or by drinking untreated milk from infected sheep or goats.

Early discussions on the relationship of TBE to global warming predicted the disease would expand its range and become more of a threat to humans in a warmer world. However, Randolph and Rogers note, "like many vector-borne pathogen cycles that depend on the interaction of so many biotic agents with each other and with their abiotic environment, enzootic cycles of TBEV have an inherent fragility," so "their continuing survival or expansion cannot be predicted from simple univariate correlations."

Confining their analysis to Europe, Randolph and Rogers first matched the present-day distribution of TBEV to the present-day distributions of five climatic variables: monthly mean, maximum, and minimum temperatures, plus rainfall and saturation vapor pressure, "to provide a multivariate description of present-day areas of disease risk." They applied this understanding to outputs of a general circulation model of the atmosphere that predicted how these five climatic variables may change in the future.

The results indicate the distribution of TBEV might expand both north and west of Stockholm, Sweden in a warming world. For most other parts of Europe, however, the two researchers say "fears for increased extent of risk from TBEV caused by global climate change appear to be unfounded." They report, "the precise conditions required for enzootic cycles of TBEV are predicted to be disrupted" in response to global warming, and the new climatic state "appears to be lethal for TBEV." This finding, they write, "gives the lie to the common perception that a warmer world will necessarily be a world under greater threat from vector-borne diseases." In the case of TBEV, they report the predicted change "appears to be to our advantage."

Noting "it is often suggested that one of the most important societal consequences of climate change may be an increase in the geographic distribution and transmission intensity of vector-borne disease," Estrada-Peña (2003) evaluated the effects of various abiotic factors on the habitat suitability of four tick species that are major vectors of livestock pathogens in South Africa. They report "year-to-year variations in the forecasted habitat suitability over the period 1983–2000 show a clear decrease in habitat availability, which is attributed primarily to increasing temperature in the region over this period." In addition, when climate variables were projected to the year 2015, Estrada-Peña found "the simulations show a trend toward the destruction of the habitats of the four tick species," just the opposite of what is often predicted about this disease.

Zell (2004) also has noted many people "assume a correlation between increasing disease incidence and global warming." He reviewed the scientific literature pertaining to the subject and determined "the factors responsible for the emergence/reemergence of vector-borne diseases are complex and mutually influence each other." He cites as an example of this complexity, "the incidence and spread of parasites and arboviruses are affected by insecticide and drug resistance, deforestation, irrigation systems and dams, changes in public health policy (decreased resources of surveillance, prevention and vector control), demographic changes (population growth, migration, urbanization), and societal changes (inadequate housing conditions, water deterioration, sewage, waste management)."

Zell says "it may be over-simplistic to attribute emergent/re-emergent diseases to climate change and sketch the menace of devastating epidemics in a warmer world." Indeed, he concludes, "variations in public health practices and lifestyle can easily outweigh changes in disease biology."

Sarah Randolph (2010) of the University of Oxford's Department of Zoology in the United Kingdom examined the roles played by various factors that may influence the spread of tick-borne diseases. She begins by noting many vector-borne diseases "have shown marked increases in both distribution and incidence during the past few decades, just as human-induced climate change is thought to have exceeded random fluctuations." She adds, "this coincidence has led to the general perception that climate change has driven disease emergence." However, she notes, "climate change is the inevitable backdrop for all recent events," most of which no one would otherwise consider attributing to changes in the planet's temperature.

After describing some of the outbreaks of tick-borne disease in Europe over the past couple of decades, Randolph states "the inescapable conclusion is that the observed climate change alone cannot explain the full heterogeneity in the epidemiological change, either within the Baltic States or amongst Central and Eastern European countries," citing Sumilo et al. (2007). Instead, she writes, "a nexus of interrelated causal factors—abiotic, biotic and human—has been identified," and "each factor appears to operate synergistically, but with differential force in space and time, which would inevitably generate the observed epidemiological heterogeneity."

Many of these factors, she continues, "were the unintended consequences of the fall of Soviet rule and the subsequent socio-economic transition (Sumilo et al., 2008b)," among which she cites "agricultural reforms resulting in changed land cover and land use, and an increased reliance on subsistence farming; reduction in the use of pesticides, and also in the emission of atmospheric pollution as industries collapsed; increased unemployment and poverty, but also wealth and leisure time in other sectors of the population as market forces took hold."

Randolph concludes "there is increasing evidence from detailed analyses that rapid changes in the incidence of tick-borne diseases are driven as much, if not more, by human behavior that determines exposure to infected ticks than by tick population biology that determines the abundance of infected ticks," as per Sumilo et al. (2008a) and Randolph et al. (2008). She ends her analysis by stating, "while nobody would deny the sensitivity of ticks and tick-borne disease systems to climatic factors that largely determine their geographical distributions, the evidence is that climate change has not been the most significant factor driving the recent temporal patterns in the epidemiology of tick-borne diseases."

7.8 Effects of CO_2

Among the lesser-known findings about CO_2 enrichment of the air is that several health-promoting substances are often enhanced in plants growing at higher CO_2 concentrations. As discussed in the subsections below, these enhancements portend great benefits for human health, and they represent an important reality the IPCC assessment reports ignore.

7.8.1 Antioxidants

Oxidation is a chemical process that occurs naturally in plants, animals, and humans. Although the process is vital for life, it also can produce free radicals, including reactive oxygen species (ROS), in a series of chain reactions that lead to cell damage and cell death. In humans, oxidative stress has been linked to cardiovascular disease, cancer, neurodegenerative disorders, and other chronic diseases. Nature's way of responding to the threats posed by such radicals is to neutralize and inhibit their reactions via complex systems of multiple types of antioxidants.

Plants, animals, and humans each harbor defense systems comprised of various types of antioxidants, including vitamin A, vitamin C, and vitamin E, and enzymes such as catalase, superoxide dismutase, and various peroxidases. Inadequate levels of anti-oxidants, or inhibition of antioxidant enzymes, can lead to oxidative stress.

The following subsections examine the impact of rising atmospheric CO_2 on antioxidant compounds and enzymes found in plants, illustrating major benefits it provides for both plants and humans. With respect to plants, higher levels of atmospheric CO_2 tend to reduce oxidative stress, resulting in a reduction in antioxidant enzyme activity because fewer such enzymes are needed to counter the stress. As a result, plants are able to direct more of their limited resources into the production of other plant tissues or processes essential to their continued growth and development. In some cases, such resources are invested into the production and enhancement of antioxidative compounds, and these compounds are known to provide health benefits to animals and humans.

7.8.1.1 Benefits to Plants

Environmental stresses induced by exposure to pollutants, drought, intense solar radiation, and high air or water temperatures generate highly reactive oxygenated compounds that damage plants. Ameliorating these stresses typically involves the production of antioxidant enzymes that scavenge and detoxify the highly reactive oxygenated compounds. When stresses are present, concentrations and/or activities of antioxidants in plants are generally observed to be high so as to counter the effects of the stress. A number of researchers have examined the impact of atmospheric CO_2 enrichment on this relationship, the results of which are discussed below.

In a study of two soybean genotypes, Pritchard *et al*. (2000) report three months' exposure to twice-ambient CO_2 concentrations reduced the activities of superoxide dismutase and catalase by an average of 23 and 39%, respectively. Likewise, Polle *et al*. (1997) show two years of atmospheric CO_2 enrichment reduced the activities of several key antioxidative enzymes, including catalase and superoxide dismutase, in beech seedlings. And Schwanz and Polle (1998) demonstrate this phenomenon can persist indefinitely, for they discovered similar reductions in these same enzymes

in mature oak trees that had been growing near natural CO_2-emitting springs for 30 to 50 years.

The standard interpretation of these results is the observed reductions in the activities of antioxidative enzymes under CO_2-enriched conditions imply plants exposed to higher-than-current atmospheric CO_2 concentrations experience less oxidative stress and thus have a reduced need for antioxidant protection. This conclusion further suggests "CO_2-advantaged" plants will be able to funnel more of their limited resources into the production of other plant tissues or processes essential to their continued growth and development.

On the other hand, when oxidative stresses do occur under high CO_2 conditions, the enhanced rates of photosynthesis and carbohydrate production resulting from atmospheric CO_2 enrichment generally enable plants to better deal with such stresses by providing more of the raw materials needed for antioxidant enzyme synthesis. Thus, when CO_2-enriched sugar maple seedlings were subjected to an additional 200 ppb of ozone, Niewiadomska *et al.* (1999) report ascorbate peroxidase, which is the first line of enzymatic defense against ozone, significantly increased. Likewise, Schwanz and Polle (2001) note poplar clones grown at 700 ppm CO_2 exhibited a much greater increase in superoxide dismutase activity upon chilling induction than clones grown in ambient air. In addition, Lin and Wang (2002) found activities of superoxide dismutase and catalase were much higher in CO_2-enriched wheat than in ambiently grown wheat following the induction of water stress.

Baczek-Kwinta and Koscielniak (2003) grew two hybrid maize (*Zea mays* L.) genotypes—KOC 9431 (chill-resistant) and K103xK85 (chill-sensitive)—from seed in air of either ambient (350 ppm) or elevated (700 ppm) CO_2 concentration (AC or EC, respectively), after which the plants were exposed to air of 7°C for 11 days and then recovered in ambient air of 20°C for one day. Throughout this period, a number of physiological and biochemical parameters were measured on the plants' third fully expanded leaves. Among their many findings, the researchers note, "EC diminished the rate of superoxide radical formation in leaves in comparison to the AC control." In addition, "electrolyte leakage from the [leaf membrane] tissue, a parameter reflecting membrane injury, was significantly lower in samples of plants subjected to EC than AC." Finally, they discovered enrichment of the air with CO_2 successfully inhibited the decrease in the maximal quantum efficiency of photosystem 2, both after chilling and during the one-day recovery period.

Lumping these positive effects of elevated CO_2 together, the two scientists conclude, "the increase in atmospheric CO_2 concentration seems to be one of the protective factors for maize grown in cold temperate regions."

In a study focusing solely on temperature, Yu *et al.* (2004a) investigated how global warming might affect crop reactive oxygen species (ROS) scavenging activities and chelating capacities, the latter of which may inhibit radical-mediated oxidative chain reactions by stabilizing transition metals required to catalyze the formation of the first few radicals needed to initiate the radical reactions (Nawar, 1996). In one of the few studies to broach this subject, Wang and Zheng (2001) examined the effects of a group of day/night temperature combinations on the antioxidant activities of the juice of two strawberry varieties, finding, in the words of Yu *et al.*, "the highest day/night temperature resulted in fruits with the greatest phenolic content as well as antioxidant activities." Encouraged by this finding, Yu *et al.* (2004a) decided to explore the subject further in a study of winter wheat.

Yu *et al.* examined and compared flour extracts of three hard winter wheat varieties grown at five locations in Colorado for their radical scavenging properties, chelating capacities, and total phenolic contents. Although they found no statistically significant correlations, the scientists report "a correlation coefficient of 0.890 (P = 0.110) was detected for the chelating activity of Akron flour and the total hours of the growth location exceeding 32°C during the 6-week grain-filling period." Thus, although no firm conclusions could be drawn from the results of their study, in contrast to the study of Wang and Zheng (2001), Yu *et al.*'s findings are intriguing enough to lead them to state, "more research is needed to clarify how varieties and growing conditions alter the antioxidant properties of wheat, wheat flour and bran."

A different set of authors, Yu *et al.* (2004b), note "oxidative stress is potentially experienced by all aerobic life when exposed to UV-B radiation," and "elevated CO_2 can enhance the capacity of plants to resist stress-induced oxidative damage," citing Ren *et al.* (2001), who worked with terrestrial plants. Yu *et al.* set out to see whether this was also true of marine plants, focusing their attention on phytoplankton, which they describe as "the single most important ecosystem on our planet."

They grew the marine microalgae *Platymonas subcordiformis* (Wille) Hazen in the laboratory at ambient levels of atmospheric CO_2 concentration and

UV-B radiation flux density, and at elevated levels of 5,000 ppm CO_2 and UV-B radiation characteristic of that anticipated to result from a 25% stratospheric ozone depletion under clear sky conditions in summer. By itself, and by these means, the five researchers determined the elevated UV-B treatment significantly decreased microalgal dry weight, photosynthetic rate, chlorophyll *a* and carotenoid contents. The elevated CO_2 treatment by itself enhanced dry weight and photosynthetic rate, and chlorophyll *a* content and carotenoid content exhibited no major differences compared with those of ambient UV-B and ambient CO_2. They also report elevated UV-B by itself significantly increased the production of the toxic superoxide anion and hydrogen peroxide, as well as malonyldialdehyde, an end product of lipid peroxidation, whereas elevated CO_2 by itself did just the opposite. In addition, in the treatment consisting of both elevated UV-B and elevated CO_2, the concentrations of these three substances were lower than those observed in the elevated UV-B and ambient CO_2 treatment. Finally, they note elevated CO_2 decreased the levels of several antioxidative enzymes found in the microalgae, reflecting their reduced need for detoxification of reactive oxygen species in the elevated CO_2 treatment.

Yu *et al*. write their results suggest "CO_2 enrichment could reduce oxidative stress of reactive oxygen species to *P. subcordiformis*, and reduce the lipid peroxidation damage of UV-B to *P. subcordiformis*." They also state, "CO_2 enrichment showed a protective effect against the oxidative damage of UV-B-induced stress," and therefore, "elevated CO_2 can be [in] favor of enhancing the capacity of stress resistance." Put more simply, they conclude, "we have shown that algae grown under high CO_2 would better overcome the adverse impact of environmental stress factor[s] that act via generation of activated oxygen species."

Plants cultured *in vitro* are know to typically suffer from a number of physiological and biochemical impairments, such that upon transfer to *ex vitro* conditions they often experience severe oxidative stress. Carvalho *et al*. (2005) conducted an analysis of the extent to which this stress might be alleviated by a nominal doubling of the air's CO_2 content. They evaluated the damage done to the large subunit of rubisco in grapevine (*Vitis vinifera* L.) plantlets while exposed to *in vitro* conditions and the degree to which that damage was ameliorated by atmospheric CO_2 enrichment during subsequent exposure to *ex vitro* conditions.

The *in vitro* plantlet cultures were maintained in a growth chamber at a photon flux density (PFD) of 45 μmol m^{-2} s^{-1}, after which they were transferred to *ex vitro* conditions having a PFD of either 150 (low light) or 300 (high light) μmol m^{-2} s^{-1} and an air CO_2 concentration of either 350 (low CO_2) or 700 (high CO_2) ppm. A number of physiological and biochemical measurements were made on the plantlets at seven-day intervals over a period of 28 days.

Carvalho *et al*. found rubisco degradation products were present in the leaves of plantlets in both *in vitro* and *ex vitro* conditions. However, "under low CO_2 they were maintained for almost all of the 28 days of the acclimatization period, while becoming scarcely detected after 14 days under high CO_2 and after 7 days when high CO_2 was associated with high light." In addition, "patterns of soluble sugars in acclimatizing leaves under high light and high CO_2 also gave an indication of a faster acquisition of autotrophic characteristics." Carvalho *et al*.'s results thus demonstrate the beneficial impact of high CO_2 concentrations in reducing the oxidative stress induced by the transfer of *in vitro*-produced plantlets to *ex vitro* conditions, as "a net benefit from high CO_2 treatments was clearly visible, contributing to an increased stability of Rubisco." Also, "the disappearance of Rubisco large subunit degradation products in persistent leaves subjected to the *ex vitro* treatments may be considered an indicator of recovery from stress," they write.

Levine *et al*. (2008) grew well-watered and fertilized wheat plants (*Triticum aestivum*, cv Yocoro roho) from seed in custom-designed root modules—"consisting of a porous tube embedded in Turface (1–2 mm particle size) substrate containing 5 g Osmocote time release fertilizer per liter"—which were housed in Plexiglas chambers maintained at atmospheric CO_2 concentrations of either 400, 1,500, or 10,000 ppm for periods of 14, 21, and 28 days. The scientists measured a number of plant metabolic properties along with the leaf concentrations of several flavonoids that are capable of scavenging ROS. The 13 researchers report "elevated CO_2 promoted the accumulation of secondary metabolites (flavonoids) progressively to a greater extent as plants became mature." As best as can be determined from the bar graphs of their results, for example, the percentage increase in total wheat leaf flavonoid concentration in going from an atmospheric CO_2 concentration of 400 to 1,500 ppm was 22%, 38%, and 27% at 14, 21, and 28 days after planting, respectively, whereas in going from a CO_2

concentration of 400 to 10,000 ppm, the percentage increase in total flavonoid concentration was 38%, 56% and 86%, respectively, at 14, 21 and 28 days after planting. They report "both elevated CO_2 levels resulted in an overall 25% increase in biomass over the control plants."

The U.S., Japanese, and German scientists write, "the increased accumulation of secondary metabolites in plants grown under elevated CO_2 may have implications regarding plant-herbivore interactions, decomposition rates for inedible biomass, and potential beneficial effects on plant tolerance to water stress (Idso, 1988) and cold stress (Solecka and Kacperska, 2003) due to their potentials for the scavenging of reactive oxygen species (ROS)."

Varga *et al*. (2012) write, "as well as damaging numerous physiological functions, abiotic stress [such as drought] also leads to higher concentrations of reactive oxygen species, which are present in nature in all plants, but which may damage cell components and disturb metabolic processes when present in larger quantities," citing Omran (1980), Larson (1988), and Dat *et al*. (2000). They say "many authors have demonstrated that the [atmosphere's] CO_2 concentration has a substantial influence on the stress sensitivity of plants via changes in antioxidant enzyme activity," citing Fernandez-Trujillo *et al*. (2007), Ali *et al*. (2008), and Varga and Bencze (2009), so increases in the atmosphere's CO_2 concentration may increase various plant antioxidant enzymes and thereby reduce the negative effects of various abiotic stresses.

Varga *et al*. grew two varieties of winter wheat within phytotrons maintained at either 380 or 750 ppm CO_2, where the potted plants were watered daily and supplied with nutrient solution twice a week until the start of drought treatments, when drought was induced in three phases—at first node appearance, heading, and grain filling—by completely withholding water for seven days, which dropped the volumetric soil water content in the pots from 20–25% to 3–5%. The four researchers—all of whom were associated with the Agricultural Research Institute of the Hungarian Academy of Sciences—report they observed "changes in enzyme activity" that "indicated that enhanced CO_2 concentration delayed the development of drought stress up to first node appearance, and stimulated antioxidant enzyme activity when drought occurred during ripening, thus reducing the unfavorable effects of [drought] stress." Varga *et al*. conclude the increases in the antioxidant enzymes they analyzed "may help to neutralize the reactive oxygen species induced by stress during various parts of the vegetation period," which may help society's crops better cope with whatever extremes of moisture insufficiency might be lurking in the future.

Perez-Lopez *et al*. (2009) noted soil salinity "is one of the major environmental constraints limiting plant productivity and distribution," affecting, as it does, "19.5% of the world's irrigated area" as well as "non-irrigated croplands and rangelands." They grew two barley (*Hordeum vulgare* L.) cultivars, Alpha and Iranis, within controlled-environment growth chambers at either ambient (350 ppm) or elevated (700 ppm) atmospheric CO_2 concentrations in a 3:1 perlite:vermiculite mixture watered with Hoagland's solution every two days until the first leaf was completely expanded at 14 days, after which a salinity treatment was administered by adding 0, 80, 160, or 240 m*M* NaCl to the Hoagland's solution every two days for 14 more days. After a total of 28 days, the primary leaf of each barley plant was harvested and assessed for a number of biochemical properties.

In the various ambient-air salinity treatments, the deleterious effects of reactive oxygen species on barley leaves were made apparent through ion leakage and increases in thiobarbituric acid reactive substances (TBARS), which rose as salt concentrations rose, Perez-Lopez *et al*. report. "On the other hand," they continue, "when [the] salinity treatment was imposed under elevated CO_2 conditions, lower solute leakage and TBARS levels were observed, suggesting that the oxidative stress caused by salinity was lower."

Perez-Lopez *et al*. write, "it is concluded that elevated CO_2 protects barley cultivars from oxidative stress," noting "the relief of oxidative stress damage observed in our barley leaves grown under a CO_2 enriched atmosphere has also been observed in alfalfa (Sgherri *et al*., 1998), pine (Vu *et al*., 1999) and oak (Schwanz and Polle, 2001b)." Thus it would appear the ongoing rise in the air's CO_2 content may help a wide variety of Earth's plants better cope with the many serious problems caused by high soil salinity.

Farfan-Vignolo and Asard (2012) note "grassland communities constitute an important fraction of the green surface of the Earth, and are worldwide an important source of cattle-food (Carlier *et al*., 2009; Ciais *et al*., 2011)." The pair of Belgian researchers investigated several physiological and molecular (antioxidant) responses to water deficit in two major grassland species (*Lolium perenne* L. and *Medicago lupulina* L.) under current ambient (A) and future elevated (E) atmospheric CO_2 concentrations and air temperatures (T), where $ECO_2 = ACO_2 + 375$ ppm,

and where ET = AT + 3°C.

"Not surprisingly," they write, "drought caused significant increases in oxidative damage, i.e., in protein oxidation and lipid peroxidation levels." But they found "in both species the impact of drought on protein oxidation was reduced in future climate conditions [ECO_2 and ET]." And speaking of the stress-reducing effect of ECO_2, they say "this 'CO_2-protection effect' is reported for a variety of abiotic stress conditions and species," citing Schwanz and Polle (1998), Sgherri *et al.* (2000), Geissler *et al.* (2009), Perez-Lopez *et al.* (2009), Vurro *et al.* (2009), and Salazar-Parra *et al.* (2012). The scientists conclude they "find support for this effect at the level of oxidative cell damage and protein oxidation in water-deficit responses of *L. perenne* and *M. lupulina*."

These observations make it clear plants exposed to higher-than-current atmospheric CO_2 concentrations are better equipped to deal with oxidative stress than plants growing at lower CO_2 concentrations. IPCC currently ignores these benefits.

7.8.1.2 Benefits to Humans

As discussed in the prior section, various environmental stresses generate highly reactive oxygenated compounds that damage plants. Ameliorating these stresses typically involves the production of antioxidant enzymes that scavenge and detoxify the highly reactive oxygenated compounds. When stresses are present, concentrations and/or activities of antioxidants in plants are generally observed to be high so as to counter the effects of the stress. However, plants exposed to higher-than-current atmospheric CO_2 concentrations experience less oxidative stress and thus have a reduced need for antioxidant protection, allowing them to funnel more of their limited resources into the production of other plant tissues or processes essential to their continued growth and development.

In some cases, such resources are invested into the production and enhancement of antioxidative compounds, and these compounds are known to provide health benefits to animals and humans that ingest these plants. The material in this section examines this CO_2-induced stimulation of antioxidant compounds, revealing another important benefit of atmospheric CO_2 enrichment that remains unreported by IPCC.

It is well-known that reactive oxygen species (ROS) generated during cellular metabolism or peroxidation of lipids and proteins play a causative role in the pathogenesis of cancer and coronary heart disease (CHD), as demonstrated by Slaga *et al.* (1987), Frenkel (1992), Marnett (2000), and Zhao *et al.* (2000). Wilcox *et al.* (2004), for example, note oxidative stress "has been related to cardiovascular disease, cancer, and other chronic diseases that account for a major portion of deaths today."Yu *et al.* (2004) note "antioxidant treatments may terminate ROS attacks and reduce the risks of CHD and cancer,

as well as other ROS-related diseases such as Parkinson's disease (Neff, 1997; Chung *et al*., 1999; Wong *et al*., 1999; Espin *et al*., 2000; Merken and Beecher, 2000)," and "developing functional foods rich in natural antioxidants may improve human nutrition and reduce the risks of ROS-associated health problems."

Willcox *et al*. (2004) investigated the role of exogenous antioxidants in controlling oxidation and reviewed the evidence for their roles in preventing disease. The three nutrition experts state, "diet plays a vital role in the production of the antioxidant defense system by providing essential nutrient antioxidants such as vitamin E, C, and ß-carotene, other antioxidant plant phenols including flavonoids, and essential minerals that form important antioxidant enzymes." In addition, they note, "epidemiological data generally indicate a benefit of consuming diets that are higher in antioxidant nutrients, specifically diets high in fruits and vegetables."

While it may be much easier to obtain these antioxidants by simply popping a pill or two (or even three or four), and millions of people do so daily, that approach is probably not as effective as obtaining needed antioxidants via the food one eats.

Willcox *et al*. report, for example, that in many studies of antioxidant health benefits "it is not clear whether the benefit is derived from the specific nutrients under study or another food component having health benefits yet to be discovered," or perhaps "there is a particular combination of antioxidant nutrients that provide protection." Although some epidemiological studies "appear to demonstrate clear associations, direct tests of the relationships with clinical trials have not yielded similar results." They say "the most convincing evidence of antioxidant effect on cancer prevention involves feeding fruits and vegetables rather than individual antioxidants." But what role might atmospheric CO_2 play in the matter?

Wang *et al*. (2003) evaluated the effects of elevated CO_2 on the antioxidant activity and flavonoid content of strawberry fruit they grew out-of-doors in six clear-acrylic open-top chambers, two of which they maintained at the ambient atmospheric CO_2 concentration, two of which were maintained at ambient + 300 ppm CO_2, and two of which they maintained at ambient + 600 ppm CO_2 for a period of 28 months (from early spring of 1998 through June 2000). The fruits of their labor were harvested twice—"at the commercially ripe stage" in both 1999 and 2000—after which they had them analyzed for a number of antioxidant properties and flavonol

contents.

Wang *et al*. note "strawberries are good sources of natural antioxidants (Heinonen *et al*., 1998)." They further report, "in addition to the usual nutrients, such as vitamins and minerals, strawberries are also rich in anthocyanins, flavonoids, and phenolic acids," and "strawberries have shown a remarkably high scavenging activity toward chemically-generated radicals, thus making them effective in inhibiting oxidation of human low-density lipoproteins (Heinonen *et al*., 1998)." They note previous studies (Wang and Jiao, 2000; Wang and Lin, 2000) have shown "strawberries have high oxygen radical absorbance activity against peroxyl radicals, super-oxide radicals, hydrogen peroxide, hydroxyl radicals, and singlet oxygen."

They found strawberries had higher concentrations of ascorbic acid (AsA) and glutathione (GSH) when grown under enriched CO_2 conditions. In going from ambient to +300 ppm and +600 ppm CO_2, for example, AsA concentrations rose by 10 and 13%, respectively, and GSH concentrations increased by 3 and 171%, respectively. They also learned "an enriched CO_2 environment resulted in an increase in phenolic acid, flavonol, and anthocyanin contents of fruit." For nine flavonoids, for example, there was a mean concentration increase of 55 ± 23% in going from the ambient atmospheric CO_2 concentration to +300 ppm CO_2, and a mean concentration increase of 112 ± 35% in going from ambient to +600 ppm CO_2. In addition, the "high flavonol content was associated with high antioxidant activity."

Wang *et al*. note "anthocyanins have been reported to help reduce damage caused by free radical activity, such as low-density lipoprotein oxidation, platelet aggregation, and endothelium-dependent vasodilation of arteries (Heinonen *et al*., 1998; Rice-Evans and Miller, 1996)." In summarizing their findings, they write, "strawberry fruit contain flavonoids with potent antioxidant properties, and under CO_2 enrichment conditions, increased the[ir] AsA, GSH, phenolic acid, flavonol, and anthocyanin concentrations," further noting, "plants grown under CO_2 enrichment conditions also had higher oxygen radical absorbance activity against [many types of oxygen] radicals in the fruit."

Caldwell *et al*. (2005) note "the beneficial effects of isoflavone-rich foods have been the subject of numerous studies," specifically citing Messina (1999) and Birt *et al*. (2001), adding, "foods derived from soybeans are generally considered to provide both specific and general health benefits." They investigated how the isoflavone content of soybean

seeds might be affected by the ongoing rise in the air's CO_2 content.

They grew well-watered and fertilized soybean plants from seed to maturity in pots within two controlled-environment chambers, one maintained at an atmospheric CO_2 concentration of 400 ppm and one at 700 ppm. The chambers were initially kept at a constant air temperature of 25°C. At the onset of seed fill, air temperature was reduced to 18°C until seed development was complete, in order to simulate average outdoor temperatures at this stage of plant development. In a second experiment, this protocol was repeated, except that the temperature during seed fill was maintained at 23°C, with and without drought (a third treatment). In a third experiment, seed-fill temperature was maintained at 28°C, with or without drought.

In the first experiment, where air temperature during seed fill was 18°C, the elevated CO_2 treatment increased the total isoflavone content of the soybean seeds by 8%. In the second experiment, where air temperature during seed fill was 23°C, the extra CO_2 increased total seed isoflavone content by 104%. In the third experiment, where air temperature during seed fill was 28°C, the CO_2-induced isoflavone increase was 101%. When drought stress was added as a third environmental variable, the extra CO_2 boosted total seed isoflavone content by 186% when seed-fill air temperature was 23°C, and at a seed-fill temperature of 28°C, it increased isoflavone content by 38%.

Under all the environmental circumstances studied by Caldwell *et al.*, enriching the air with an extra 300 ppm of CO_2 increased the total isoflavone content of soybean seeds. The percent increases measured under the stress situations investigated were always greater than the percent increase measured under optimal growing conditions. Thus the direct effects of atmospheric CO_2 enrichment on the health-promoting properties of soybean seeds are likely universally beneficial and a boon to humans; Bernacchi *et al.* (2005) characterized the soybean as "the world's most important seed legume."

Ginseng (*Panax ginseng*), the roots of which are widely cultivated in China, South Korea, and Japan and have been used for medicinal purposes since Greek and Roman times, is known for its anti-inflammatory, diuretic, and sedative properties and is acknowledged to be an effective healing agent (Gillis, 1997; Ali *et al.*, 2005). Normally, four to six years are required for ginseng roots to accumulate the amounts of the various phenolic compounds needed to produce their health-promoting effects. In an important step in

the quest to develop an efficient culture system for the commercial production of ginseng root, Ali *et al.* (2005) investigated the effects of growing ginseng roots in suspension culture in bioreactors maintained in equilibrium with air enriched to CO_2 concentrations of 10,000 ppm, 25,000 ppm and 50,000 ppm for periods of up to 45 days.

Of most immediate concern in such an experiment would be the effects of the ultra-high CO_2 concentrations on root growth. Would they be toxic and lead to biomass reductions or even root death? The answer was a resounding *no*. After 45 days of growth at 10,000 ppm CO_2, for example, root dry weight was increased by fully 37% relative to the dry weight of roots produced in bioreactors in equilibrium with normal ambient air, and root dry mass was increased by 27% after 45 days at 25,000 ppm CO_2 and by a still smaller 9% after 45 days at 50,000 ppm CO_2. Although the optimum CO_2 concentration for ginseng root growth clearly resided at some value lower than 10,000 ppm in this study, the concentration at which root growth rate was reduced below that characteristic of ambient air was somewhere significantly above 50,000 ppm, for even at that high CO_2 concentration, root growth was still greater than in ambient air.

Almost everything else measured by Ali *et al.* was even more dramatically enhanced by the ultra-high CO_2 concentrations they employed in their experiment. After 45 days of treatment, total root phenolic concentrations were 58% higher at 10,000 ppm CO_2 than at ambient CO_2, 153% higher at 25,000 ppm CO_2, and 105% higher at 50,000 ppm CO_2, as best as can be determined from the bar graphs of their results. Total root flavonoid concentrations were enhanced by 228%, 383%, and 232%, respectively, at the same ultra-high CO_2 concentrations. Total protein contents rose by 14%, 22%, and 30%; non-protein thiol contents by 12%, 43%, and 62%; and cysteine contents by 27%, 65%, and 100% under the identical respective sets of conditions. In addition, there were equally large CO_2-induced increases in the activities of a large number of phenol biosynthetic enzymes.

Ali *et al.* note "the consumption of foodstuffs containing antioxidant phytonutrients such as flavonoids, polyphenolics, ascorbate, cysteine and non-protein thiol is advantageous for human health," citing Cervato *et al.* (2000) and Noctor and Foyer (1998). They conclude their technique for the culture of ginseng roots in CO_2-enriched bioreactors could be used for the large-scale production of an important health-promoting product that could be provided to

the public in much greater quantities than is currently possible.

Stutte *et al*. (2008) studied *Scutellaria* plants, herbaceous perennials that possess numerous medicinal properties, noting they are "rich in physiologically active flavonoids that have a wide spectrum of pharmacological activity." They say leaf extracts of *Scutellaria barbata* have been found to be "limiting to the growth of cell lines associated with lung, liver, prostate, and brain tumors (Yin *et al*., 2004)," and "extracts of *S. lateriflora* and the isolated flavonoids from the extracts have been shown to have antioxidant, anticancer, and antiviral properties (Awad *et al*., 2003)." They investigated how the growth of these important plants, and their significant medicinal properties, might be affected by the ongoing rise in the air's CO_2 content.

Stutte *et al*. measured effects of elevated atmospheric CO_2 (1,200 and 3,000 ppm vs. a control value of 400 ppm) on plant biomass production and plant concentrations of six bioactive flavonoids—apigenin, baicalin, baicalein, chrysin, scutellarein, and wogonin—all of which, they write, "have been reported to have anticancer and antiviral properties," as described in the review papers of Joshee *et al*. (2002) and Cole *et al*. (2007). These experiments were conducted in a large step-in controlled-environment chamber that provided a consistent light quality, intensity, and photoperiod to six small plant growth chambers that had "high-fidelity control of relative humidity, temperature, and CO_2 concentration." Each chamber was designed to monitor nutrient solution uptake by six individual plants that they grew from seed for a period of 49 days.

With respect to plant productivity (fresh and dry weight production), the three U.S. researchers determined increasing the air's CO_2 concentration from 400 to 1,200 ppm resulted in a 36% increase in shoot fresh weight in *S. barbata* and a 54% increase in shoot dry matter, with no further increases between 1,200 and 3,000 ppm CO_2. In *S. lateriflora*, the corresponding increases in going from 400 to 1,200 ppm CO_2 were 62% and 44%, and in going to 3,000 ppm CO_2, the total increases were 122% and 70%, respectively.

For total flavonoid concentrations in the plants' vegetative tissues, Stutte *et al*. found, in *S. barbata* "the combined concentration of the six flavonoids measured increased by 48% at 1200 and 81% at 3000 ppm CO_2," and for *S. lateriflora* they report "the total flavonoid content increased by over 2.4 times at 1200 and 4.9 times at 3000 ppm CO_2." In consequence of the compounding effect of increases in both plant biomass and flavonoid concentration, the total flavonoid content in *S. barbata* rose by 72% in going from 400 to 1,200 ppm CO_2, and by 128% in going to 3,000 ppm CO_2. In *S. lateriflora* the corresponding increases were 320% and 1,270%. Stutte *et al*. conclude their results indicate "the yield and pharmaceutical quality of *Scutellaria* species can be enhanced with controlled environment production and CO_2 enrichment," and massively so, it appears. In addition, since they say more than 200 substances—of which more than 80% are flavonoids—have been found in a total of 65 *Scutellaria* species, it would also appear the "increased concentration of flavonoids through CO_2 enrichment," as they conclude, "has the potential to enhance the production and quality of medicinal plants."

7.8.2 Common Food Plants

- The ongoing rise in the air's CO_2 content is not only raising the productivity of Earth's common food plants but also significantly increasing the quantity and potency of the many health-promoting substances found in their tissues, which are the ultimate sources of sustenance for essentially all animals and humans.

Studies of the effects of atmospheric CO_2 enrichment on the quality of the plants that comprise our diets have typically lagged far behind studies designed to assess the effects of elevated CO_2 on the quantity of plant production. Some noteworthy exceptions were the early studies of Barbale (1970) and Madsen (1971, 1975), who discovered increasing the air's CO_2 content produced a modest increase in the vitamin C concentration of tomatoes, and Kimball and Mitchell (1981), who demonstrated enriching the air with CO_2 also stimulated the tomato plant's production of vitamin A. A few years later, Tajiri

(1985) found a mere one-hour-per-day doubling of the air's CO_2 concentration doubled the vitamin C contents of bean sprouts, and did so when applied over a period of only seven days.

Fast-forwarding a couple of decades, Idso *et al.* (2002) grew well-watered and fertilized sour orange trees out-of-doors at Phoenix, Arizona, in clear-plastic-wall open-top enclosures maintained at atmospheric CO_2 concentrations of either 400 or 700 ppm since November 1987, while evaluating the effects of the extra 300 ppm of CO_2 on the vitamin C concentrations of fully ripened fruit harvested over the eight-year period 1992–1999. In years when the production of fruit was approximately doubled by the extra CO_2, they found the fruit produced in the two CO_2 treatments were of approximately the same size, and the vitamin C concentration of the juice of the oranges grown in the CO_2-enriched air was enhanced by approximately 7% above that of the juice of the ambient-treatment oranges. In years when CO_2-enriched fruit numbers were more than doubled, however, the CO_2-enriched fruit were slightly smaller than the fruit produced in normal air, and the vitamin C concentration of the juice of the CO_2-enriched fruit rose even higher, to as much as 15% above that of the ambient-treatment fruit. In years when fruit numbers were less than doubled, the CO_2-enriched fruit were slightly larger than the ambient-treatment fruit, and the enhancement of the vitamin C concentration of the juice of the CO_2-enriched fruit was somewhat less than the base value of 7% typical of equal-size fruit.

With respect to the likely long-term equilibrium response of the trees, Idso *et al.* (2002) report that in five of the last six years of the study, "the 75% increase in atmospheric CO_2 concentration has increased: (1) the number of fruit produced by the trees by $74 \pm 9\%$, (2) the fresh weight of the fruit by $4 \pm 2\%$, and (3) the vitamin C concentration of the juice of the fruit by $5 \pm 1\%$." The eight researchers conclude, "there is reason to believe that an atmospheric CO_2 enrichment of the magnitude expected over the current century may induce a large and sustained increase in the number of fruit produced by orange trees, a small increase in the size of the fruit, and a modest increase in the vitamin C concentration of the juice of the fruit, all of which effects bode well for this key agricultural product that plays a vital role in maintaining good health in human populations around the globe."

Further support for the significance of these observations was provided by Idso and Idso (2001), who note "these findings take on great significance when it is realized that scurvy—which is brought on by low intake of vitamin C—may be resurgent in industrial countries, especially among children (Ramar *et al.*, 1993; Gomez-Carrasco *et al.*, 1994), and that subclinical scurvy symptoms are increasing among adults (Dickinson *et al.*, 1994)." In addition, they report, "Hampl *et al.* (1999) have found that 12 to 20% of 12–18-year-old school children in the United States 'drastically under-consume' foods that supply vitamin C; while Johnston *et al.* (1998) have determined that 12 to 16% of U.S. college students have marginal plasma concentrations of vitamin C." Hence, "since vitamin C intake correlates strongly with the consumption of citrus juice (Dennison *et al.*, 1998), and since the only high-vitamin-C juice consumed in any quantity by children is orange juice (Hampl *et al.*, 1999), the modest role played by the ongoing rise in the air's CO_2 content in increasing the vitamin C concentration of orange juice could ultimately prove to be of considerable significance for public health in the United States and elsewhere."

Wang *et al.* (2003) grew strawberry plants in six clear-acrylic open-top chambers—two of which were maintained at the ambient atmospheric CO_2 concentration, two of which were maintained at ambient + 300 ppm CO_2, and two of which were maintained at ambient + 600 ppm CO_2—for a period of 28 months (from early spring of 1998 through June 2000), harvesting their fruit at the commercially ripe stage in both 1999 and 2000 and analyzing them for antioxidant properties and flavonol contents.

Wang *et al.* note strawberries are good sources of natural antioxidants and state, "in addition to the usual nutrients, such as vitamins and minerals, strawberries are also rich in anthocyanins, flavonoids, and phenolic acids," and "strawberries have shown a remarkably high scavenging activity toward chemically generated radicals, thus making them effective in inhibiting oxidation of human low-density lipoproteins (Heinonen *et al.*, 1998)." They note previous studies (Wang and Jiao, 2000; Wang and Lin, 2000) "have shown that strawberries have high oxygen radical absorbance activity against peroxyl radicals, superoxide radicals, hydrogen peroxide, hydroxyl radicals, and singlet oxygen."

The researchers determined, first, that strawberries had higher concentrations of ascorbic acid (AsA) and glutathione (GSH) "when grown under enriched CO_2 environments." In going from ambient to +300 ppm and +600 ppm CO_2, for example, AsA concentrations increased by 10 and 13%, respectively, and GSH concentrations increased by 3 and 171%, respectively. They also learned "an enriched CO_2 environment resulted in an increase in

phenolic acid, flavonol, and anthocyanin contents of fruit." For nine flavonoids, for example, there was a mean concentration increase of $55 \pm 23\%$ in going from the ambient atmospheric CO_2 concentration to +300 ppm CO_2, and a mean concentration increase of $112 \pm 35\%$ in going from ambient to +600 ppm CO_2. In addition, the "high flavonol content was associated with high antioxidant activity." As for the significance of these findings, Wang *et al.* note "anthocyanins have been reported to help reduce damage caused by free radical activity, such as low-density lipoprotein oxidation, platelet aggregation, and endothelium-dependent vasodilation of arteries (Heinonen *et al.*, 1998; Rice-Evans and Miller, 1996)."

Wang *et al.* write, "strawberry fruit contain flavonoids with potent antioxidant properties, and under CO_2 enrichment conditions, increased their AsA, GSH, phenolic acid, flavonol, and anthocyanin concentrations," further noting "plants grown under CO_2 enrichment conditions also had higher oxygen radical absorbance activity against radicals in the fruit."

With respect to a major staple crop, soybeans, Caldwell *et al.* (2005) write "the beneficial effects of isoflavone-rich foods have been the subject of numerous studies (Birt *et al.*, 2001; Messina, 1999)," and "foods derived from soybeans are generally considered to provide both specific and general health benefits." Caldwell *et al.* examined how the isoflavone content of soybean seeds might be affected by the ongoing rise in the air's CO_2 content, growing well-watered and fertilized soybean plants from seed to maturity in pots within two controlled-environment chambers, one maintained at an atmospheric CO_2 concentration of 400 ppm and one at 700 ppm. The chambers were initially kept at a constant air temperature of 25°C; at the onset of seed fill, air temperature was reduced to 18°C until seed development was complete, to simulate average outdoor temperatures at this stage of plant development. In a second experiment, this protocol was repeated, except the temperature during seed fill was maintained at 23°C, with and without drought (a third treatment). In a third experiment, seed-fill temperature was maintained at 28°C, with or without drought.

In the first experiment, where air temperature during seed fill was 18°C, the elevated CO_2 treatment increased the total isoflavone content of the soybean seeds by 8%. In the second experiment, where air temperature during seed fill was 23°C, the extra CO_2 increased total seed isoflavone content by 104%. In

the third experiment, where air temperature during seed fill was 28°C, the CO_2-induced isoflavone increase was 101%. When drought-stress was added as a third environmental variable, the extra CO_2 boosted total seed isoflavone content by 186% when seed-fill air temperature was 23°C, and at a seed-fill temperature of 28°C, it increased isoflavone content by 38%.

Under all environmental circumstances studied, therefore, enriching the air with an extra 300 ppm of CO_2 increased the total isoflavone content of soybean seeds. The percent increases measured under the stress situations were always greater than the percent increase measured under optimal growing conditions. Consequently, the direct effects of atmospheric CO_2 enrichment on the health-promoting properties of soybeans, which Bernacchi *et al.* (2005) characterize as "the world's most important seed legume," are likely universally beneficial.

Kim *et al.* (2005) note important flavonoids "are mainly found in the form of isoflavones in soybean seeds," including "phytoestrogens with various bio-logical potentials such as antioxidative, pharmaceutical, oestrogenic and anticarcinogenic properties, with some acting as antiestrogens and being used as anticancer agents (Peterson and Barnes, 1991; Anderson *et al.*, 1995; Anthony *et al.*, 1996; Arjmandi *et al.*, 1996; Holt, 1997; Chung *et al.*, 2000)." They grew well-watered plants from seed to maturity in pots of sandy loam soil within the closed-environment plant growth facility of the National Horticultural Research Institute of Korea, where the plants were exposed to natural solar radiation and the natural daily course of ambient air temperature or elevated air temperature (= ambient + 5°C) with either normal soil nitrogen content or added nitrogen equivalent to an extra 40 kg N/ha, and they were maintained at either ambient CO_2 (360 ppm) or elevated CO_2 (650 ppm). At the end of the growing season, the plants were harvested and their total biomass determined. The concentrations of 12 isoflavones found in their seeds—three aglycons, three glucosides, three acetyl conjugates, and three malonyl conjugates—were quantitatively analyzed

Kim *et al.* found the CO_2-induced increase in total plant biomass at normal ambient temperatures was 96% in the case of normal soil nitrogen and 105% in the case of added nitrogen, and at the warmer temperatures it was 59% in the case of normal soil nitrogen and 68% in the case of added nitrogen. With respect to seed isoflavone concentrations, the CO_2-induced increases of all 12 isoflavones were fairly similar. As a group, at normal ambient temperatures

the mean increase was 72% in the case of normal soil nitrogen and 59% in the case of added nitrogen, and at the warmer temperatures it was 72% in the case of normal soil nitrogen and 106% in the case of added nitrogen. Irrespective of soil nitrogen status and air temperature, therefore, increases in the air's CO_2 content produced large increases in soybean biomass, as well as soybean seed concentrations of 12 major isoflavones.

Schonhof *et al*. (2007) stated the glucosinolates contained in broccoli plants comprise a group of bioactive compounds responsible for many physiological effects, including enhancing the plant's flavor and helping to prevent cancer in people who consume them, citing Mikkelsen *et al*. (2002). In a set of three experiments conducted in a controlled greenhouse environment, Schonhof *et al*. grew well-watered and fertilized broccoli plants in large soil-filled containers at ambient (430–480 ppm) and elevated (685–820 ppm) atmospheric CO_2 concentrations to the stage where fully developed heads could be harvested for glucosinolate analyses. They report the roughly 65% increase in atmospheric CO_2 concentration increased the fresh weight of the broccoli heads by approximately 7% and increased the total glucosinolate concentration of the broccoli inflorescences by 14%, due primarily to identical 37% increases in two particular glucosinolates: glucoiberin and glucoraphanin. The four researchers conclude atmospheric CO_2 enrichment "can enhance the health-promoting quality of broccoli because of induced glucosinolate content changes."

Jin *et al*. (2009) grew well-watered and fertilized spinach from seed (five to each 3.5-liter pot filled with a loam soil) for approximately three weeks in controlled-environment chambers containing air of either 350 ppm or 800 ppm CO_2. They harvested the plants, weighed them, and measured the concentrations of several of the nutritive substances contained in their leaves. As best as can be determined from the graphs of their results, the extra 450 ppm of CO_2 increased the fresh weight of the spinach shoots by about 67% and their dry weight by approximately 57%. In addition, it boosted the soluble sugar concentrations of their leaves by approximately 29% and soluble protein concentrations by about 52%. The extra CO_2 also increased spinach leaf concentrations of ascorbate, glutathione, and total flavonoids by 21%, 16%, and 3%, respectively.

La *et al*. (2009) noted "epidemiological studies show there is a negative relationship between Brassicaceae vegetable intake and the risk of a number of cancers (Wattenberg, 1993; Kohlmeier and Su, 1997; Price *et al*., 1998)," adding, "it has been widely recognized that some of the cancer-chemoprotective activities in these vegetables are attributable to their contents of glucosinolates (Zhao *et al*., 1992; Wattenberg, 1993; Tawfiq *et al*., 1995; Fahey *et al*., 1997; Rosa *et al*., 1997; Holst and Williamson, 2004)." They set out to determine what effect the ongoing rise in the air's CO_2 content might have on the production of these important cancer-fighting agents in yet another common food plant.

The five scientists placed pairs of seedlings of Chinese kale in 1.8-L pots "fixed in a foam cavity with sponge" within growth chambers maintained at either 350 or 800 ppm CO_2, where the plant's roots were immersed in culture solutions treated with either 5.0 mmol nitrogen (N) per L (low N), 10 mmol N per L (medium N), or 20 mmol N per L (high N) and allowed to grow for 35 days. The plants then were separated into their primary morphological parts and weighed, and their bolting stems were ground into powder for glucosinolate analyses.

"Regardless of N concentration," the researchers write, the elevated CO_2 treatment "significantly increased plant height [15.64%], stem thickness [11.79%], dry weights of the total aerial parts [11.91%], bolting stems [15.03%], and roots [16.34%]." Also, the elevated CO_2 increased the total glucosinolate concentrations of the bolting stems in the low and medium N treatments by 15.59% and 18.01%, respectively, compared with those at ambient CO_2, although there was no such effect in the high N treatment. Consequently, in terms of the total amount of glucosinolate production within the bolting stems of Chinese kale, these results suggest increases of 33 to 36% may be obtained for plants growing in low to medium N conditions in response to a 450 ppm increase in the air's CO_2 concentration.

Gwynn-Jones *et al*. (2012) note "dwarf shrub berries are particularly valued by the human populations at Northern Latitudes as an autumn harvest, but are also consumed by a wide range of animals (Anderson, 1985)." They note the fruit of these shrubs contain high concentrations of flavonoids and anthocyanins (Heinonen *et al*., 1998; Faria *et al*., 2005; Heinonen, 2007), which can scavenge cancer-causing free-radicals (Martin-Aragon *et al*., 1998; Taruscio *et al*., 2004) and reduce the oxidative stress caused by these compounds in animals (Johnson and Felton, 2001). They state "there is already laboratory evidence suggesting that the consumption of *Vaccinium myrtillus* berry flavonoids by small mammals can increase the antioxidant capacity of their blood plasma which could promote

their fitness," citing Talavera *et al*. (2006).

In an open-top chamber study conducted at the Abisko Scientific Research Station in Northern Sweden, Gwynn-Jones *et al*. assessed the impact of atmospheric CO_2 enrichment (600 vs. 360–386 ppm) on the berry quality of *Vaccinium myrtillus* and *Empetrum hermaphroditum* in the final year (2009) of a 17-year experiment. As best as can be determined from the 10 researchers' graphically presented results, it appears the mean concentration of quercetin glycosides in *V. myrtillus* was increased by approximately 46% by the approximate mean CO_2 concentration increase of 227 ppm. In *E. hermaphroditum*, syringetin glycoside concentrations were increased by about 36% by the extra CO_2, and five anthocyanins had their concentrations increased as follows: delphinidin-3-hexoside by about 51%, cyanidin-3-hexoside by about 49%, petunidin-3-hexoside by about 48%, malvidin-3-pentoside by about 46%, and malvidin-3-hexoside by about 59%. Gwynn-Jones *et al*. conclude, "consumers of *E. hermaphroditum* may gain higher antioxidant intake at elevated CO_2," and "some European bird species show preferential feeding towards berries with higher antioxidant contents (Catoni *et al*., 2008), which could have important implications for the palatability and, therefore, seed dispersal of these species."

It is becoming increasingly evident the ongoing rise in the air's CO_2 content is not only raising the productivity of Earth's common food plants but also significantly increasing the quantity and potency of the many health-promoting substances found in their tissues, which are the ultimate sources of sustenance for essentially all animals and humans. As these foods make their way onto our dinner tables, they improve our health and help us better contend with the multitude of diseases and other maladies that regularly afflict us. It is possible, if not likely, that the lengthening of human lifespan that has occurred over the past half-century or more—as described by Horiuchi (2000) and Tuljapurkar *et al*. (2000)—may in some significant part be due to the concomitant CO_2-induced increases in the concentrations of the many health-promoting substances found in the various plant-derived foods we eat. Yet these real and many benefits continue to be ignored by IPCC.

7.8.3 Medicinal Plants

- Atmospheric CO_2 enrichment positively impacts the production of numerous health-promoting substances found in medicinal or "health food" plants, and this phenomenon may have contributed to the increase in human life span that has occurred over the past century or so.

Studies of the effects of atmospheric CO_2 enrichment on the amounts and concentrations of various health-promoting substances produced by medicinal or "health food" plants have lagged behind studies designed to assess the effects of elevated CO_2 on the quantity of plant production. Nevertheless, enough research has been conducted on this topic to reveal atmospheric CO_2 enrichment positively impacts these important substances.

Stuhlfauth *et al.* (1987), for example, found a near-tripling of the air's CO_2 content increased the dry weight production of the woolly foxglove plant (which produces the cardiac glycoside digoxin used in the treatment of cardiac insufficiency) by 63% under dry conditions and by 83% when well-watered, and the concentration of digoxin within the plant dry mass was enhanced by 11% under well-watered conditions and by 14% under conditions of water stress. Stuhlfauth and Fock (1990) obtained similar results in a field study, with a near-tripling of the air's CO_2 content leading to a 75% increase in plant dry weight production per unit land area and a 15% increase in digoxin per unit dry weight of plant material, resulting in an actual doubling of total digoxin yield per hectare of cultivated land.

Idso *et al.* (2000) grew spider lily plants out-of-doors at Phoenix, Arizona in clear-plastic-wall open-top enclosures that had their atmospheric CO_2 concentrations maintained at either 400 or 700 ppm for two consecutive two-year growth cycles. The 75% increase in the air's CO_2 concentration increased aboveground plant biomass by 48% and belowground (bulb) biomass by 56%. In addition, the extra CO_2 increased the concentrations of five bulb constituents possessing anticancer and antiviral properties. Mean percentage increases in these concentrations were, the researchers write, "6% for a two-constituent (1:1) mixture of 7-deoxynarciclasine and 7-deoxy-trans-dihydronarciclasine, 8% for pancratistatin, 8% for trans-dihydronarciclasine, and 28% for narciclasine, for a mean active-ingredient percentage concentration increase of 12%." Combined with the 56% increase in bulb biomass, these percentage concentration increases resulted in a mean active-ingredient increase of 75% for the 75% increase in the air's CO_2 concentration. The substances described above have been shown to be effective in fighting a number of devastating human maladies, including leukemia; ovary sarcoma; melanoma; and brain, colon, lung, and renal cancers, as well as Japanese encephalitis and yellow, dengue, Punta Tora, and Rift Valley fevers.

Zobayed and Saxena (2004) studied St. John's wort, a perennial herb native to Europe and West Asia that has been used for treatment of mild to moderate depression, inflammation, and wound healing (Brolis *et al.*, 1998; Stevinson and Ernst, 1999), and which has been reported to be a potential source for anticancer, antimicrobial, and antiviral medicines (Schempp *et al.*, 2002; Pasqua *et al.*, 2003). The two scientists grew shoots of the plant for 42 days under well-watered and fertilized conditions within a greenhouse, where the air's CO_2 concentration averaged 360 ppm, as well as in computer-controlled environment chambers maintained at a mean CO_2 concentration of 1,000 ppm, with all other environmental conditions being comparable between the two treatments.

On the final day of the study, Zobayed and Saxena determined the net photosynthetic rates of the plants in the CO_2-enriched chambers were 124% greater than those of the plants growing in ambient air, and their dry weights were 107% greater. The extra 640 ppm of CO_2 in the high-CO_2 treatment increased plant concentrations of hypericin and pseudohypericin (two of the major health-promoting substances in the plants) by just over 100%. Consequently, the 180% increase in the air's CO_2

content more than doubled the dry mass produced by the well-watered and fertilized St. John's wort plants, and it more than doubled the concentrations of hypericin and pseudohypericen found in their tissues. Thus the CO_2 increase more than quadrupled the total production of these two health-promoting substances.

Mosaleeyanon *et al.* (2005) also studied St. John's wort, growing well-watered and fertilized seedlings for 45 days in controlled-environment chambers at low, medium, and high light intensities (100, 300, and 600 µmol m^{-2} s^{-1}, respectively) at atmospheric CO_2 concentrations of 500, 1,000, and 1,500 ppm. On the 45th day of their experiment, the plants were harvested, and the hypericin, pseudohypericin, and hyperforin (another important health-promoting substance) they contained were extracted from their leaves and quantified.

Under all three light intensities employed in the study, the four researchers found the 1,000–ppm increase in atmospheric CO_2 concentration experienced in going from 500 to 1,500 ppm produced total plant biomass increases of approximately 32%. Over this same CO_2 range, hypericin concentrations rose by 78, 57, and 53%, respectively, under the low, medium, and high light intensities. Pseudohypericin concentrations rose by 70, 57, and 67%, and hyperforin concentrations rose by 102, 23, and 3%. Compared to plants growing out-of-doors in air of 380 ppm CO_2 and at light intensities on the order of 1,770 µmol m^{-2} s^{-1}, Mosaleeyanon *et al.* discovered total plant biomass was fully 30 times greater in the high-light, high-CO_2 controlled-environment treatment, and under the same conditions the concentrations of hypericin and pseudohypericin were 30 and 41 times greater. Thus the researchers demonstrated growing St. John's wort plants in CO_2-enriched air in controlled-environment chambers can enormously enhance both plant biomass and hypericin and pseudohypericin contents.

Ziska *et al.* (2005) grew well-watered and fertilized tobacco and jimson weed plants from seed in controlled-environment chambers maintained at atmospheric CO_2 concentrations of either 378 ppm (ambient) or 690 ppm (elevated) and mean air temperatures of either 22.1 or 27.1°C for 50 and 47 days after planting for tobacco and jimson weed, respectively. They sampled the plants at weekly intervals beginning at 28 days after planting for tobacco and 16 days for jimson weed, to determine the effects of these treatments on three plant alkaloids possessing important pharmacological properties: nicotine, in the case of tobacco, and atropine and scopolamine, in the case of jimson weed. At the time of final harvest they found the elevated CO_2 had increased the aboveground biomass production of tobacco by approximately 89% at 22.1°C and 53% at 27.1°C, and had increased that of jimson weed by approximately 23% and 14% at the same respective temperatures. The extra CO_2 also was found to have reduced the concentration of nicotine in tobacco and increased the concentration of scopolamine in jimson weed, but it had no significant effect on the concentration of atropine in jimson weed.

The two significant changes (reduced nicotine in tobacco and increased scopolamine in jimson weed) likely would be characterized as beneficial by most people; as the six scientists report, nicotine is acknowledged to have significant negative impacts on human health, and scopolamine is used as a sedative and as "an antispasmodic in certain disorders characterized by restlessness and agitation, (e.g., delirium tremens, psychosis, mania and Parkinsonism)." Nevertheless, Ziska *et al.* state "it can be argued that synthetic production of these secondary compounds alleviates any concern regarding environmental impacts on their production from botanical sources," but they note "developing countries (i.e., ~75% of the world population) continue to rely on ethno-botanical remedies as their primary medicine (e.g. use of alkaloids from jimson weed as treatment for asthma among native Americans and in India)." In addition, "for both developed and developing countries, there are a number of economically important pharmaceuticals derived solely from plants whose economic value is considerable (Raskin *et al.*, 2002)."

Another plant with an impressive history of medicinal use is ginseng. Well-known for its anti-inflammatory, diuretic, and sedative properties, and long acknowledged to be an effective healing agent (Gillis, 1997), ginseng is widely cultivated in China, South Korea, and Japan, where it has been used for medicinal purposes since Greek and Roman times. Normally, ginseng roots take four to six years to accumulate the amounts of the various phenolic compounds needed to produce their health-promoting effects.

Ali *et al.* (2005) investigated the consequences of growing ginseng plants in suspension culture in bioreactors maintained in equilibrium with air enriched to CO_2 concentrations of 10,000 ppm, 25,000 ppm, and 50,000 ppm for periods of up to 45 days. Of most immediate concern in such an experiment are the effects of the ultra-high CO_2 concentrations on root growth and whether they would be toxic and lead to biomass reductions or even

root death. The answer, according to Ali *et al.*'s experiment was a resounding *no*. After 45 days of growth at 10,000 ppm CO_2, root dry weight was increased by about 37% relative to the dry weight of roots produced in bioreactors in equilibrium with ambient air, and it was increased by a lesser 27% after 45 days at 25,000 ppm CO_2 and by a still smaller 9% after 45 days at 50,000 ppm CO_2. Consequently, although the optimum CO_2 concentration for ginseng root growth likely resides somewhere below 10,000 ppm, the concentration at which root growth is reduced below that characteristic of ambient air resides somewhere above 50,000 ppm, for even at that extremely high CO_2 concentration, root growth was still greater than it was in ambient air.

Almost everything else measured by Ali *et al.* was even more dramatically enhanced by the ultra-high CO_2 concentrations. After 45 days of treatment, total root phenolic concentrations were 58% higher at 10,000 ppm CO_2 than at ambient CO_2, 153% higher at 25,000 ppm CO_2, and 105% higher at 50,000 ppm CO_2, as best as can be determined from the bar graphs of their results. Total root flavonoid concentrations were enhanced by 228%, 383%, and 232%, respectively; total protein contents rose by 14%, 22%, and 30%; non-protein thiol contents by 12%, 43%, and 62%; and cysteine contents by 27%, 65%, and 100%. There were equally large CO_2-induced increases in the activities of a large number of phenol biosynthetic enzymes.

Ali *et al.* state "the consumption of foodstuffs containing antioxidant phytonutrients such as flavonoids, polyphenolics, ascorbate, cysteine and non-protein thiol is advantageous for human health," citing Cervato *et al.* (2000) and Noctor and Foyer (1998). They conclude their technique for the culture of ginseng roots in CO_2-enriched bioreactors could be used for the large-scale production of an important health-promoting product that could be provided to the public in much greater quantities than is currently possible. It should be further noted that as the air's CO_2 content continues to climb, it likely will bring forth a substantial natural increase in the concentrations of health-promoting substances in ginseng and other medicinal plants, leading to better human health the world over. It is likely this phenomenon already has played some role in the lengthening of human life span that has occurred since the dawn of the Industrial Revolution, as described by Horiuchi (2000) and Tuljapurkar *et al.* (2000), when the air's CO_2 concentration rose from roughly 280 ppm to its current value of close to 400 ppm.

Zou (2005) studied the brown seaweed *Hizikia fusiforme*, which serves as both a health-promoting food and a delicacy in China, Japan, and Korea. The researcher collected specimens from intertidal rocks along the coast of Nanao Island, Shantou (China) and maintained them in glass aquariums in filtered natural seawater enriched with 60 μM $NaNO_3$ and 6.0 μM NaH_2PO_4, where the plants were continuously aerated with either ambient air of 360 ppm CO_2 or CO_2-enriched air of 700 ppm CO_2. Zou measured the seaweed's relative growth and nitrogen assimilation rates as well as its nitrate reductase activity. Zou reports the slightly less than a doubling of the air's CO_2 concentration increased the seaweed's mean relative growth rate by about 50%, its mean rate of nitrate uptake during the study's 12-hour light periods by around 200%, and its nitrate reductase activity by approximately 20% over a wide range of substrate nitrate concentrations.

Zou notes "the extract of *H. fusiforme* has an immune-modulating activity on humans and this ability might be used for clinical application to treat several diseases such as tumors (Suetsuna, 1998; Shan *et al.*, 1999)." He also states the alga is "becoming one of the most important species for seaweed mariculture in China, owing to its high commercial value and increasing market demand." In addition, Zou reports "the intensive cultivation of *H. fusiforme* would remove nutrients more efficiently with the future elevation of CO_2 levels in seawater, which could be a possible solution to the problem of ongoing coastal eutrophication," which in turn suggests rising atmospheric CO_2 concentrations may additionally assist in the amelioration of this important environmental problem.

Hoshida *et al.* (2005) grew the marine alga unicellular *Nannochloropsis* sp.alga in batch culture under normal (370 ppm) and elevated (3,000 and 20,000 ppm) air CO_2 concentrations in an attempt to learn how elevated CO_2 impacted the alga's ability to produce eicosapentaenoic acid (EPA), a major polyunsaturated omega-3 fatty acid that may play an important role in human health related to the prevention of certain cardiovascular diseases (e.g. atherosclerosis, thrombogenesis) and the inhibition of tumor growth and inflammation, as described by Dyerberg *et al.* (1978), Hirai *et al.* (1989), Kinsella *et al.* (1990), and Sanders (1993).

The five researchers note "Nitsan *et al.* (1999) showed that supplementing the diet of hens with *Nannochloropsis* sp. led to an increased content of n-3 fatty acids in the egg yolk, indicating an additional role in enhancing the nutritional value of eggs," and they report "feeding *Nannochloropsis* sp. to rats

caused a significant increase in the content of n-3 polyunsaturated fatty acids (Sukenik *et al*., 1994)," suggesting the alga may play an "important role as the source for n-3 polyunsaturated fatty acids in human nutrition."

The Japanese scientists found "maximum EPA production was obtained when 20,000 ppm CO_2 was supplied 12 hours prior to the end of the exponential growth," and "total EPA production during 4-day cultivation was about twice that obtained with ambient air." They also report other researchers have obtained similar results, noting EPA is found mainly in thylakoid membranes (Sukenik *et al*., 1989; Hodgson *et al*., 1991), and prior experiments have shown "the amount of stroma thylakoid membrane increased in several plants under elevated CO_2 concentrations (Griffin *et al*., 2001)." In addition, "in *Synechococcus lividus*, reduction and synthesis of thylakoid membrane occurred by CO_2 deprivation and elevation, respectively (Miller and Holt, 1977)," and "in *Chlorella vulgaris*, altering the ambient CO_2 concentration varied fatty acid composition (Tsuzuki *et al*., 1990)." Finally, Hoshida *et al*. report, "the effect of CO_2 on fatty acid composition and/or fatty acid content had been reported in algae and higher plants (Tsuzuki *et al*., 1990; Sergeenko *et al*., 2000; He *et al*., 1996; Radunz *et al*., 2000)," and "increased EPA production caused by elevated CO_2 concentration was reported in *P. tricornutum* (Yongmanitchai and Ward, 1991)." Consequently, as the atmospheric CO_2 concentration continues to rise, concentrations of omega-3 fatty acids will be widely enhanced in both aquatic and terrestrial plants.

Ziska *et al*. (2008) note, "among medicinal plants, the therapeutic uses of opiate alkaloids from poppy (*Papaver* spp.) have long been recognized," and they considered it important "to evaluate the growth and production of opiates for a broad range of recent and projected atmospheric carbon dioxide concentrations," which they did for the wild poppy (*P. setigerum*). The authors grew well-watered and fertilized plants from seed within growth chambers maintained at atmospheric CO_2 concentrations of 300, 400, 500, and 600 ppm for a period of 90 to 100 days, quantifying plant growth and the production of the alkaloids morphine, codeine, papaverine, and noscapine, which were derived from latex obtained from capsules produced by the plants.

Relative to the plants grown at 300 ppm CO_2, those grown at 400, 500, and 600 ppm produced approximately 200, 275, and 390% more aboveground biomass, respectively, as best as can be determined from the researchers' bar graphs. In addition, "reproductively, increasing CO_2 from 300 to 600 ppm increased the number of capsules, capsule weight and latex production by 3.6, 3.0 and 3.7 times, respectively, on a per plant basis," so, ultimately, "all alkaloids increased significantly on a per plant basis." They conclude, "as atmospheric CO_2 continues to increase, significant effects on the production of secondary plant compounds of pharmacological interest (i.e. opiates) could be expected." These effects, they write, "are commonly accepted as having both negative (e.g. heroin) and positive (e.g. codeine) interactions with respect to public health."

Vurro *et al*. (2009) note thyme (a well-known culinary and medicinal herb) has "a considerable economic value in the nutraceutical and pharmaceutical industry (Vardar-Uenlue *et al*., 2003; Konyalioglu *et al*., 2006)," and "thyme essential oil possesses *per se* considerable antioxidant capacity (Economou *et al*., 1991), and may therefore contribute towards the control of antioxidant status in the leaves." They grew well-watered one-year-old thyme plants for three additional months (10 June–10 September) in pots (filled with 40% sand, 25% clay, and 35% silt) out-of-doors within a mini-free-air CO_2-enrichment (FACE) system at Ravenna, Italy. The air's CO_2 concentration was maintained at approximately 500 ppm (during daylight hours only), and control plants were continuously exposed to air of approximately 370 ppm CO_2. They measured a number of plant characteristics at the end of each of the three months of the study.

The four researchers state "none of the plants grown under high levels of CO_2 for 90 days presented either significant differences in fresh weight and dry weight compared with controls, or macroscopic alteration of morphogenesis (number and length of nodes/internodes, branching, leaf area and chlorosis, etc.), at any of the sampling times." However, "in plants grown under elevated CO_2, a relative increase in oil yield of 32, 34 and 32% was, respectively, recorded in the first, second and third sampling-time (July, August and September)," and they observed a "general depression of the oxidative stress under elevated CO_2" that led to a "down-regulation of leaf reactive oxygen species-scavenging enzymes under elevated CO_2." In layman's terms, the Italian scientists say their results pointed to "a 'low cost' life strategy for growth under elevated CO_2, not requiring synthesis/activation of energy-intensive and expensive metabolic processes." This change in behavior should allow the plants to invest more energy in the production of essential plant oils that have, as Vurro *et al*. describe it, "considerable economic value in the

1029

nutraceutical and pharmaceutical industry."

Goncalves *et al*. (2009) write, "the impact of elevated carbon dioxide concentration on the quality of berries, must, and red wine (with special reference to volatile composition, phenolic content, and antioxidant activity) made from Touriga Franca, a native grape variety of *Vitis vinifera* L. for Port and Douro wine manufacturing grown in the Demarcated Region of Douro [northern Portugal], was investigated during 2005 and 2006." The six Portuguese researchers grew grapevines in open-top chambers maintained at either 365 or 550 ppm CO_2, finding, "in general, the increase of CO_2 did not affect berry characteristics" and "did not significantly change the total antioxidant capacity of the red wines." They write, "thirty-five volatile compounds belonging to seven chemical groups were identified," and, "generally, the same volatile compounds were present in all of the wines." Although some of these compounds were "slightly affected," they note "the red wine quality remained almost unaffected." Thus, Goncalves *et al*. say their study shows "the predicted rise in CO_2 might strongly stimulate grapevine photosynthesis and yield without causing negative impacts on the quality of grapes and red wine."

Bindi *et al*. (2001) conducted a two-year (1996, 1997) FACE study of 20-year-old grapevines (*Vitis vinifera* L., cv Sangiovese) near Rapolano, Siena (Italy). They enriched the air around the plants to 550 and 700 ppm (compared to ambient CO_2 levels in those two years that averaged 363 ppm, per Mauna Loa data), measuring numerous plant parameters in the process, including—after the fermentation process was completed—"the principal chemical compounds that determine the basic red wine quality." They report "elevated atmospheric CO_2 levels had a significant effect on biomass components (total and fruit dry weight) with increases that ranged from 40 to 45% in the 550 ppm treatment and from 45 to 50% in the 700 ppm treatment." In addition, "acid and sugar contents were also stimulated by rising CO_2 levels up to a maximum increase in the middle of the ripening season (8–14%)," but as the grapes reached the maturity stage, the CO_2 effect on these parameters gradually disappeared. In terms of various health-promoting substances contained in the wine itself, in response to the ~50% increase in atmospheric CO_2 concentration in going from ~363 to ~550 ppm CO_2, as can be calculated from the bar graphs of their results, the concentrations of total polyphenols, total flavonoids, total anthocyanins, and non-anthocyanin flavonoids in the wine rose by approximately 19%, 33%, 31%, and 38%, respectively. Bindi *et al*.

conclude, "the expected rise in CO_2 concentrations may strongly stimulate grapevine production without causing negative repercussions on quality of grapes and wine," and in fact their data suggest the ongoing rise in the air's CO_2 content might slightly enhance the health-protective properties of the wine.

Oliveira *et al*. (2010) write, "there is a growing interest in the use of inulin as a health food ingredient, as an alternative for low-calorie sweeteners, and as a dietary fiber and fat substitute (Ritsema and Smeekens, 2003)." In addition, they say "it is suggested" a daily intake of low amounts of inulin or its derivatives promotes the growth of beneficial bacteria in the intestinal tract, as well as anti-tumor effects, citing Roberfroid (2005). Hence, they studied *Vernonia herbacea*, a plant from the Brazilian Cerrado that accumulates inulin-type fructans in underground organs called rhizophores. The five Brazilian researchers grew well-watered and fertilized *V. herbacea* plants from rhizophore fragments for two months and then transferred them in groups of three to 3-L pots containing forest soil. The plants were maintained in open-top chambers in a glasshouse for 120 days at atmospheric CO_2 concentrations of either 380 or 760 ppm, and the scientists measured the plants' net photosynthetic rates, water use efficiencies, and fructan concentrations after 15, 30, 60, 90, and 120 days of treatment, as well as above- and below-ground biomass at the end of the experiment.

Oliveira *et al*. write, the "plants under elevated CO_2 presented increases in height (40%), photosynthesis (63%) and biomass of aerial (32%) and underground (47%) organs when compared with control plants." In addition, "water use efficiency was significantly higher in treated plants, presenting a 177% increase at day 60." They found fructan concentration remained unchanged, but because of the significant CO_2-induced increase in underground organ biomass, "a 24% increase in total fructan yield occurred."

Ghasemzadeh *et al*. (2010) write, "free radicals and single oxygen are recognized as major factors causing various chronic diseases such as cancer, diabetes, *etc*.," and as a result, they note, "the health maintenance function of antioxidant components in various foods has received much attention," citing Byers and Guerrero (1995) and Namiki (1990). They further observe, "phenolic acids and flavonoids are antioxidants with health benefits such as anti-inflammatory and anti-tumor effects (Heijnen *et al*., 2001; Chun *et al*., 2003; Harborne and Williams, 2000; Chen, 2004)," specifically noting "Sung-jin *et*

al. (2008) showed that some flavonoid components in green tea are effective in inhibiting cancer or induce mechanisms that may kill cancer cells and inhibit tumor invasion."

The Malaysian researchers grew two varieties of Malaysian young ginger (*Zingiber officinale*)—Halia Bentong and Halia Bara—from rhizomes planted in a drip-irrigated 1:1 mixture of burnt rice husk and coco peat in polyethylene bags placed within controlled-environment chambers maintained at atmospheric CO_2 concentrations of either 400 or 800 ppm for a period of 16 weeks. They then harvested the plants and analyzed their leaves and rhizomes for a wide variety of phenolics and flavonoids, along with their free radical scavenging power, which is a measure of their ability to prevent dangerous reactive oxygen species from attacking various parts of the body and causing a large number of potentially life-threatening maladies. Malaysian young ginger is one of the medicinal/food plants used by Polynesians for more than 2,000 years in treating cancer, diabetes, high blood pressure, and many other illnesses

Ghasemzadeh *et al.* found, on average, "flavonoid compounds increased 44.9% in leaves and 86.3% in rhizomes of Halia Bentong and 50.1% in leaves and 79% in rhizomes of Halia Bara when exposed to elevated carbon dioxide conditions." Phenolic compounds increased even more: by 79.4% in leaves and 107.6% in rhizomes of Halia Bentong and 112.2% in leaves and 109.2% in rhizomes of Halia Bara. In addition, the increase in the CO_2 concentration from 400 to 800 ppm increased the free radical scavenging power by 30.0% in Halia Bentong and 21.4% in Halia Bara. Also, "the rhizomes exhibited more enhanced free radical scavenging power, with 44.9% in Halia Bentong and 46.2% in Halia Bara."

The three scientists say their results indicate "the yield and pharmaceutical quality of Malaysian young ginger varieties can be enhanced by controlled environment production and CO_2 enrichment."

Ghasemzadeh and Jaafar (2011) also focused on ginger (*Zingiber officinale* Roscoe), noting it is "an important horticultural crop in tropical Southeast Asia" and is the Asian continent's "most widely used herb." It "contains several interesting bioactive constituents and possesses health promoting properties (Rozanida *et al.*, 2005)." Ghasemzadeh and Jaafar lament "no information is available on the effect of CO_2 concentration on the polyphenolic content and scavenging capacity against active oxygen species of Malaysian young ginger varieties."

The two Malaysian scientists grew two varieties

of ginger (Halia Bentong and Halia Bara) from rhizomes placed in polyethylene bags filled with a 1:1 mixture of burnt rice husk and coco peat for a period of 16 weeks in controlled-environment chambers maintained at two atmospheric CO_2 concentrations (400 and 800 ppm). They measured a number of important plant properties during and after the growing period.

In response to the increase in the air's CO_2 content, Ghasemzadeh and Jaafar state, their research showed the rate of photosynthesis was increased by 65% in Halia Bentong and by 46% in Halia Bara, which led to total biomass increases of 48% in Halia Bentong and 76% in Halia Bara. Total flavonoids in the new rhizomes of Halia Bentong and Halia Bara rose by 82% and 118%, respectively, and total phenolics in the same two varieties rose by 154% and 183%, respectively.

The two researchers say their study revealed "ginger has good free radical scavenging ability and therefore can be used as a radical inhibitor or scavenger, acting possibly as a primary antioxidant." Also, increasing the CO_2 content of the atmosphere "can enhance the antioxidant activity of ginger extract, especially in its rhizomes," which can be of great value because it thereby "increases the concentrations of several therapeutic compounds."

Ibrahim and Jaafar (2011) report "the antioxidant properties in food have been a focus of interest in recent years due to the health maintenance functions of these components that can help reduce the risk of chronic diseases such as cancer, hypertension and diabetes." This phenomenon, they note, "is attributed to the high scavenging activity of antioxidants towards free radicals that are usually associated with these diseases (Namiki, 1990; Byers and Guerrero, 1995)." They used a randomized complete block design 3 by 3 experiment to study and distinguish the relationships among production of secondary metabolites, total phenolics, total flavonoids, gluthatione, oxidized gluthatione, soluble carbohydrate, and antioxidant activities of the Malaysian medicinal herb *Labisia pumila* Blume under three levels of CO_2 enrichment (400, 800, and 1,200 ppm) for 15 weeks.

The two Universiti Putra Malaysia researchers write, "secondary metabolites, glutathione, oxidized gluthathione and antioxidant activities in a descending manner came from the leaf enriched with 1200 ppm CO_2 > leaf 800 ppm CO_2 > leaf 400 ppm CO_2 > stem 1200 ppm CO_2 > stem 800 ppm CO_2 > stem 400 ppm CO_2 > root 1200 ppm CO_2 > root 800 ppm CO_2 > root 400 ppm CO_2," and "correlation analyses

revealed strong significant positive coefficients of antioxidant activities with total phenolics, flavonoids, gluthatione and oxidized gluthatione," indicating "an increase in antioxidative activity of *L. pumila* under elevated CO_2 might be up-regulated by the increase in production of total phenolics, total flavonoids, glutathione, oxidized gluthatione and soluble sugar." Ibrahim and Jaafar conclude their study results imply "the medicinal potential of herbal plants such as *L. pumila* can be enhanced under elevated CO_2, which simultaneously improved the antioxidative activity that was indicated by the high oxygen radical absorbance activity against peroxyl radicals, superoxide radicals, hydrogen peroxide and hydroxyl radicals."

Also studying *Labisia pumila* Blume, Jaafar *et al.* (2012) wrote, "plant antioxidants have been a focus of attention in recent years due to the health preservation functions of these components that can help reduce the threat of chronic diseases such as cancer, diabetes and hypertension." These benefits, they note, are "attributed to the high scavenging activity of antioxidants towards free radicals that are usually associated with these diseases (Byers and Guerrero, 1995)." Among this group of plant compounds are phenolic acids and flavonoids, both of which exhibit, they state, "high anti-inflammatory and anti-carcinogenic activities (Heijnen *et al.*, 2001; Chun *et al.*, 2003)." In addition, phenolics and flavonoids can function as reducing agents, free radical scavengers, and quenchers of singlet oxygen formation (Chan *et al.*, 2008). Many of the components of polyphenols have been proven to have significant roles in curing cancer and other human ailments (Harborne and Williams, 2000).

Jaafar *et al.* conducted a split plot 3 x 3 experiment designed to examine the impact of 15 weeks of exposure to three concentrations of CO_2 (400, 800, and 1,200 ppm) on the phenolic and flavonoid compound profiles—as well as the antioxidant activities—of three varieties (*alata, pumila,* and *lanceolata*) of *Labisia pumila* Benth. or kacip fatimah, as it is commonly known throughout Southeast Asia. They describe the latter as "a sub-herbaceous plant with creeping stems from the family Myrsinaceae that is found widespread in Indochina and throughout the Malaysian forest"; it has historically been used to help maintain a healthy female reproductive system.

The three Malaysian researchers report that when exposed to elevated CO_2 (1200 ppm), "gallic acid increased tremendously, especially in var. *alata* and *pumila* (101–111%), whilst a large quercetin increase was noted in var. *lanceolata* (260%), followed closely by *alata* (201%)." They also found "caffeic acid was enhanced tremendously in var. *alata* (338–1100%) and *pumila* (298–433%)," and "rutin continued to increase by 262% after CO_2 enrichment." In addition, they note naringenin was enhanced by 1,100% in var. *pumila*. Finally, they report "the increase in production of plant secondary metabolites in *L. pumila* was followed by enhancement of the antioxidant activity under exposure of elevated CO_2."

Moghaddam *et al.* (2011) explain *Centella asiatica* or Gotu Kola is a small herbaceous annual plant that has been used as a medicinal herb or nutraceutical in Ayurvedic, African, and traditional Chinese medicine for more than 2,000 years, valued for its mildly antibacterial, antiviral, and anti-inflammatory properties. It also has been used as a rejuvenating diuretic herb that is purported to clear toxins, reduce inflammations and fevers, improve healing and immunity, improve memory, and provide a balancing effect on the nervous system.

The six scientists grew well-watered and fertilized *C. asiatica* plants for four to five weeks in individual polybags filled with a 1:1:1 mix of sand, coco dust, and compost within controlled environment chambers, where CO_2 concentrations of 400 and 800 ppm were maintained, the researchers write, "for two hours every day between 8:30 to 10:30 am." At the end of these four- to five-week periods the plants were harvested and their leaves assessed for total biomass and total flavonoid content. The latter substance is considered to be the source of the many health benefits attributed to the species.

Moghaddam *et al.* report the daily two-hour 400 ppm increase in the controlled environment chambers' atmospheric CO_2 concentration led to a 193% increase in *C. asiatica* leaf biomass, a 264% increase in plant water use efficiency, and a 171% increase in leaf total flavonoid content. The six scientists conclude, "collectively, the enhancement in yield and quality provides an economic motivation to produce a consistent pharmaceutical-grade product for commercial purposes," via what they describe as "controlled environment plant production." It also stands to reason the ongoing rise in the atmosphere's CO_2 concentration should be gradually increasing the medicinal potency of *C. asiatica* plants either growing wild or cultivated out-of-doors.

Ibrahim and Jaafar (2012) studied the oil palm *Elaeis guineensis* (Jacq.)—the highest-yielding vegetable oil producer in the world—which has gained wide recognition because of the health-promoting properties of some of its flavonoids and phenolics, which the two scientists describe as

"natural antioxidants that may reduce oxidative damage to the human body," citing Mandel and Youdim (2004). For 15 weeks, the pair of researchers grew initially-five-month-old seedlings of three progenies of oil palm (deli AVROS, Deli Yangambi, and Deli URT) within growth chambers maintained at atmospheric CO_2 concentrations of either 400, 800, or 1,200 ppm, measuring a large number of important plant properties and processes.

Ibrahim and Jaafar discovered the production of total flavonoids and phenolics was highest under 1,200 and lowest at 400 ppm CO_2, and "the antioxidant activity, as determined by the ferric reducing/antioxidant potential (FRAP) activity increased with increasing CO_2 levels." In leaves, for example, they found the quantity of "total flavonoids was enhanced by 86% and 132%, respectively, in 800 and 1200 ppm compared to 400 ppm CO_2," and total phenolics "increased by 52% to 91% under elevated CO_2 compared to the ambient CO_2 condition." Ibrahim and Jaafar say their findings "suggest that enrichment with higher than ambient CO_2 level is able to enhance the production of gallic acid and rutin in oil palm seedlings." This finding is important because these bioactive components, as they describe them, "act as free radical scavengers, and hence can reduce the possibilities of major diseases such as cancers of leukemia, breast, bone and lung," citing Kaufman *et al.* (1999) and Wink (1999).

In light of the research discussed above, it is clear atmospheric CO_2 enrichment positively impacts the production of numerous health-promoting substances found in medicinal or "health food" plants, and this phenomenon may have contributed to the increase in human life span that has occurred over the past century or so (Horiuchi, 2000; Tuljapurkar and Boe, 2000). As the atmosphere's CO_2 content continues to rise, humanity may be helped even more in this regard in the years and decades to come.

7.8.4 Health-Harming Substances

- There appears to be little reason to expect any significant CO_2-induced increases in human-health-harming substances produced by plants as the atmosphere's CO_2 concentration continues to rise.

Whereas IPCC makes no mention of the CO_2-induced enhancement of certain health-promoting substances in plants, as described in the subsections above, it is quick to point out the possibility of a CO_2-induced enhancement in certain health-*harming* substances. The research on that topic is the focus of this subsection.

Wayne *et al.* (2002) grew common ragweed plants from seed in controlled-environment glass-houses maintained at ambient (350 ppm) and enriched (700 ppm) atmospheric CO_2 concentrations for 84 days. They then sampled the pollen from the central plants of each stand, assessed the pollen's characteristics, and harvested all mature seeds and above-ground shoot material. They report, "stand-level pollen production was 61% higher in elevated versus ambient CO_2 environments" and "CO_2-induced growth stimulation of stand shoot biomass was similar to that of total pollen production." Although the researchers admit it would be "challenging to accurately predict the future threat to public health caused by CO_2-stimulated pollen production"—because "it is likely that plant pollen production will also be influenced by factors expected to change in concert with CO_2, including temperature, precipitation, and atmospheric pollutants"—they nevertheless suggest "the incidence of hay fever and related respiratory diseases may increase in the future."

Weber (2002) discussed the study of Wayne *et al.* in a guest editorial published in the same issue of the *Annals of Allergy, Asthma & Immunology*. He begins by noting "one can always wonder whether such manipulations [i.e., those employed in Wayne *et al.*'s study] have any relationship to present reality, or indeed, conditions that one can expect in the near future," and then proceeds methodically to his

conclusion: "it would be premature to assume that increased pollen grain numbers necessarily lead to an increased aeroallergen exposure."

Weber notes, "allergenic activity of short ragweed will vary from year to year, even from the same source and supplier (Maasch *et al.*, 1987)," and he cites Lee *et al.* (1979) as having found "varying potency in plants at the same site from year to year, which [were] attributed to seasonal climatic differences, primarily of rainfall." The latter researchers found a four-fold range in the allergenic potency of ragweed pollen within a single county in Illinois (USA). Consequently, Weber concludes "a constant relationship between pollen mass and allergenic protein content is not a given," and it will remain speculative until scientists determine whether "the increased pollen grains seen with the increased ambient CO_2 levels maintain the same ratio of allergenic proteins."

A further demonstration of the tenuousness of the suggestion of Wayne *et al.*—that "the incidence of hay fever and related respiratory diseases may increase in the future" because of the near-universal growth-promoting effects of atmospheric CO_2 enrichment—is provided by Rogers *et al.* (2006). They collected and vernalized ragweed seeds by sowing them in containers kept in a refrigerator maintained at 4°C. They transferred one-third of the seeded containers at 15-day intervals to glasshouse modules maintained at atmospheric CO_2 concentrations of either 380 or 700 ppm, and the seeds were allowed to germinate (also at 15-day intervals, with the middle germination date approximating that of plants currently growing naturally in the vicinity of where the seeds were collected). They kept the seeds under well-watered and fertilized conditions until the seeds senesced. The researchers then harvested the seeds and conducted assessments of plant and allergenic pollen biomass.

As best as can be determined from the graphical representations of Rogers *et al.*'s data, the end-of-season CO_2-induced increase in aboveground plant biomass was about 16% for the date of emergence typical of the present, and the corresponding increase in pollen production was about 32%. For the 15-day earlier date of emergence, which was chosen to represent "anticipated advances of spring several decades into the future" based upon projected rates of future global warming, the end-of-season CO_2-induced change in aboveground plant biomass was only about +3%, and the end-of-season CO_2-induced change in pollen production was actually a negative 3%.

The most meaningful way of viewing the results, then, is to determine the change in pollen production that would occur in going from today's atmospheric CO_2 concentration and date-of-onset of spring (380 ppm, middle date of germination) to the elevated CO_2 concentration and earlier date-of-onset of biological spring (700 ppm, 15-day earlier date of germination); when this is done, the production of allergenic pollen is seen to rise by just 1–2%.

Caporn *et al.* (1999) studied bracken, a weed that poses a potential threat to human health in the United Kingdom and other regions, growing specimens for 19 months in controlled-environment chambers maintained at atmospheric CO_2 concentrations of 370 and 570 ppm and normal and high levels of fertilization. They found the elevated CO_2 consistently increased rates of net photosynthesis in bracken from 30 to 70%, depending on soil fertility and time of year. The elevated CO_2 did not increase total plant dry mass or the dry mass of any plant organs, including rhizomes, roots, and fronds. The only significant effect of the elevated CO_2 on bracken growth was observed in the normal nutrient regime, where elevated CO_2 reduced the area of bracken fronds.

Matros *et al.* (2006) grew tobacco plants in pots filled with quartz sand placed in controlled-climate chambers maintained at either 350 or 1,000 ppm CO_2 for eight weeks, irrigating them daily with a complete nutrient solution containing either 5 or 8 mM NH_4NO_3. Some of the plants in each treatment were mechanically infected with potato virus Y (PVY) when they were six weeks old. At the end of the study, the researchers report, the plants grown at elevated CO_2 and 5 mM NH_4NO_3 "showed a marked and significant decrease in content of nicotine in leaves as well as in roots," and at 8 mM NH_4NO_3 the same was found to be true of upper leaves but not of lower leaves and roots. In addition, with respect to the PVY part of the study, they found the plants grown at high CO_2 "showed a markedly decreased spread of virus."

Matros *et al.* report "tobacco plants grown under elevated CO_2 show a slight decrease of nicotine contents," and "elevated CO_2 resulted in reduced spread of PVY." Most people likely would consider both of these impacts beneficial; potato virus Y is economically important because it infects many crops and ornamental plants throughout the world, and nicotine is nearly universally acknowledged to have significant negative effects on human health (Topliss *et al.*, 2002).

Mohan *et al.* (2006) investigated the effects of an extra 200 ppm of atmospheric CO_2 on the growth and development of *Toxicodendron radicans*, commonly known as poison ivy, as well as its effect on the plant's toxicity, over a period of six years at the Duke Forest FACE facility, where the noxious vine grew naturally in a loblolly pine plantation's understory. The researchers surrounded clumps of it with 4 cm plastic-mesh enclosures to protect them from damage by indigenous white-tailed deer. This long and detailed study revealed atmospheric CO_2 enrichment increased poison ivy photosynthesis by 77% and boosted its water use efficiency by 51%. At the end of the study's sixth year, the aboveground biomass of poison ivy plants in the CO_2-enriched plots was 62% greater than that of poison ivy plants in the ambient-treatment plots. In addition, the high-CO_2-grown plants produced "a more allergenic form of urushiol," the substance that produces the plant's allergic reaction in humans.

Not unsurprisingly, the seven scientists say their findings indicate under future levels of atmospheric CO_2, poison ivy "may grow larger and become more noxious than it is today." And so it may, but the story is not quite that simple, as the next study indicates.

Londre and Schnitzer (2006) studied woody vines or lianas, focusing on changes over a period of 45 years in 14 temperate deciduous forests of southern Wisconsin (USA). During that time (1959–1960 to 2004–2005), the air's CO_2 concentration rose by 65 ppm, the mean annual air temperature of the region rose by 0.94°C, and its mean winter air temperature rose by 2.40°C, but its mean annual precipitation did not change. The researchers found, contrary to their initial hypothesis, "liana abundance and diameter did not increase in the interiors of Wisconsin (USA) forests over the last 45 years." *Toxicodendron radicans,* or poison ivy—which they note "grew markedly better under experimentally elevated CO_2 conditions than did competing trees" in the study of Mohan *et al.* (2006)—decreased in abundance over this time period, and significantly.

The two researchers say their study suggests "lianas are limited in the interiors of deciduous forests of Wisconsin by factors other than increased levels of CO_2." It is likely, for example, the growth of interior-forest lianas was limited by the enhanced tree growth provided by the CO_2 increase, which resulted in the trees becoming more competitive with the vines because of CO_2-induced increases in tree leaf numbers, area, and thickness, all of which would lead to less light being transmitted to the lianas growing beneath the forest canopy. This phenomenon apparently negated the enhanced propensity for growth that was provided the vines by the increase in

the atmosphere's CO_2 concentration—the potential growth was not realized because the declining light intensity prevented it.

Londre and Schnitzer provide support for this reasoning in their finding that "compared to the forest interior, lianas were >4 times more abundant within 15 m of the forest edge and >6 times more abundant within 5 m of the forest edge." The two researchers note this "strong gradient in liana abundance from forest edge to interior" "was probably due to light availability." In addition, they say their results "are similar to findings in tropical forests, where liana abundance is significantly higher along fragmented forest edges and within tree fall gaps."

In conclusion, there appears to be little reason to expect any significant CO_2-induced increases in human-health-harming substances produced by plants as the atmosphere's CO_2 concentration continues to rise.

CH_2CII	iodocarbon chloroiodomethane
CH_3C_1	methyl chloride
CH_4	methane
CH_2I_2	diiodomethane
CHD	coronary heart disease
CLEH	climate-linked epidemic hypothesis
CO_2	carbon dioxide
CPR	Continuous Plankton Recorder
CS_2	carbon disulfide
CSIRO	Commonwealth Scientific and Industrial Research Organization (Australia)

Cu	copper
CVD	cardiovascular disease
CZCS	Coastal Zone Color Scanner
DAE	days after emergence
DAS	days after seeding
DBH	diameter at breast height
DGGE	denaturant gradient gel electrophoresis
DHZR	dihydrozeatin ribosidem
DIC	dissolved organic carbon
DM	dry matter
DMS	dimethyl sulfide
DNA	deoxyribonucleic acid
DOC	dissolved organic carbon
DTR	diurnal temperature range
ECM	ectomycorrhizal
EF-Tu	protein synthesis elongation factor
ENSO	El Niño-Southern Oscillation
EPA	Environmental Protection Agency
EU	European Union
EVI	Enhanced Vegetation Index
FA	fluctuating asymmetry
FACE	free-air CO_2 enrichment
FACTS	Forest Atmosphere Carbon Transfer and Storage
FATI	free-air temperature increase
FAO	Food and Agriculture Organization
Fe	iron
FRAP	ferric reducing/antioxidant potential
GA3	gibberellic acid
GAM	generalized additive model
GBR	Great Barrier Reef
GCM	General Circulation Models
GCTE	Global Change and Terrestrial Ecosystems
GDP	Gross Domestic Product
GIMMS	Global Inventory Modeling and Mapping Studies
GLO-PEM	Global Production Efficiency Model
gNDVI	Normalized Difference Vegetation Index over the Growing Season

GPCP	Global Precipitation Climatology Project
GPP	gross primary production
gr	gram(s)
GSH	glutathione
GtC	gigatons of carbon
H$_2$O$_2$	hydrogen peroxide
H$_2$S	hydrogen sulfide
HC1	Hidden Cave (Guadalupe Mountains)
HR	heterotrophic respiration
HSG	hematite stained grain
IAA	indole-3 acetic acid
IC	ischemic stroke
IE	infection efficiency
IMAR	Inner Mongolia Autonomous Region
iPA	isopentenyl adenosine

Table 1.1.1 — Plant Dry Weight (Biomass) Responses to Atmospheric CO$_2$ Enrichment

Table 1.1.1 reports the results of hundreds of peer-reviewed scientific studies indicating the biomass growth response of plants to a standardized 300 ppm increase in atmospheric CO$_2$ concentration. Plants are listed by common and/or scientific names, followed by the number of experimental studies conducted on each plant, the mean biomass response to a 300 ppm increase in the air's CO$_2$ content, and the standard error of that mean. Whenever the CO$_2$ increase for a given study was not exactly 300 ppm, a linear adjustment was computed. For example, if the CO$_2$ increase was 350 ppm and the growth response was a 60 percent enhancement, the adjusted 300 ppm CO$_2$ growth response was calculated as (300/350) x 60% = 51%.

The data in this table are printed by permission of the Center for the Study of Carbon Dioxide and Global Change and were taken from its Plant Growth database on 1 January 2014. The table summarizes CO$_2$ enrichment results from 3,586 separate experimental conditions conducted on 549 plant species. New data are added to the database at approximately weekly intervals and can be accessed free of charge at the center's Web site at http://www.co2science.org/data/plant_growth/dry/dry_subject.php. This online database also archives information pertaining to the experimental conditions under which each plant growth experiment was conducted, as well as the complete reference to the journal article from which the experimental results were obtained. The center's online database also lists percent increases in plant biomass for 600 and/or 900 ppm increases in the air's CO$_2$ concentration.

Plant Name	# of Studies	Mean CO$_2$ Growth Response	Standard Error
Abelmoschus esculentus [Okra]	1	8%	0%
Abies alba [Silver Fir]	5	33.20%	11.60%
Abies faxoniana [Minjiang Fir]	4	20.30%	2.90%
Abutilon theophrasti [Velvet Leaf]	14	32.10%	13.70%
Acacia karroo [Sweet Thorn]	3	53.70%	5.90%
Acacia aneura [Mulga Acacia]	1	0%	0%

Table 1.1.2 — Plant Photosynthesis (Net CO_2 Exchange Rate) Responses to Atmospheric CO_2 Enrichment

Table 1.1.2. reports the results of peer-reviewed scientific studies measuring the photosynthetic growth response of plants to a 300 ppm increase in atmospheric CO_2 concentration. Plants are listed by common and/or scientific names, followed by the number of experimental studies conducted on each plant, the mean photosynthetic response to a 300 ppm increase in the air's CO_2 content, and the standard error of that mean. Whenever the CO_2 increase for a given study was not exactly 300 ppm, a linear adjustment was computed. For example, if the CO_2 increase was 350 ppm and the growth response was a 60 percent enhancement, the adjusted 300 ppm CO_2 growth response was calculated as (300/350) x 60% = 51%.

The data in this table appear by permission of the Center for the Study of Carbon Dioxide and Global Change and were taken from its Plant Growth database on 1 January 2014. In all, the table summarizes CO_2 enrichment results from 2,094 separate experimental conditions conducted on 472 plant species. New data are added to the database at approximately weekly intervals and can be accessed free of charge at the center's website at http://www.co2science.org/data/plant_growth/dry/dry_subject.php. This online database also archives information pertaining to the experimental conditions under which each plant growth experiment was conducted, as well as the complete reference to the journal article from which the experimental results were obtained. The center's online database also lists percent increases in plant photosynthetic rate for 600 and/or 900 ppm increases in the air's CO_2 concentration.

THE NONGOVERNMENTAL INTERNATIONAL PANEL ON CLIMATE CHANGE

The Nongovernmental International Panel on Climate Change (NIPCC) is an international network of scientists first convened in 2003 to examine the same climate data used by the United Nations-sponsored Intergovernmental Panel on Climate Change (IPCC). Unlike IPCC, NIPCC is not a government agency and does not receive government funding. Whereas the mission of IPCC is to justify control of greenhouse gas emissions, NIPCC has no agenda other than discovering the truth about climate change.

CLIMATE CHANGE RECONSIDERED

Climate Change Reconsidered is a publication series produced by NIPCC and published by The Heartland Institute. Series editors Craig D. Idso, Robert M. Carter, and S. Fred Singer have assembled and oversee an international team of scholars devoted to producing a thorough and unbiased review of the extensive research on climate change. Four volumes were published prior to the present publication: *Nature, Not Human Activity, Rules the Climate* (2008), *Climate Change Reconsidered: The 2009 Report of the Nongovernmental International Panel on Climate Change (NIPCC)* (2009), *Climate Change Reconsidered: The 2011 Interim Report of the Nongovernmental International Panel on Climate Change (NIPCC)* (2011), and *Climate Change Reconsidered II: Physical Science* (2013). All are available for purchase from The Heartland Institute and for free online at www.climatechangereconsidered.org and www.nipccreport.org.

CCR II: BIOLOGICAL IMPACTS

The current report, *Climate Change Reconsidered II: Biological Impacts,* is the most comprehensive and up-to-date review of science on the impacts of climate change. This report combines the research and analysis of previous volumes in the series with new research published as recently as the first quarter of 2014 (well after the cut-off date for IPCC's *Fifth Assessment Report*). This volume tracks and critiques the expected 2014 report of the IPCC's Working Group II on "Impacts, Adaptation, and Vulnerability." A third and final volume of CCR-II series, *Human Welfare, Energy, and Policies*, is being released concurrently with the present volume.

ABOUT THE COAUTHORS

Dr. Craig D. Idso is founder and chairman of the Center for the Study of Carbon Dioxide and Global Change. Since 1998, he has been the editor and chief contributor to the online magazine CO_2 Science. He is the author of several books, including *The Many Benefits of Atmospheric CO_2 Enrichment* (2011) and *CO_2, Global Warming and Coral Reefs* (2009). He earned a Ph.D. in geography from Arizona State University (ASU), where he lectured in meteorology and was a faculty researcher in the Office of Climatology.

Dr. Sherwood B. Idso is president of the Center for the Study of Carbon Dioxide and Global Change. Previously he was a research physicist with the U.S. Department of Agriculture's Agricultural Research Service at the U.S. Water Conservation Laboratory in Phoenix, Arizona. He is the author or co-author of more than 500 scientific publications including the books *Carbon Dioxide: Friend or Foe?* (1982) and *Carbon Dioxide and Global Change: Earth in Transition* (1989). He served as an adjunct professor in the Departments of Geology, Geography, and Botany and Microbiology at Arizona State University. He earned a Ph.D. in soil science from the University of Minnesota.

Dr. Robert M. Carter is a stratigrapher and marine geologist with degrees from the University of Otago (New Zealand) and University of Cambridge (England). He is the author of *Climate: The Counter Consensus* (2010) and *Taxing Air: Facts and Fallacies About Climate Change* (2013). Carter's professional service includes terms as head of the Geology Department, James Cook University, chairman of the Earth Sciences Panel of the Australian Research Council, chairman of the national Marine Science and Technologies Committee, and director of the Australian Office of the Ocean Drilling Program. He is currently an emeritus fellow of the Institute of Public Affairs (Melbourne).

Dr. S. Fred Singer is one of the most distinguished atmospheric physicists in the U.S. He established and served as the first director of the U.S. Weather Satellite Service, now part of the National Oceanic and Atmospheric Administration (NOAA), and earned a U.S. Department of Commerce Gold Medal Award for his technical leadership. He is coauthor, with Dennis T. Avery, of *Unstoppable Global Warming Every 1,500 Years* (2007, second ed. 2008) and many other books. Dr. Singer served as professor of environmental sciences at the University of Virginia, Charlottesville, VA (1971-94), and is founder and chairman of the nonprofit Science and Environmental Policy Project. He earned a Ph.D. in physics from Princeton University.
