The nine scientists first note their data pertaining to forest-floor carbon pools indicate the existence of "a long-term steady-state sink" of about 30 g C per m^2 per year, which represents, they write, "a substantial increase in forest-floor C storage under elevated CO_2 (i.e. 29%)," which they attribute to "increased litterfall and root turnover during the first 9 years of the study." Second, below the forest floor, they say, "approximately 20% [of the mineral soil carbon formed during the prior nine years] has been allocated to stable pools that will likely remain protected from microbial activity and associated release as CO_2."

A third important finding was "a significant

widening of the C/N ratio of soil organic matter in the upper mineral soil under both elevated and ambient CO_2," which suggests, as they describe it, "enhanced rates of soil organic matter decomposition are increasing mineralization and uptake to provide the extra N required to support the observed increase in primary productivity under elevated CO_2." And at the Duke Forest FACE site, Pritchard *et al.* (2008b) say this CO_2-induced increase in productivity amounted to approximately 30% annually, adding there is "little evidence to indicate a diminished response through time." They cite Finzi *et al.* (2007), who found the same to be true at the long-term forest FACE studies at Rhinelander, Wisconsin (USA), Oak Ridge National Laboratory (USA), and Tuscania (Italy).

Contrary to the early expectations of many scientists, many forests thought to have had access to less-than-adequate soil nitrogen supplies appear to be able to acquire the extra nitrogen they need to maintain the sizable increases in their growth rates driven by elevated concentrations of atmospheric CO_2. In North Carolina's Duke Forest, for example, "even after nine years of experimental CO_2 fertilization," as Lichter *et al.* (2008) note, "attenuation of the CO_2-induced productivity enhancement has not been observed," as Finzi *et al.* (2006) also found. This finding at this location is extremely significant because the growth of pine-hardwood forests in the southeastern United States often removes so much nitrogen from the soil they induce what Finzi and Schlesinger (2003) describe as "a state of acute nutrient deficiency that can only be reversed with fertilization," which, as noted earlier in this section, was not employed at the Duke Forest FACE study.

Jackson *et al.* (2009) describe new belowground data they obtained at the Duke Forest Face site, then present a synthesis of these and other results obtained from 1996 through 2008 to determine which variables may have shown a decrease in their response to atmospheric CO_2 enrichment during that period. Among many other things, they found, "on average, in elevated CO_2, fine-root biomass in the top 15 cm of soil increased by 24%," and in recent years the fine-root biomass increase "grew stronger, averaging ~30% at high CO_2." Regarding coarse roots with diameters greater than 2 mm and extending to a soil depth of 32 cm, they report, biomass sampled in 2008 was "twice as great in elevated CO_2." The graphical representation of their results indicates the coarse-root biomass was 130% greater, quite extraordinary given that the extra 200 ppm of CO_2 supplied to the air

surrounding the CO_2-enriched trees represented an enhancement of only about 55% above ambient conditions. They conclude, "overall, the effect of elevated CO_2 belowground shows no sign of diminishing."

The four researchers also remark, "if progressive nitrogen limitation were occurring in this system, we would expect differences in productivity to diminish for trees in the elevated vs. ambient CO_2 plots," but "there is little evidence from estimates of aboveground or total net primary productivity in the replicated Duke experiment that progressive nitrogen limitation is occurring there or at other forest FACE experiments," citing Finzi *et al.* (2007).

McCarthy *et al.* (2010) analyzed data from the Duke Forest FACE experiment for the years 1996–2004, calculating the net primary productivity (NPP) of the entire ecosystem—including the loblolly pines' understory of various broadleaf species (*Liriodendron tulipifera, Liquidambar styraciflua, Acer rubrum, Ulmus alata, Cornus florida*) plus various other trees, shrubs, and vines—as "the sum of the production of coarse wood (stems, branches, coarse roots), leaf litter (lagged for pines), fine roots and reproductive structures."

They report "elevated CO_2 increased pine biomass production, starting in 1997 and continuing every year thereafter"; "the CO_2-induced enhancement remained fairly consistent as the stand developed"; and "elevated CO_2 increased stand (pine plus all other species) biomass production every year from 1997 onwards with no trend over time." They also noted the average yearly increase in NPP caused by the approximate 54% increase in the air's CO_2 content was 28%. In contradiction of the PNL hypothesis, the trees, bushes, and shrubs constituting the Duke Forest has continued to maintain the extra CO_2-enabled vitality it exhibited from the start of the study, with no subsequent sign of it tapering off.

Drake *et al.* (2011) described how the CO_2-induced enhanced rates of net primary production at the Duke Forest FACE site likely were sustained by a carbon cascade through the root-microbe-soil system. They write, "increases in the flux of carbon belowground under elevated CO_2 stimulated microbial activity" that in turn "accelerated the rate of soil organic matter decomposition and stimulated tree uptake of nitrogen bound to this soil organic matter." This process "set into motion a positive feedback maintaining greater carbon gain under elevated CO_2 as a result of increases in canopy nitrogen content and higher photosynthetic nitrogen-use efficiency," the

consequence of which was "the dominance of carbon storage in tree biomass."

Drake *et al*. write, "the long-term increase in forest productivity under elevated CO_2 at the Duke FACE site appears to be maintained by a belowground exchange of tree carbon for soil nitrogen, with the quantity of carbon allocated belowground set by the availability of nitrogen in the soil and the demand for nitrogen to meet growth requirements." They note, "all of the belowground carbon fluxes thought to increase decomposition rates increased under elevated CO_2, including root production and mortality (Pritchard *et al*., 2008a), root exudation (Phillips *et al*., 2011), fungal rhizomorph production (Pritchard *et al*., 2008b) and allocation of carbon to mycorrhizal fungi (Garcia *et al*., 2008)." They conclude, "the preponderance of the evidence points to increased decomposition [of organic matter] in surface soils as the primary source of additional nitrogen taken up by the trees growing under elevated CO_2."

Phillips *et al*. (2011) opine "increased root exploration alone is unlikely to sustain plant nitrogen requirements under rising CO_2 unless accompanied by the concomitant stimulation of soil microbial activity and the release of nutrients from soil organic matter." Despite the presumed importance of root exudates in this scenario, they note no studies had yet quantified the effects of CO_2 enrichment on exudation by mature trees. They set out to do so in order to understand why progressive nitrogen limitation was not observed in some long-term studies of trees growing on nutrient-poor soil (Langley *et al*., 2009; McCarthy *et al*., 2010). Working at the Duke Forest FACE facility, the three researchers examined plant-microbe interactions in the rhizospheres and bulk soils of the various treatments, measuring differences in rhizosphere microbial activity and root exudation rates.

On an annual basis, Phillips *et al*. state, "exudation increased by *c*. 50% for trees enriched with CO_2 in non-fertilized plots," but trees were unaffected in this manner by CO_2 enrichment in fertilized plots, demonstrating "increased root carbon efflux from CO_2-enriched trees stimulates rhizosphere N cycling in low fertility soils." Their work provides additional evidence that "rhizosphere microbes such as actinomycetes, which produce NAGase enzymes and respond strongly to CO_2 at this site (Billings and Ziegler, 2008), are using energy derived from exudates to synthesize enzymes that release nitrogen from soil organic matter (Cheng and Kuzyakov,

2005)." They emphasize "this dramatic contrast between the fertilized and unfertilized treatments provides evidence that enhanced exudation is a mechanism trees employ for increasing nitrogen availability."

Phillips *et al*. write "the enhanced carbon flux from roots to soil in low fertility forests exposed to elevated CO_2 creates hotspots for microbial activity that are associated with faster rates of soil organic matter turnover and N cycling." This phenomenon provides the trees the extra nitrogen they need to take full advantage of the enhanced potential for growth provided by atmospheric CO_2 enrichment, contrary to the incorrect implications of the progressive nitrogen limitation hypothesis. Phillips *et al*. state their results "provide field-based empirical support suggesting that sustained growth responses of forests to elevated CO_2 in low fertility soils are maintained by enhanced rates of microbial activity and N cycling fueled by inputs of root-derived carbon."

Hofmockel *et al*. (2011) write, "several free-air CO_2 enrichment (FACE) experiments in North America have shown a continual stimulation in forest productivity under elevated CO_2 over time scales nearly reaching a decade (Finzi *et al*., 2006; Norby and Iversen, 2006; Zak *et al*., 2007; McCarthy *et al*., 2010)." In their own examination of the effects of elevated CO_2 on nitrogen (N) cycling in the Duke Forest, where elevated atmospheric CO_2 concentrations "consistently stimulated forest productivity" throughout the decade-long experiment being conducted there, Hofmockel *et al*. provide "an integrated understanding" of this phenomenon that serves as "a basis for inferring how C and N cycling in this forest may respond to elevated CO_2 beyond the decadal time scale."

"Using natural-abundance measures of nitrogen isotopes together with an ecosystem-scale ^{15}N tracer experiment," as the six scientists describe it, they "quantified the cycling of ^{15}N in plant and soil pools under ambient and elevated CO_2 over three growing seasons to determine how elevated CO_2 changed nitrogen cycling between plants, soil and microorganisms," after having first measured natural abundances of ^{15}N in plant and soil pools in the two CO_2 treatments over the prior year. They discovered "at the Duke FACE site, the rate at which N is being sequestered in plant biomass is greater than the rate of atmospheric deposition and heterotrophic N fixation," a finding also established by Finzi *et al*. (2002), Hofmockel and Schlesinger (2007), and Sparks *et al*. (2008). These findings suggest, they write, "soil

organic matter decomposition supplies a significant fraction of plant N in both ambient and elevated-CO_2 conditions, but that this is greater under elevated CO_2."

Hofmockel *et al.* conclude, "in pine forests of the southeastern United States, rising CO_2 may elicit shifts in the mechanisms by which plants acquire nitrogen, allowing a sustained increase in net primary productivity for decades," further stating, "increased mineralization of nitrogen in the organic and 0–15 cm mineral horizon and deeper rooting are likely sustaining the elevated CO_2 enhancement of net primary productivity."

Ellsworth *et al.* (2012) "compiled a comprehensive dataset measured over ten years for a temperate pine forest of *Pinus taeda*, but also including deciduous species, primarily *Liquidambar styraciflua*," derived from "over one thousand controlled-response curves of photosynthesis as a function of environmental drivers (light, atmospheric CO_2 concentration [Ca] and temperature) measured at canopy heights up to 20 meters over eleven years (1996–2006)." From that data they generated "parameterizations for leaf-scale models for the Duke free-air CO_2 enrichment (FACE) experiment."

They found the enhancement of light-saturated leaf net photosynthesis (Anet) in *P. taeda* trees produced by an elevated Ca of +200 ppm was 67% for current-year needles in the upper crown of the trees in summer conditions over the 10-year period, and previous-year foliage Anet was enhanced by 30%. They note "the mean stimulation in light-saturated Anet averaged over the growing season of all years and across canopy positions and needle age classes was 53 ± 7%." In addition, "the photosynthetic enhancement responses to elevated Ca are mirrored in part by the pine biomass accumulation responses to elevated Ca across different years."

The eight researchers also report "co-dominant and sub-canopy *L. styraciflua* trees showed Anet enhancement of 62%," and "various understory deciduous tree species showed an average Anet enhancement of 42%." In addition, "the photosynthetic responses of shaded, understory leaves suggest a capacity to increase photosynthetic carbon capture in elevated Ca in shade-grown plants when measured in sunflecks," citing DeLucia and Thomas (2000). They note this response suggests "a competitive advantage to shade-tolerant species adapted for carbon capture in high sunlight or sunflecks in the understory over less shade-tolerant species."

This comprehensive set of photosynthesis measurements compiled over the course of the Duke Forest FACE study rebuts the progressive nitrogen limitation hypothesis, which posits the initial growth stimulation of atmospheric CO_2 enrichment will dwindle away as time progresses, especially in the case of the pine-hardwood forests of the southeastern United States, which often remove so much nitrogen from the soils in which they grow as to induce what Finzi and Schlesinger (2003) once described as "a state of acute nutrient deficiency that can only be reversed with fertilization." Ellsworth *et al.*'s work demonstrates this is simply not true. In another implication of their findings, the eight researchers conclude the observed "differences in photosynthetic responses between the over-story pines and deciduous tree sub-canopy suggest that increased Ca may have the potential to enhance the mixed-species composition of planted pine stands," and, by extension, "naturally regenerating pine-dominated stands."

Rounding out this review of the progressive nitrogen limitation hypothesis are Phillips *et al.* (2012), who write, "after nearly two decades of research on forest ecosystem responses to global change, uncertainty about the role of roots and rhizosphere processes in soil C and N retention and loss has limited our ability to predict biogeochemical feedbacks to long-term forest productivity." Working at the Duke Forest FACE site, where eight 30-meter-diameter plots of loblolly pine (*Pinus taeda* L.) trees were enriched with an extra 200 ppm of CO_2 from 1996 to 2010, and four similar plots were maintained under then-current ambient-air conditions, Phillips *et al.* measured root-induced changes in soil C dynamics of trees exposed to CO_2 and nitrogen enrichment by combining stable isotope analyses, molecular characterizations of soil organic matter, and microbial assays.

The six scientists conclude the CO_2-enriched trees "may be both enhancing the availability of N by stimulating microbial decomposition of soil organic matter via priming and increasing the rate at which N cycles through the microbial pools owing to the rapid turnover of N-rich fungal tissues," noting "the accelerated turnover of hyphal tissues under elevated CO_2 may represent an important source of N to plants and microbes." Referring to this CO_2-induced phenomenon as the Rhizo-Accelerated Mineralization and Priming, or RAMP, hypothesis, Phillips *et al.* suggest it may have "important consequences for N availability and forest productivity," which could be expected to sustain CO_2-enhanced tree growth over their lifetimes.

3.11.3 Other Plants

- Although the progressive nitrogen limitation hypothesis initially was embraced by many scientists, a vast array of observational data has subsequently shown it dos not explain changes in real ecosystems.

The progressive nitrogen limitation (PNL) hypothesis—which contends low concentrations of soil nitrogen will gradually inhibit the aerial fertilization effect of atmospheric CO_2 enrichment—had its origins in the writings of Hungate *et al*. (2003) and Luo *et al*. (2004). Interestingly, the first of these papers contains considerable evidence that argues against its authors' contentions, as does a subsequent publication (Luo *et al*., 2006), the senior author of which was also senior author of the second paper.

Hungate *et al*. (2003) report the C:N ratio of tree biomass increases with increases in the air's CO_2 concentration, citing Hungate (1999) and Rastetter *et al*. (1992). This indicates increasing amounts of carbon can be stored in tree tissues per unit of nitrogen stored therein as the air's CO_2 content rises; as Hungate and his coauthors state, "soil C:N could also increase with rising atmospheric CO_2 concentration, allowing soil carbon accumulation without

additional nitrogen."

Lou *et al*. (2006) conducted a meta-analysis of various C and N processes in plants and soils in response to atmospheric CO_2 enrichment based on experimentally derived data contained in 104 scientific publications. In response to atmospheric CO_2 enrichment, the carbon and nitrogen contents in all the plant and soil pools studied significantly increased, "leading to more net C and N accumulations in ecosystems at elevated than ambient CO_2." They found the mean CO_2-induced increases in C pools of shoot, root, whole plant, litter, and soil were 22.4%, 31.6%, 23.0%, 20.6%, and 5.6%, respectively, and the corresponding CO_2-induced increases in N pools were 4.6%, 10.0%, 10.2%, 25.4%, and 11.2%. In addition, "N accumulations in ecosystems have long been documented in association with C accumulations during both primary and secondary successions (Crocker and Major, 1955; Binkley *et al*., 2000; Vitousek, 2004)." They conclude, "the net C and N accumulations revealed in this study," which were produced by atmospheric CO_2 enrichment, "together with studies of C and N dynamics during succession over hundreds to millions of years, suggest that ecosystems may have intrinsic capabilities to stimulate N accumulation by C input," which is typically increased by atmospheric CO_2 enrichment. They further conclude "net N accumulation likely supports long-term C sequestration in response to rising atmospheric CO_2 concentration." They state "concomitant increases in C and N contents in plant and soil pools at elevated CO_2 as shown in this study point toward a long-term trend of terrestrial C sequestration in response to rising atmospheric CO_2 concentration," just the opposite of what the PNL hypothesis predicts.

Norby and Iverson (2006) reviewed what they had learned about the PNL hypothesis from "a six-year record of N dynamics of a sweetgum (*Liquidambar styraciflua*) stand exposed to elevated CO_2 in the free-air CO_2 enrichment (FACE) experiment at Oak Ridge, Tennessee, USA," focusing on N uptake, content, distribution, turnover, and N-use efficiency. They write, "net primary productivity in this stand has been significantly higher in CO_2-enriched plots, and the response has been sustained through time, thereby meeting one of the criteria for the development of PNL." They further report, "none of the measured responses of plant N dynamics in this ecosystem indicated the occurrence of PNL."

Hungate *et al*. (2006) tested the PNL hypothesis against what they had observed over seven years in an

open-top chamber study of a scrub oak woodland dominated by *Quercus myrtifolia*, *Q. geminate,* and *Q. chapmanii* on an island in NASA's Kennedy Space Center on the coast of central Florida (USA). Their experiment commenced just a few months after a complete burning of the ecosystem located on well-drained but nutrient-poor soil. They report "litterfall production (one measure of aboveground primary productivity) increased initially in response to elevated CO_2, but the CO_2 stimulation declined during years five through seven, concurrent with the accumulation of N in the O [soil] horizon and the apparent restriction of plant N availability." They state these changes in N cycling were "likely to reduce the response of plant production to elevated CO_2." However, they acknowledge, "at the level of aboveground plant biomass (estimated by allometry), progressive N limitation was less apparent." In fact, there was a persistent CO_2-induced increase in aboveground plant carbon, which led them to conclude "some mechanisms are partially alleviating progressive N limitation," as Finzi *et al*. (2006) also concluded in their study of loblolly pines, where by some unknown means the pines obtained the extra nitrogen they needed.

Idso and Kimball (2001) also observed a large initial CO_2-induced increase in aboveground biomass production, followed by a rapid but slowing decline in this parameter, in their long-term sour orange tree study. Because the trees of their experiment were periodically fertilized so as never to lack nitrogen, the similar productivity vs. time pattern Hungate *et al*. observed may have had nothing to do with "restriction of plant N availability," which they characterized as being merely "apparent." It is also important to note the slow decline in the CO_2-induced growth stimulation of the sour orange trees came to a halt at the ten-year point of the experiment, when the declining growth stimulation finally leveled out at an essentially constant value that was maintained to the end of the 17-year study—a 69% increase in yearly total biomass production in response to a 75% increase in the air's CO_2 content (Kimball *et al*., 2007).

Consequently, as Norby and Iverson (2006) and Finzi *et al*. (2006) both found, the pattern of CO_2-induced growth stimulation in the scrub oak ecosystem Hungate *et al*. studied provides no evidence for the PNL hypothesis. In fact, it and others of their observations point to one or more unknown means of ecosystem N acquisition that allow the aerial fertilization effect of atmospheric CO_2

enrichment to continue, albeit at a level of impact lower than its peak manifestation, even with "apparent" N limitations.

Johnson *et al*. (2006) studied the effects of elevated CO_2 (ambient, +175, +350 ppm) and N fertilization (unfertilized, +100, +200 kg N ha^{-1} yr^{-1}, provided as ammonium sulfate) on C and N accumulations in the biomass of ponderosa pines (*Pinus ponderosa* Laws, grown from seed) and the soils that supported them, in a six-year open-top chamber experiment conducted near Placerville, California (USA). This study, like several others according to Johnson *et al*., "showed that growth response to elevated CO_2 more than offset declines in tissue N concentrations, necessitating increased N uptake by trees," which led them to ask, "How did the trees manage to obtain this 'extra' N in an N-limited environment?"

In the fertilized treatments, the four researchers suggest, the extra N could readily have been supplied by the added fertilizer, but in the unfertilized treatments they opine a substantial amount of the N uptake "probably came from the soil," as both wet and dry deposition were not great enough to have supplied all of the extra N, and "no symbiotic N fixer was present in the study plots." Citing other investigators' results as supplying circumstantial evidence for what they finally concluded, they write, "the additional N needed to respond to elevated CO_2 came from the soil and was facilitated by greater root exploration under elevated CO_2." Acknowledging they could not "provide an accurate prediction from the results of this study," Johnson *et al*. nevertheless state they could "see no evidence that either growth or additional N uptake at the +350 ppm CO_2 level are being inhibited by PNL as of year 6 in this study."

Studying the same trees, Phillips *et al*. (2006) collected video images every two months of roots growing against the surfaces of three minirhizotron tubes installed in each chamber. Yearly values of fine-root standing crop, production, and mortality were consistently higher in the elevated CO_2 treatments throughout the study, and they write, "in this same study, Johnson *et al*. (2000) found that elevated CO_2 increased fine-root life span." Because elevated CO_2 also increased fine-root length, Phillips *et al*. note, "the amount of root length dying per year was actually greater." Therefore, they write, "the higher rates of mortality in absolute terms for elevated CO_2 are driven by increased standing crop and not reduced life spans." In addition, they report Tingey *et al*. (2005) found "in the elevated CO_2

treatments, fine roots explored the soil more extensively and deeper, and filled in the explored areas more intensively." With respect to the PNL hypothesis, therefore, Phillips *et al*. state "the increased fine-root length reported here explains how additional N was provided to support the increased whole plant growth in elevated CO_2 treatments, and corresponds with the increased extent and intensity of the root system architecture discussed by Tingey *et al*. (2005)." This "mining of soil N," they continue, "can in some cases go on for substantial lengths of time, and there is no evidence that PNL occurred during the course of this study."

Barnard *et al*. (2006) injected ^{15}N-labelled NH_4 into the soil of mesocosms of *Holcus lanatus* (L.) grown for more than 15 months at either ambient or elevated atmospheric CO_2 concentrations to determine whether the uptake capacity of soil micro-organisms had remained higher at elevated CO_2, and to shed further light on the short-term (48 hours) partitioning of N between plants and soil micro-organisms. Their results and data from other plant-microbial ^{15}N partitioning experiments at elevated CO_2 suggest "the mechanisms controlling the effects of CO_2 on short- vs. long-term N uptake and turnover differ." They state "short-term immobilization of added N by soil micro-organisms at elevated CO_2 does not appear to lead to long-term increases in N in soil microbial biomass," noting the increased soil microbial C:N ratios they observed at elevated CO_2 "suggest that long-term exposure to CO_2 alters either the functioning or structure of these microbial communities." Barnard *et al*. conclude "short-term immobilization of inorganic soil nitrogen or exploitation of nutrient pulses may be altered under conditions of elevated atmospheric CO_2 concentration," and this alteration undermines the PNL hypothesis, likely allowing long-lived plants and ecosystems to maintain positive growth responses to atmospheric CO_2 enrichment.

Noting the photosynthetic down-regulation posited by the PNL hypothesis "may occur in ecosystems that have a low soil N availability, such as piedmont loblolly pine forests"—the setting in which the long-term Duke Forest FACE study was being conducted—Springer and Thomas (2007) tested the validity of the hypothesis on some of the site's understory tree species. They "hypothesized that after seven years of exposure to elevated CO_2, significant photosynthetic down-regulation would be observed in these tree species," which included red maple (*Acer rubrum* L.), hickory (*Carya glabra* Mill.), redbud

(*Cercis canadensis* L.), and sweetgum (*Liquidambar styraciflua* L.).

During the first year of the Duke Forest FACE experiment, DeLucia and Thomas (2000) examined the photosynthetic responses of these particular saplings to the 200 ppm increase in atmospheric CO_2 concentration employed in that study. Subsequently, Springer and Thomas "reexamined the photosynthetic responses of saplings of the same four understory species to determine whether the enhancement of photosynthesis observed during the first year of exposure to elevated CO_2 was sustained in the seventh year of the experiment." They found "no evidence of photosynthetic down-regulation in any species in either early or late summer." Not only did their measurements reveal no down-regulation of photo-synthesis, they observed "a small increase in the photosynthetic capacity of all of the study species in response to elevated CO_2," which they say "has been demonstrated in several studies (Campbell *et al*., 1988; Ziska and Teramura, 1992; Idso *et al*., 1991)."

Springer and Thomas note "the progressive N limitation hypothesis predicts a diminished response of plant productivity to elevated CO_2 as N availability decreases because of the increased nutrient demands of greater plant biomass production (Luo *et al*., 2004)." They go on to reiterate their own finding: "after seven years of elevated CO_2 treatment in the Duke Forest FACE experiment, we see little evidence of progressive N limitation in the leaf level processes of these four species of understory trees."

Working at the EUROFACE facility in central Italy near Viterbo, Liberloo *et al*. (2007) grew three species of poplar trees—robusta poplar (*Populus x euramericana*), white poplar (*P. alba*), and black poplar (*P. nigra*)—for two three-year periods, between which times the trees were coppiced and allowed to regrow, in either ambient air or air enriched with an extra 180 ppm of CO_2 (an approximate 49% enhancement). They applied no fertilization to any of the plots over the first growth cycle, then fertilized half of the trees over the second growth cycle. During the last year of the last cycle, they measured a number of plant processes and parameters and compared them with similar observations made throughout earlier years of the experiment.

The five researchers discovered, after six years of growth under elevated atmospheric CO_2, the poplar trees did not experience any down-regulation of leaf net photosynthesis, and the long-term stimulation was substantial. In response to the 49% increase in the

atmosphere's CO_2 concentration, the CO_2-induced stimulation of net photosynthesis, averaged over the three species, was 49%. In addition, they found no difference in CO_2-induced net photosynthetic stimulation between Sun and shade leaves, nor was there any difference in CO_2 effects between the fertilized and non-fertilized trees.

After thus finding "photosynthetic stimulation of poplar leaves was sustained in elevated CO_2 after six years of fumigation, even under non-fertilized conditions," Liberloo et al. state "these results give optimistic perspectives for the future, as the maintained enhancement of photosynthesis in poplar trees is likely to continue over several rotations, thereby providing more carbon for growth in a closed canopy forest."

Finzi et al. (2007) evaluated the PNL hypothesis based on data obtained from four well-known FACE experiments conducted on forests—the Rhinelander, Duke, and Oak Ridge National Laboratory (ORNL) studies in the United States and the POP-EUROFACE study in Europe—where previous research described by Norby et al. (2005) showed net primary production (NPP) increased by 23 ± 2% in response to a CO_2 concentration increase of 174 ppm (46%) above the mean ambient-air concentration. Finzi et al. found the CO_2-induced increase in forest productivity at the POP-EUROFACE site, which they note was "located on former agricultural land where soil nitrogen availability was high and not limiting," not to have been supported by greater nitrogen uptake from the soil but instead by an increase in nitrogen use efficiency (NUE). At the other three sites, however, the CO_2-induced increase in forest productivity was supported by greater N uptake from the soil, with no change in NUE. They state this result was "unexpected," especially for the Duke and ORNL sites, where they say "tree growth is demonstrably N-limited."

Focusing on the findings of the three U.S. studies, Finzi et al. state "the response of N uptake and NUE in these young temperate forests exposed to FACE is the opposite of that predicted by the current generation of biogeochemical models," meaning those based on the PNL hypothesis. After discussing how these forests might be obtaining the seemingly impossible-to-obtain nitrogen they needed to maintain their significantly CO_2-enhanced growth rates, the scientists conclude, "regardless of the specific mechanism, this analysis demonstrates that larger quantities of carbon entering the below-ground system under elevated CO_2 result in greater N uptake,

even in N-limited ecosystems."

Zak et al. (2007) initiated a year-long ecosystem-level ^{15}N tracer experiment at the Rhinelander, Wisconsin (USA) FACE facility at the seven-year point of a long-term study of aspen (*Populus tremuloides*) and aspen-birch (*P. tremuloides-Betula papyrifera*) communities exposed to treatments of CO_2 (ambient and elevated to 200 ppm above ambient) and O_3 (ambient and elevated to 30–40 ppb above ambient). One year after adding tracer amounts of [15]NH_4^+ to the forest floor of the young tree stands, they found "both forest communities exposed to elevated CO_2 obtained greater amounts of [15]N (29%) and N (40%) from soil, despite no change in soil N availability or plant N-use efficiency." They attribute this to greater belowground root growth and a more thorough exploration of the soil for nitrogen in the CO_2-enriched treatment. In contrast, they note the elevated O_3 treatment "decreased the amount of [15]N (-15%) and N (-29%) in both communities." These decreases were significantly smaller than the corresponding CO_2-induced increases. Consequently, Zak et al. conclude "progressive nitrogen limitation is presently not a factor governing plant growth response to elevated CO_2 in these young, developing forest communities." In addition, they state their findings "are consistent with those in young sweet gum (*Liquidambar styraciflua*) and loblolly pine (*Pinus taeda*) forests exposed to elevated CO_2 (Finzi et al., 2006; Norby and Iversen, 2006)."

Langley et al. (2009) "employed an acid-hydrolysis-incubation method and a net nitrogen-mineralization assay to assess stability of soil carbon pools and short-term nitrogen dynamics in a Florida scrub-oak ecosystem after six years of exposure to elevated CO_2" at the multiple open-top-chamber facility at NASA's Kennedy Space Center. Their research showed elevated atmospheric CO_2 (to 350 ppm above ambient concentrations) tended to increase net N mineralization in the top 10 cm of the soil, but it also decreased total soil organic carbon content there by 21%. That loss of carbon mass was equivalent only to "roughly one-third of the increase in plant biomass that occurred in the same experiment." They found the strongest increases in net N mineralization were in the 10–30 cm depth increment, and "release of N from this depth may have allowed the sustained CO_2 effect on productivity in this scrub-oak forest," which over the four years leading up to their study "increased litterfall by 19–59%."

Thus yet another experiment demonstrates

atmospheric CO_2 enrichment generally enables plants to find the extra nitrogen they need to take full advantage of the aerial fertilization effect of elevated atmospheric CO_2 concentrations, thus increasing total ecosystem carbon content. Although the PNL hypothesis sounds logical enough and many scientists initially embraced it as a fact, a vast array of observational data has subsequently proven it unfounded.

3.12 Salinity Stress

- The buildup of soil salinity from repeated irrigation can produce growth stresses in agricultural plants, but the rise in the air's CO_2 concentration can overcome these stresses.

In agricultural enterprises the buildup of soil salinity from repeated irrigations can reduce crop yields. Similarly, in unmanaged ecosystems where exposure to brackish or salty water is commonplace, saline soils can induce growth stresses in plants not adapted to these conditions. It is important to understand how rising atmospheric CO_2 concentrations may interact with soil salinity to affect plant growth. Experiments addressing this issue are discussed below.

Ball *et al*. (1997) grew two Australian mangrove species—*Rhizophora stylosa* and *Rhizophora apiculata*, the former of which has a slower relative growth rate than the latter but a greater salt tolerance—for 14 weeks in glasshouses with different combinations of atmospheric CO_2 (340 and 700 ppm), relative humidity (43 and 86%), and salinity (25 and 75% of seawater), to determine the effects of these variables on their development and growth. Averaged across the entire experiment, the elevated CO_2 treatment significantly increased the rates of net photosynthesis in both species, but only at the lower salinity level.

Mavrogianopoulos *et al*. (1999) grew parnon melons (*Cucumis melo*) in greenhouses subjected to atmospheric CO_2 concentrations of 400, 800, and 1,200 ppm for the first five hours of each day, irrigating them with nutrient solutions containing 0, 25, and 50 mM NaCl to determine the interactive effects of elevated CO_2 and salinity on plant growth and yield. Exposure to CO_2 concentrations of 800 and 1,200 ppm increased net photosynthetic rates by averages of 75 and 120%, respectively—regardless of salinity—relative to rates measured at 400 ppm CO_2. The CO_2 enrichment partially reversed the negative effects of salinity on shoot growth, leaf growth, and leaf chlorophyll content, and although melon yields were significantly increased with atmospheric CO_2 enrichment at all salinity levels, the greatest CO_2-induced enhancement was observed at the lowest salinity level.

Also working in the agricultural sector, Maggio *et al*. (2002) grew tomato (*Lycopersicon esculentum* Mill.) plants in controlled-environment chambers maintained at atmospheric CO_2 concentrations of either 400 or 900 ppm in combination with varying degrees of soil salinity for one month. They found plants grown in the elevated CO_2 treatment tolerated an average root-zone salinity threshold value about 60% greater than plants grown in the low CO_2 treatment, and the water-use of the CO_2-enriched plants was about half the low-CO_2 plants. In addition, the amount of chloride in the leaves of the CO_2-enriched plants was significantly lower than in the leaves of the low-CO_2 plants.

Poorter and Perez-Soba (2001) reported very similar findings in a review paper. They found the positive effects of elevated CO_2 on the growth responses of most plants over a wide range of soil salinities remained the same, which concurred with the earlier findings of Idso and Idso (1994) in their review. Hence, there is abundant evidence indicating

plants respond positively to increases in the air's CO_2 content, even where high soil salinity levels present mild to moderate stresses.

Syvertsen and Levy (2005) reviewed what was known about salinity stress in citrus trees and how atmospheric CO_2 enrichment might modify it. They note rapidly growing plants almost always use more water than slower-growing plants, and "in citrus, many vigorous rootstocks that produce fast-growing trees also tend to have poor salt tolerance (Castle *et al*., 1993)," possibly because they accumulate more salt in their tissues because of their greater uptake of water. When growing plants in CO_2-enriched air, however, plant stomatal conductance and water use are often decreased at the same time net photosynthesis and growth are increased, so, in the words of the two scientists, "elevated CO_2 almost always leads to higher water use efficiency as it disconnects rapid tree growth from high water use." They explain, "if salt uptake is coupled with water uptake, then leaves grown at elevated CO_2 should have lower salt concentrations than leaves grown at ambient CO_2 (Ball and Munns, 1992)."

"As expected," Syvertsen and Levy continue, "all citrus rootstock species studied increased growth and water use efficiency in response to elevated CO_2 that was twice ambient," and generally, but not always, "the salinity-induced accumulation of sodium (Na^+) in leaves was less when seedlings were grown at elevated CO_2 than at ambient CO_2." One exception—where Na^+ accumulation was not affected by elevated CO_2—was Rangpur lime (*Citrus reticulata*), but they report this citrus variety was already relatively salt-tolerant, and another variety of the same species (Cleopatra mandarin) had lower leaf chloride concentrations in CO_2-enriched air than in ambient air.

Rasse *et al*. (2005) reported on the long-term effects of atmospheric CO_2 enrichment on the net CO_2 exchange, shoot density, and shoot biomass of the wetland sedge, *Scirpus olneyi*, as well as how those effects were influenced by salinity (one of the main environmental stressors of the wetlands), in one of the longest (17 years) *in situ* atmospheric CO_2 enrichment experiments ever conducted—in a natural wetland located at the Smithsonian Environmental Research Center on the Chesapeake Bay (USA). In every year of that period, the net CO_2 exchange rate and shoot biomass and density of the plants growing in the CO_2-enriched (ambient +340 ppm) air were greater than they were among the plants growing in ambient air. In the case of the net CO_2 exchange rate, for example,

the extra CO_2 boosted it by 80% in the first year of the study, but the enhancement declined to about 35% by the end of the third year and remained relatively constant at that value over the following 15 years. Shoot biomass and density also increased; while the CO_2-induced stimulation of the net CO_2 exchange rate remained essentially constant over the past 15 years, the CO_2-induced stimulations of shoot biomass and density increased over time. After five years of a nearly constant stimulation of 16%, for example, shoot density increased in near-linear fashion to a value 128% above the ambient-air value at the end of year 17. The response of shoot biomass to CO_2 enrichment was also nearly linear, reaching a value approximately 70% above ambient at year 17. The trends in shoot density and biomass did not appear to be leveling off.

Net CO_2 exchange, shoot density, and shoot biomass were also closely correlated with salinity—the higher the salinity, the more detrimental were its effects on these variables. But even at the highest levels of salinity reported, atmospheric CO_2 enrichment was able to produce a positive, albeit reduced, stimulation of net CO_2 exchange. For shoot biomass and density, the responses were better still. Not only did atmospheric CO_2 enrichment essentially eradicate the detrimental effects of salinity, there was, Rasse *et al*. write, "evidence suggesting that salinity stress increased the stimulation of shoot density by elevated atmospheric CO_2 concentration."

This experiment demonstrated several important facts. First, as the researchers state, their results "leave no doubt as to the sustained response of the salt marsh sedge to elevated atmospheric CO_2 concentration." Second, as the initial responses of the three growth variables declined or remained low during the first few years of the study, but leveled out or increased thereafter, it is clear long-term research must be carried out to ascertain the full and correct impacts of atmospheric CO_2 enrichment on plants. In the wetland sedge of this study, for example, it took about 10 growing seasons before an increasing trend in the shoot density could be recognized. Finally, there is what the researchers called their "most important finding": "a species response to elevated atmospheric CO_2 concentration can continually increase when [it] is under stress and declining in its natural environment."

Garcia-Sanchez and Syvertsen (2006) grew well-watered and -fertilized three-month-old rootstock seedlings of Cleopatra mandarin (*Citrus reticulata* Blanco) and Carrizo citrange (*Citrus sinensis* (L.)

Osb. x *Poncirus trifoliata* L.), with or without salt stress (an additional 50 mM NaCl), for eight additional weeks, one plant each in 1.5-liter containers located in controlled-environment greenhouses maintained at either 360 or 700 ppm CO_2. During that time and at the end of the experiment, they measured a number of plant properties and physiological processes that allowed them to determine whether "salinity tolerance of citrus rootstock seedlings would be increased when grown in elevated CO_2."

The two researchers found "elevated CO_2 increased plant growth, shoot/root ratio, leaf dry weight per area, net assimilation of CO_2, chlorophyll, and water-use efficiency." The increase in the last parameter was caused by a decrease in transpiration and an increase in plant biomass. In Cleopatra mandarin, biomass received a 27% CO_2-induced boost in the salt-stress treatment and a 40% boost in the non-salt-stress treatment; in Carrizo citrange, biomass received a 49% boost in the salt-stress treatment and 43% in the non-salt-stress treatment. They note "elevated CO_2 increased salinity tolerance in the relatively salt-sensitive Carrizo more than in the salt-tolerant Cleopatra."

Takagi *et al.* (2008) grew well-watered and well-fertilized *Solanum lycopersicum* (formerly *Lycopersicon esculentum*) tomato plant seedlings for two weeks at two levels of irrigation-water salinity (0 or 100 mM NaCl) in 3-L pots inside the greenhouse of Hiroshima University (Japan), at atmospheric CO_2 concentrations of either 370 or 1,000 ppm, measuring various plant properties and physiological responses. They report the "salt-stress treatment severely decreased whole-plant biomass" and "leaf photosynthesis and transport of carbon assimilates," but "the impact of stress on these activities was alleviated under elevated CO_2 concentration." This alleviation, they write, "was promoted when sink activity relative to source activity was higher," which they say was "probably owing to improvement of oxidative stress," due "at least partially to the higher constitutive antioxidant enzymes' activities" as well as improved water status "through stomatal closure at high CO_2 concentration." They conclude their study "corroborates earlier reports that the interaction between salinity stress and CO_2 concentration results in the alleviative effect of elevated CO_2 on the negative effects of salinity on plant growth."

Geissler *et al.* (2009a) note, "desertification is often accompanied by soil salinization ... leading to growth conditions unacceptable for most conventional crops." They suggest "a promising solution" to the problem is "the desalinization and reclamation of degraded land by making sustainable use of naturally salt-tolerant halophytes under seawater irrigation (including drainage mechanisms which avoid salt accumulation in the soil)."

The three researchers grew well-fertilized two-month-old *Aster tripolium* plants in a hydroponic system maintained at seawater salinity (sws) levels of 0, 50, and 100% in open-top chambers at atmospheric CO_2 concentrations of either 380 ppm (ambient) or 520 ppm (elevated), during which time they measured several plant properties and processes. Growing the plants with water of 100% sws (as opposed to 0% sws) resulted in "a significant decrease in photosynthesis and water use efficiency and to an increase in oxidative stress." When they raised the air's CO_2 concentration by 37% (from 380 to 520 ppm), there was a subsequent increase of 84% in photosynthesis and 60% in water use efficiency. The researchers note "the improved water and energy supply was used to increase the investment in mechanisms reducing water loss and oxidative stress." They conclude, because "elevated CO_2 concentration enhances the energy and water supply of *Aster tripolium*, ameliorates oxidative stress, and thus enhances the survival of this plant in saline habitats," it "can help in desalinizing and reclaiming degraded land and sequestering CO_2, thus counteracting the greenhouse effect."

Geissler *et al.* (2009b) write halophytes are "naturally salt tolerant plants which are able to complete their life cycle on a substrate rich in NaCl," and cash-crop halophytes "can be used for various economical and ecological purposes, e.g. for food, fodder, for obtaining timber, fibers, reeds or chemicals, as ornamental plants, for coastal protection, land reclamation or greenification of deserts." They note *Aster tripolium*, in particular, "can be used for food (the leaves have a high nutritional value and can be eaten as salad or vegetable), for fodder and as an ornamental plant."

The three scientists state the 40% increase in the air's CO_2 content in their experiment increased the light-saturated rate of net photosynthesis by 56%, 82%, and 71%, respectively, in the plants irrigated with water of 0, 50, and 100% sws, and it increased their water use efficiencies by 14, 26, and 61%, respectively. Other positive impacts of the CO_2-enriched air were "an enhanced synthesis of proline, carbohydrates and proteins," and "these mechanisms led to a higher survival rate under saline conditions,

i.e. to an improved salt tolerance." Thus, they conclude "*A. tripolium* is a promising cash crop halophyte which will probably benefit from rising atmospheric CO_2 concentrations in the future," and "its sustainable use can help feeding the growing world population."

Working with a more common crop, Perez-Lopez *et al*. (2009a) grew two barley (*Hordeum vulgare* L.) cultivars, Alpha and Iranis, in controlled-environment growth chambers at either ambient (350 ppm) or elevated (700 ppm) atmospheric CO_2 concentrations in a 3:1 perlite:vermiculite mixture watered with Hoagland's solution every two days (until the first leaf was completely expanded at 14 days), after which they administered a salinity treatment by adding 0, 80, 160, or 240 mM NaCl to the Hoagland's solution every two days for 14 more days. After a total of 28 days, the primary leaf of each barley plant was harvested and assessed for a number of biochemical properties.

In the various ambient-air salinity treatments, the deleterious effects of reactive oxygen species on barley leaves were made apparent through ion leakage and increases in thiobarbituric acid reactive substances (TBARS), which rose as salt concentrations rose. "On the other hand," the seven scientists continue, "when [the] salinity treatment was imposed under elevated CO_2 conditions, lower solute leakage and TBARS levels were observed, suggesting that the oxidative stress caused by salinity was lower." They conclude "elevated CO_2 protects barley cultivars from oxidative stress," noting "the relief of oxidative stress damage observed in our barley leaves grown under a CO_2 enriched atmosphere has also been observed in alfalfa (Sgherri *et al*., 1998), pine (Vu *et al*., 1999) and oak (Schwanz and Polle, 2001)."

Working with the same plants in the same experiment, but focusing on different phenomena, Perez-Lopez *et al*. (2009b) measured relative water content, water potential and its components, transpiration rate, hydraulic conductance, and water use efficiency, computed as plant dry weight produced per unit of water transpired. They found "elevated CO_2 improves barley water relations under saline conditions because elevated CO_2 permits a greater osmotic adjustment, most likely due to a greater carbon supply from increased photosynthesis, and a lower passive dehydration due to reductions in stomatal conductance and hydraulic conductance." Specifically, by the end of their study the water use efficiency of salt-stressed plants grown in the elevated CO_2 treatment was 61% greater in Alpha and 43%

greater in Iranis than that of plants grown in the ambient CO_2 treatment. The five researchers conclude, "elevated CO_2 will mitigate the negative impact of salinity on barley growth and will enable plants to remain turgid and functional for a longer period and for a higher salt concentration," noting "these facts open the possibility of a future successful development of this species in saline areas in which nowadys growth is not possible." This finding has enormous implications, as Frommer *et al*. (1999) have estimated approximately one-third of the world's irrigated land is currently unsuitable for crop production because of its high salinity.

Also working with barley plants grown in the same experiment, Perez-Lopez *et al*. (2010) measured midday leaf water potential, osmotic potential, osmotic potential at full turgor, dehydration, and osmotic adjustment; they subsequently harvested the primary leaf of each plant and made assessments of its concentrations of various minerals and organic compounds. They write, "elevated CO_2 permitted plant metabolism to be maintained at a better status under salt stress than did ambient CO_2," and "growth was reduced more at ambient than at elevated CO_2." They also report, "elevated CO_2 widens the range of salt concentrations at which osmotic adjustment continues to be efficient by providing a greater supply of carbon and Adenosine-5'-triphosphate," a multi-functional nucleotide that transports chemical energy in cells for metabolism and is "needed to perform the energetically expensive salt tolerance mechanisms." Thus, they conclude—as they had in their earlier papers—"under future environmental conditions, barley species will be able to succeed in salinized areas in which growth is not currently possible."

Azam *et al*. (2005) note "in agro-ecosystems, green manuring legumes occupy a key position in maintaining/improving soil fertility and productivity," and the important role of these plants as a source of nitrogen has increased further due to economic and pollution concerns associated with nitrogen supplied by chemical fertilizers. They state, "species of sesbania have generally been considered as most important for green manuring, especially in wheat-rice rotation systems."

In many situations, the growth of sesbania is suppressed by varying degrees of water stress and salinity, but the five Pakistani scientists state "elevated CO_2 favors different physiological processes of plants, thereby leading to increased biomass production and ecosystem functioning," citing Drake and Leadley (1991), Idso and Idso

(1994), and Azam and Farooq (2001). They report this effect is more pronounced for plants facing stresses imposed through the soil or atmosphere, citing the collection of papers compiled and edited by Koch and Mooney (1996). They hypothesized rising atmospheric CO_2 concentrations might mitigate salinity stress in sesbania, enabling the rotation cover-crop to more effectively "fix" atmospheric nitrogen and deposit the plant-usable form of it in the soil, where it could help promote the growth of such important agricultural staples as wheat and rice.

Conducting greenhouse experiments designed to assess the effects of elevated atmospheric CO_2 concentrations on growth and nitrogen fixation in *Sesbania aculeata* exposed to different salinity and water regimes, Azam *et al*. report "elevated CO_2 favored N_2 fixation leading to a greater contribution of fixed N to the total plant N." In addition, "biological nitrogen fixation decreased with salinity" but "elevated CO_2 arrested the decrease to a significant extent."

Perez-Lopez *et al*. (2012) write, "salt stress has a threefold effect on plant health" because it reduces water availability, causes ion imbalance, and causes toxicity, all of which phenomena, they write, "curtail growth, photosynthesis, protein synthesis, energy storage, and lipid metabolism," as described in detail by Munns (2005) and Parida and Das (2005). In a study designed to explore the negative consequences of potentially greater salt stress in a CO_2-enriched environment, they grew barley (*Hordeum vulgare*) plants in pots containing a 3:1 mix of perlite: vermiculite in controlled-environment chambers maintained at either ambient or elevated atmospheric CO_2 concentrations (350 or 700 ppm) for the last 14 days of a 28-day post-planting period. They also instituted four salt-stress treatments on the 15th day by supplying the plants then and thereafter with water of one of four degrees of saltiness (0, 80, 160, or 240 mM NaCl). At the end of the 28-day period they measured a number of plant physiological properties and processes related to the maximal rate of net photosynthesis (Amax) exhibited by the first fully expanded attached leaf of each plant.

The five Spanish scientists report, "in the zero-saline treatment, elevated CO_2 increased the Amax by 49% compared with the Amax measured at ambient CO_2," whereas "under ambient CO_2 conditions, saline treatments (80-, 160- and 240-mM NaCl) reduced the Amax by 18, 32 and 39%, respectively." They add, "these reductions were lower at elevated CO_2: 8, 22 and 28% for 80-, 160-, and 240-mM NaCl." Based on

the graphical representations of their results, the CO_2-induced enhancements of Amax in the four saline treatments (0-, 80-, 160-, and 240-mM NaCl) appear to have been, respectively, 49%, 68%, 71%, and 76%, revealing the greater the salinity-induced percentage reduction in barley Amax becomes, the greater the CO_2-induced percentage increase in barley Amax becomes.

Also investigating salt stress in barley, Perez-Lopez *et al*. (2013) write, "soil salinization is an important growth limiting factor for most plants," citing the United Nations' Food and Agriculture Organization (FAO, 2007) and noting "around 20% of the irrigated land and one third of the world's arable soil are affected by a progressive salinization." They note "barley is one of the most extensively cultivated crops worldwide" but "salt stress reduces its productivity."

Perez-Lopez *et al*. analyzed "the effect of salinity on nitrogen acquisition, distribution and assimilation, the consequences of these effects on growth in barley (*Hordeum vulgare* L., cv. Iranis), and the possible effects on these processes provoked by elevated CO_2 levels." They sowed six barley seeds in each of several 2.5-liter pots containing a 3:1 mix of perlite: vermiculite in controlled-environment chambers maintained at either ambient (350 ppm) or elevated (700 ppm) CO_2 concentrations and watered the plants with 250 ml of Hoagland's solution containing 0, 80, 160, or 240 mM concentrations of NaCl every two days until the end of the 28-day study.

The six Spanish scientists report, "under ambient CO_2 conditions, 80, 160, and 240 mM NaCl reduced the total plant biomass by 12%, 30%, and 44%, respectively." By contrast, "growth at elevated CO_2 levels led to 24%, 20%, and 33% higher total biomass than under ambient CO_2 levels for 80, 160, and 240 mM NaCl, respectively." And because "the relative stimulation of total plant biomass in response to elevated CO_2 levels was higher in salt-stressed plants than in non-stressed ones," they conclude, "barley plants subjected to elevated CO_2 levels will likely overcome mild saline conditions."

3.13 Temperature Stress

As the atmosphere's CO_2 content rises, nearly all agricultural crops, grassland plants, and trees will exhibit enhanced rates of photosynthesis and biomass production that will not be diminished by any global warming that might accompany it. If ambient air temperatures rise concurrently, the growth-promoting effects of atmospheric CO_2 enrichment likely will rise even more, as the Earth gets "greener."

3.13.1 Agricultural Crops

- As the air's CO_2 concentration rises, nearly all agricultural crops will exhibit enhanced rates of photosynthesis and biomass production that will not be diminished by any concomitant global warming. If air temperatures rise concurrently, the growth-promoting effects of atmospheric CO_2 enrichment likely will rise even more.

As the air's CO_2 content rises, most plants exhibit increased rates of photosynthesis and biomass production (see Chapter 1), which should increase the amount of food, fiber, and timber production that can be utilized to feed, clothe, and shelter the expanding human population. However, some researchers argue the growth-promoting effects of atmospheric CO_2 enrichment may be largely negated by the global warming predicted to occur in the near future by a number of state-of-the-art climate models. Such an

outcome could compromise the planet's ability to sustain a greater human population without increasing use of land for agriculture. This section examines the scientific literature to see whether plants will continue to exhibit CO_2-induced growth increases under conditions of predicted future warming, reviewing what has been learned about the photosynthetic and growth responses of CO_2-enriched agricultural crops grown at both current and projected future growing-season temperatures.

The optimum growth temperatures of several plants have been shown to rise substantially with increasing levels of atmospheric CO_2 (Berry and Bjorkman, 1980; Stuhlfauth and Fock, 1990; McMurtrie *et al.*, 1992; McMurtrie and Wang, 1993). This phenomenon was explained by Long (1991), who calculated from well-established plant physiological principles that most C_3 plants should increase their optimum growth temperatures by approximately 5°C for a 300 ppm increase in the air's CO_2 concentration. Thus plant photosynthetic rates should rise in response to concomitant increases in both the air's CO_2 concentration and temperature, as Idso and Idso (1994) and Cowling (1999) have shown to be typically the case. These positive CO_2 x temperature interactions have been observed in subsequent scientific studies, as indicated below.

Zhu *et al.* (1999) report pineapples grown at 700 ppm CO_2 assimilated 15, 97, and 84% more total carbon than pineapples grown at the current ambient CO_2 concentration in day/night air temperature regimes of 30/20 (which is optimal for pineapple growth at ambient CO_2), 30/25, and 35/25 °C, respectively. Similarly, Taub *et al.* (2000) demonstrated net photosynthetic rates of cucumbers grown at twice-ambient levels of atmospheric CO_2 and air temperatures of 40°C were 3.2 times greater than those of control plants grown at ambient CO_2 and this same elevated air temperature. Thus, at air temperatures normally considered to be deleterious to plant growth, rates of photosynthesis are typically considerably greater for CO_2-enriched vs. ambient-grown plants.

Reddy *et al.* (1999) reported similar results when they grew cotton plants at air temperatures ranging from 2°C below to 7°C above ambient air temperature, finding the plants simultaneously exposed to 720 ppm CO_2 had photosynthetic rates 137 to 190% greater than those of plants exposed to ambient CO_2 concentrations across this temperature range. Cowling and Sage (1998) found a 200 ppm increase in the air's CO_2 concentration boosted

photosynthetic rates of young bean plants by 58 and 73% at growth temperatures of 25 and 36°C, respectively. Bunce (1998) grew wheat and barley at 350 and 700 ppm CO_2 across a wide range of temperatures and found elevated CO_2 stimulated photosynthesis in these species by 63 (wheat) and 74% (barley) at an air temperature of 10°C and by 115 (wheat) and 125% (barley) at 30°C. These studies show the percentage increase in photosynthetic rate resulting from atmospheric CO_2 enrichment often increases substantially with increasing air temperature.

Elevated CO_2 also helps plants recover from high-temperature- and drought-induced reductions in photosynthetic capacity, as Ferris *et al.* (1998) demonstrated. They grew soybeans for 52 days under normal air temperatures and soil water conditions at atmospheric CO_2 concentrations of 360 and 700 ppm, then subjected the plants to an eight-day period of high temperature and water stress. When the researchers restored normal air temperatures and soil water conditions, the CO_2-enriched plants attained photosynthetic rates 72% of their unstressed controls, and the plants grown at ambient CO_2 attained photosynthetic rates only 52% of their controls. At the end of the growing season, Ferris *et al.* (1999) report, plants growing in the elevated CO_2 treatment exhibited an average biomass 24% greater than plants grown in ambient CO_2, and a seed yield 32% greater.

CO_2-induced increases in plant growth under high air temperatures also have been observed in other agricultural plants. In the previously mentioned study of Cowling and Sage (1998), for example, the 200 ppm increase in the air's CO_2 content boosted total plant biomass for wheat and barley by a combined average of 59 and 200% at air temperatures of 25 and 36°C. Similarly, Ziska (1998) found a doubling of the atmospheric CO_2 concentration increased the total dry weight of soybeans by 36 and 42% at root zone temperatures of 25 and 30°C, respectively, and Hakala (1998) noted spring wheat grown at 700 ppm CO_2 attained total biomass values 17 and 23% greater than those attained by ambient-grown plants exposed to ambient and elevated (ambient plus 3°C) air temperatures. After inputting various observed CO_2-induced growth responses of winter wheat into plant growth models, Alexandrov and Hoogenboom (2000) predicted 12 to 49% increases in wheat yield in Bulgaria, even if air temperatures were to ultimately rise by as much as 4°C. And Reddy *et al.* (1998) found elevated CO_2 (700 ppm) increased total cotton biomass by 31 to

78% across an air temperature range of 20 to 40°C.

These studies make it clear elevated air temperatures often significantly enhance the beneficial effects of elevated atmospheric CO_2 on agricultural crop yields. In some cases, however, rising air temperatures do not interact with rising atmospheric CO_2 concentrations to further increase the growth-promoting effects of atmospheric CO_2 enrichment. Instead, they simply do not interfere with the status quo.

Demmers-Derks *et al.* (1998) found sugar beets grown at 700 ppm CO_2 produced 25% more biomass than ambient-grown plants, regardless of air temperature, which was increased by 3°C. Similarly, Fritschi *et al.* (1999) found significant warming (4.5°C above ambient) had no impact on the growth of rhizoma peanut, whereas a 300 ppm increase in the air's CO_2 content increased the plant's total biomass by 52% regardless of air temperature. In the unlikely event the air's CO_2 content were to cease rising or have no effect on the productivity of certain plants, it is possible the temperature increase itself may promote plant growth and development, as was found in the experiment conducted by Wurr *et al.* (2000), where elevated CO_2 had essentially no effect on the yield of French beans but a 4°C increase in air temperature increased their yield by approximately 50%.

Aloni *et al.* (2001) grew bell pepper (*Capsicum annuum* L. cv. Mazurka) plants under optimal conditions until eight days prior to anthesis, then placed the plants in greenhouses maintained at atmospheric CO_2 concentrations of either 350 or 800 ppm and normal (28/22°C) or elevated (32/26°C) day/night air temperatures to determine the effects of these two environmental changes on reproductive parameters associated with pollen, which is extremely sensitive to high temperatures. The high temperature stress reduced pollen germination by 75% at ambient CO_2, but atmospheric CO_2 enrichment completely ameliorated this negative effect. The high temperature treatment also reduced the number of seeds produced per fruit by 68%, but the elevated CO_2 treatment nearly compensated for this deleterious effect, reducing the warming-induced seed-per-fruit reduction to only 9%.

Tako *et al.* (2001) grew rice (*Oryza sativa* L. cv. Mutsu-homare) plants hydroponically in controlled-environment chambers having atmospheric CO_2 concentrations of 350 and 700 ppm and day/night air temperatures of 24/17 (ambient) and 26/19°C (elevated), to study the interactive effects of elevated

CO_2 and temperature on the growth of this important crop. After 18 weeks, elevated CO_2 had no effect on whole-plant biomass at ambient growth temperatures, but with the additional 2°C of warming, atmospheric CO_2 enrichment produced a whole-plant biomass enhancement of 22%.

Bunce (2001) grew strawberry (*Fragaria x ananassa* Duchesne cv. Honeoye) plants in the field in open-top chambers maintained at atmospheric CO_2 concentrations of 350, 650, and 950 ppm for two years to study the effects of elevated CO_2 on photosynthesis in this important fruit crop. They took measurements weekly to evaluate the temperature dependence of the photosynthetic stimulation result-ing from the two levels of atmospheric CO_2 enrich-ment. Plants grown at 650 and 950 ppm CO_2 exhibited mean photosynthetic rates 77 and 106% greater, respectively, than those of control plants exposed to ambient air.

Prasad *et al.* (2003) grew peanuts (*Arachis hypogaea* L. cv. Georgia Green, of the Virginia Runner type) from seed to maturity in sunlit controlled-environment growth chambers maintained at atmospheric CO_2 concentrations of 350 and 700 ppm and daytime-maximum/nighttime-minimum air temperatures of 32/22, 36/26, 40/30, and 44/34°C. During this study, leaf photosynthetic rates were unaffected by air temperatures over the range studied, but they rose by approximately 27% in response to the experimental doubling of the air's CO_2 content. Vegetative biomass increased by 51% and 54% in ambient air and CO_2-enriched air, respectively, as temperatures rose from 32/22 to 40/30°C. A further temperature increase to 44/34°C caused moderate to slight declines in vegetative biomass in ambient and CO_2-enriched air, respectively, so the final biomass increase over the entire temperature range investi-gated was 27% in the ambient air and 53% in the CO_2-enriched air. Going from the lowest-temperature, ambient CO_2 treatment to the highest-temperature, elevated CO_2 treatment led to a 106% increase in vegetative biomass.

In contrast, seed yields in both the ambient and CO_2-enriched air dropped dramatically with each of the three temperature increases studied, declining at the highest temperature regime to but a small percentage of what they were at the lowest temperature regime. Nevertheless, Prasad *et al.* report, "seed yields at 36.4/26.4°C under elevated CO_2 were similar to those obtained at 32/22°C under ambient CO_2," describing the latter pair of tem-peratures as "present-day seasonal temperatures."

Even an unrealistically large warming of 4.4°C above present-day growing temperatures for peanut production would have essentially no effect on peanut seed yields, as long as the atmosphere's CO_2 concentration rose concurrently by something on the order of 350 ppm. And more realistic values of CO_2-induced global warming—temperature increases on the order of 0.4°C or less for a doubling of the air's CO_2 content (Idso, 1998)—likely would lead to a significant increase in peanut production.

Vu (2005) grew peanut plants of the cultivar Florunner from seed to maturity in greenhouses maintained at atmospheric CO_2 concentrations of 360 and 720 ppm and at air temperatures 1.5 and 6.0°C above outdoor air temperatures, measuring a number of parameters related to the plants' photosynthetic performance. They report rubisco photosynthetic efficiency—the ratio of midday light-saturated carbon exchange rate to rubisco initial or total activity—of the elevated-CO_2 plants was 1.3- to 1.9-fold greater than rubisco efficiency of the ambient-CO_2 plants at both growth temperatures. In addition, leaf soluble sugars and starch of plants grown at elevated CO_2 were 1.3- and 2-fold higher, respectively, than those of plants grown at ambient CO_2. Leaf transpiration of the elevated-CO_2 plants relative to the ambient-CO_2 plants was 12% less at near-ambient temperatures and 17% less in the higher temperature regime, and the water use efficiency of the elevated-CO_2 plants relative to the ambient-CO_2 plants was 56% greater at near-ambient temperatures and 41% greater in the higher temperature environment. Because less rubisco protein was required by the elevated-CO_2 plants, the subsequent redistribution of excess leaf nitrogen "would increase the efficiency of nitrogen use for peanut under elevated CO_2," just as the optimization of inorganic carbon acquisition and greater accumu-lation of the primary photosynthetic products in the CO_2-enriched plants "would be beneficial for peanut growth at elevated CO_2," Vu writes. Consequently, in the absence of other stresses, "peanut photosynthesis would perform well under rising atmospheric CO_2 and temperature predicted for this century," Vu concludes.

Crafts-Brandner and Salvucci (2004) explored the concurrent effects of elevated atmospheric CO_2 concentration and temperature on photosynthetic CO_2 fixation in cotton (*Gossypium hirsutum* L. cv. Coker 100A-glandless), using "intact plants and biochemical measurements to directly determine how environ-mental change impacts specific physiological mech-anisms important to plant productivity." They report

"net photosynthesis of cotton leaves at ambient levels of CO_2 was inhibited at leaf temperatures above about 32°C." At a leaf internal CO_2 concentration 4.3 times greater than ambient, however, net photosynthesis did not begin to decline until leaf temperatures rose above 40°C. Viewed another way, the net photosynthetic rate of cotton leaves exposed to ambient air declined by approximately 77% as leaf temperature rose from 32 to 40°C, whereas in leaves exposed to the CO_2-enriched air it rose by about 9%, indicating the increase in atmospheric CO_2 concentration more than compensated for the dramatic decrease in photosynthetic rate that would ordinarily result from the 8°C increase in temperature.

Aranjuelo *et al.* (2005) grew the forage crop alfalfa (*Medicago sativa* L.) in 13-L pots for three consecutive June–July periods (2001–2003) out-of-doors in polyethylene-covered temperature gradient tunnels maintained at atmospheric CO_2 concentrations that averaged 405 and 730 ppm at ambient (AT) and elevated (ET) temperatures (ET = AT + 4°C) and at high (HW) and low (LW) soil water contents (LW = 0.5HW). They fed all of the plants adequate nutrients except for nitrogen, to ensure the only source of nitrogen for the plants was that which was fixed by their nodules in response to inoculation with *Sinorhizobium meliloti* strain 102F78. The researchers report "the effect of elevated CO_2 on plant growth interacted positively with temperature," and "higher dry mass production of plants grown under elevated CO_2 and temperature was a consequence of enhanced photosynthetic rates." Mean CO_2-induced increases in leaf net photosynthesis over the entire experiment were found to be: +5% (HW, AT), +50% (HW, ET), +17% (LW, AT), and +42% (LW, ET), as best as can be determined from the bar graphs in the paper describing their study. Mean CO_2-induced increases in leaf biomass were +4% (HW, AT), +54% (HW, ET), +23% (LW, AT), and +58% (LW, ET), with the same caveat.

For both leaf net photosynthesis and biomass production, Aranjuelo *et al.* found the stimulatory effect of the elevated CO_2 was about 2.5 times greater in the warmer of the two temperature treatments in the low soil water regime and 10 times greater in the high soil water regime. In addition, the extra CO_2 benefited plant water loss via transpiration, which declined by 25% (HW, AT), 41% (HW, ET), 31% (LW, AT), and 31% (LW, ET). Under both well-watered and droughty conditions in this study, atmospheric CO_2 enrichment enhanced photosynthesis and biomass production in alfalfa, and

simultaneously decreased transpirational water losses.

Bencze *et al.* (2005) grew specimens of three varieties (Emma, Martina, and Mezofold) of winter wheat (*Triticum aestivum*) in controlled-environment chambers under ambient (375 ppm) and elevated (750 ppm) CO_2 at minimum, maximum, and mean temperature regimes of 10, 12, and 10.7°C, respectively. Twelve days after the average date of heading, they subjected several plants of each variety to 15 more days of elevated temperatures (min/max/mean of 20, 35, and 25.2°C) to assess the independent effects of both elevated CO_2 and temperature on wheat growth and yield.

They found the temperature treatment accelerated the aging process in the three wheat varieties, and concurrent atmospheric CO_2 enrichment generally helped them maintain a higher and longer level of photosynthetic activity during grain-filling and maturation. Bencze *et al.* report the CO_2-enriched plants "suffered less damage from heat stress and produced a higher yield than at the ambient level." In addition, the extra CO_2 supplied to the Emma cultivar plants meant the difference between life and premature death, since by the end of the 15-day high-temperature treatment the plants growing in ambient air were dead, whereas those growing in elevated CO_2 survived for a few more days. In a future world of higher atmospheric CO_2 concentrations, wheat crops should be better able to withstand the stress of potentially higher temperatures, suffering less damage and producing greater yields.

Cen and Sage (2005) grew well-watered and well-fertilized sweet potato (*Ipomoea batatas* L.) plants in 20-L pots of soil in a greenhouse, periodically measuring light-saturated rates of net photosynthesis in new but fully expanded leaves in response to short-term changes in air temperature and atmospheric CO_2 concentration. In response to an approximate 370 ppm increase in the air's CO_2 concentration, the optimum leaf temperature for net photosynthesis—the leaf temperature at which net photosynthesis proceeds at its maximum rate—rose by approximately 4.5°C, and its maximal rate of net photosynthesis rose by about 75%. The doubling of the air's CO_2 concentration had no impact on net photosynthesis at a leaf temperature of 15°C but boosted it by 28% at 21°C, by 43% at 27°C, by 56% at 33°C, and by 70% at 39°C. In order for the net photosynthetic rate of sweet potatoes growing in air of 740 ppm CO_2 to drop below the maximum rate exhibited by plants growing in air of 370 ppm CO_2 (which occurred at a leaf temperature of 30°C), leaf

temperature would have to rise by 12°C to a value of 42°C.

De Costa *et al.* (2006) write, "doubts have been expressed whether the expected yield increases [of rice] in response to increased CO_2 could be sustained under high temperature regimes." The investigators set out to learn whether this might happen in sub-humid Sri Lanka, where weekly maximum temperatures during both the maha (January to March) and yala (May to August) growing seasons typically range from 30 to 33°C. They grew two crops of rice (one in the maha season and one in the yala season) in open-top chambers maintained at atmospheric CO_2 concentrations of either 363 or 567 ppm under normal field conditions at the Rice Research and Development Institute of Sri Lanka, measuring a number of meteorological and plant physiological parameters throughout both seasons, as well as total biomass production and grain yield at the times of final harvest. They found the CO_2-induced increase in total plant biomass at the time of final harvest was 23% in the maha season and 37% in the yala season, and final grain yields were enhanced by 24% and 39% in the maha and yala seasons, respectively. These increases occurred even though air temperatures in the CO_2-enriched chambers were on average 1.6°C higher than air temperatures in the ambient-air chambers.

Borjigidai *et al.* (2006) grew rice (cv Akitakomachi) plants from seed in greenhouses maintained at atmospheric CO_2 concentrations of 370 and 570 ppm and then transplanted them to the field and grew them in a well-fertilized paddy culture in a FACE study at the same CO_2 concentrations under which the seeds were sprouted in both 2003 and 2004. At various times throughout the two growing seasons during the field portion of the experiments, the researchers made photosynthetic measurements of the most recently fully expanded leaves in full sunlight at a variety of different leaf temperatures. They report "the optimal temperature of photosynthesis (T_{opt}, the value where the photosynthetic rate was maximum) was significantly higher at elevated CO_2: it ranged from 22 to 34.5°C with an average value of 28.9°C at ambient CO_2, and from 29.5 to 37°C with an average value of 33.5°C at elevated CO_2."

Bernacchi *et al.* (2006) grew soybeans (*Glycine max* (L.) Merr.) for three years at the SoyFACE facility of the University of Illinois at Urbana-Champaign, Illinois (USA) at atmospheric CO_2 concentrations of either 375 or 550 ppm under natural field conditions, measuring a number of weather and

plant physiological parameters from pre-dawn to post-dusk on several days during the three growing seasons. They found the mean daily integral of leaf-level net photosynthesis (A) was enhanced by nearly 25% in the CO_2-enriched air. In addition, the 11 scientists write, "there was a strong positive correlation between daytime maximum temperatures and mean daily integrated A at elevated CO_2." Their graphical representation of this relationship indicates at a daily maximum temperature of approximately 26.5°C, the CO_2-enriched air stimulated leaf-level net photosynthesis by about 14%, and at a daily maximum temperature of approximately 34.5°C, CO_2 enrichment stimulated photosynthesis by about 35%.

Koti *et al.* (2007) used Soil-Plant-Atmosphere-Research (SPAR) chambers at Mississippi State University (USA) to investigate the effects of doubled atmospheric CO_2 concentration (720 vs. 360 ppm) on the growth and development of six well-watered and well-fertilized soybean genotypes they grew from seed in pots filled with fine sand and exposed to the dual stresses of high day/night temperatures (38/30°C vs. 30/22°C) and high UV-B radiation levels (10 vs. 0 kJ/m^2/day). They found the elevated CO_2 partially compensated for the damaging effects on vegetative growth and physiology caused by high temperatures and enhanced UV-B radiation levels, and elevated CO_2 had a positive influence on plant height, leaf area, total biomass, net photosynthesis, total chlorophyll content, phenolic content, and wax content, as well as relative plant injury.

Mishra *et al.* (2008) documented the positive impact of atmospheric CO_2 enrichment on the photosynthetic rates of field-grown soybean plants subjected to the simultaneous negative effects of acute heat stress and elevated atmospheric ozone (O_3) concentrations at the SoyFACE facility of the University of Illinois. The seven scientists discovered elevated ozone exacerbated heat-related decreases in photosynthetic electron transport, but "elevated CO_2 minimized or prevented light-dependent O_3-related decreases in electron transport (and thus photoinhibition) during heat stress."

Alonso *et al.* (2009) sequentially grew well-watered and well-fertilized plants of the wheat cultivar Alcala in 16-liter pots of perlite (sown at a rate of 35 seeds per pot) in a controlled-environment growth chamber—first at an atmospheric CO_2 concentration of 370 ppm and then at 700 ppm—from sowing through anthesis. They measured gas exchange in flag leaves at ear emergence to obtain the values of various plant physiological parameters

required for the biochemical photosynthesis model developed by Farquhar *et al.* (1980), along with the responses of those parameters to changes in temperature. They found "photosynthesis response to temperature was negative at low air CO_2 concentrations and became progressively positive as CO_2 increased," which might have been expected "from the increase in photorespiration with temperature and the gradual inhibition of this process as CO_2 increases (Long, 1991)." In addition, "at high chloroplastic CO_2, photosynthesis in elevated growth CO_2 was lower at 15–25°C and higher at 30–35°C, than in ambient growth CO_2, implying an enhanced photosynthesis response to temperature in plants grown in elevated CO_2."

In 2004 and 2005, Gutierrez *et al.* (2009) grew well-watered and well-fertilized spring wheat (*Triticum aestivum* L. cv. Gazul) plants from seed to maturity out-of-doors in Salamanca, Spain in temperature-gradient chambers maintained at ambient (370 ppm) and elevated (700 ppm) atmospheric CO_2 concentrations and ambient air temperature (TA) and elevated air temperature (TE = TA plus 4°C). They titled their paper, "Acclimation to future atmospheric CO_2 levels increases photochemical efficiency and mitigates photochemistry inhibition by warm temperatures in wheat." They report net photosynthesis was increased by 62–72% in both years in the CO_2-enriched chambers; at the conclusions of the two growing seasons, total plant biomass production in the CO_2-enriched chambers was increased by 12–18%. They conclude, "future increases in atmospheric CO_2 and temperature may have a positive effect on photochemical efficiency," noting their work "provides evidence that with air CO_2 enrichment a reallocation of resources favoring light capture may occur."

Xiao *et al.* (2010) note "the impact of future climate change on crop production has been widely predicted by modeling the interaction between crops and climate change," adding it is currently thought "overall crop yields will decrease by 5–10% in China by 2030 as a result of climatic changes, and that the yields of wheat, rice and maize will be greatly reduced." They further note "the direct fertilization effect of rising CO_2 will offset these losses," citing Ewert *et al.* (2002) and Long *et al.* (2006). In addition, they remark, few real-world observations of the impacts of climate change on crop production have been reported.

The seven scientists conducted two sets of field experiments to evaluate the effects of warming on the productivity of winter wheat from 2006 to 2008 in the semiarid northwestern part of China: one set of experiments at the Tongwei County station located at the foot of Lulu Mountain (35°13'N, 105°14'E) at an altitude of 1,798 meters above sea level, and another set at the mountain's summit at an altitude of 2,351 meters. At each of these locations, they established four air temperature treatments (ambient and ambient plus 0.6, 1.4, and 2.2°C), which they created by placing electric heating wires on the surface of the soil between the rows of wheat, which induced the 0.6–2.2°C air temperature increases they measured at a height of 20 cm above the tops of the wheat canopies. They found this increase in temperature "will lead to a significant change in the growth stages and water use of winter wheat," and "crop yields at both high and low altitudes will likely increase," by 2.6% at low altitudes and 6.0% at high altitudes. Even without the benefits of the aerial fertilization and anti-transpiration effects of the rise in the air's CO_2 content, the increase in temperature predicted by climate models for the year 2050 likely will lead to increases in winter wheat production in the northwestern part of China, not the decreases some modeling studies have predicted.

Yoon *et al.* (2009) grew well-watered and well-fertilized cotton plants from seed to maturity—one plant to each container of washed sand, with spacing between plants similar to the plant spacing found in typical cotton fields—in the Georgia Envirotron at the University of Georgia Griffin Campus. They placed the containers with their plants in chambers maintained at all combinations of two day/night air temperatures regimes (25/15°C and 35/25°C) and three atmospheric CO_2 concentrations (400, 600, and 800 ppm). At the lower of the two air temperature regimes, the authors found "final boll weight at harvest was 1.59 times (at 600 ppm) and 6.3 times (at 800 ppm) higher compared to ambient CO_2." Further increasing the temperature tremendously increased this difference, as "the final boll weight was 34.1 times (at 600 ppm) and 23.3 times (at 800 ppm) higher compared to ambient CO_2." In addition, "the response of final lint yield to CO_2 was more or less similar to the response of boll weight."

Thus a significant body of scientific literature suggests a continuation of the rise in the air's CO_2 content likely will lead to enhanced rates of photosynthesis and biomass production by agricultural crops, which will not be diminished by any global warming that might occur concurrently. If the ambient air temperature rises, the growth-promoting

effects of atmospheric CO_2 enrichment likely will rise right along with it, in agreement with the experimental observations reviewed by Idso and Idso (1994). The biosphere will continue producing the food and fiber needed for an increasing population.

Beyond this natural phenomenon, Meerburg *et al.* (2009) describe how crop yields will continue to increase in the future because of "the development and adoption of new technologies and improved farm management," citing Ewert *et al.* (2005), who demonstrated continuing advances in agricultural technology historically have been the most important drivers of productivity change. Between 1961 and 2007, Meerburg *et al.* report, "average US corn yields increased by 240%, from 3.9 tons per hectare per year to 9.4 tons per hectare per year," citing the FAO (2009) and noting some researchers have predicted "advances in agronomics, breeding, and biotechnology will lead to an average corn yield in the US of just over 20 tons per hectare per year in 2030," citing Duvick (2005).

Meerburg *et al.* also note farmers in Brazil successfully increased the productivity of soybeans, maize, and cotton during the past decade even though the cumulative number of days of exposure to temperatures above the three crops' optimum values "is far greater than in the US." In the Brazilian state of Mato Grosso, for example, "maximum average day temperature exceeds 35°C for 118 days per year, of which 75 days are in the average soybean-growing season." Nevertheless, they report the average production of soybeans in 2008 was about 3.1 tons per hectare per year in Mexico, and the average yield in the United States was 2.8 tons per hectare per year. Similarly, they note the mean cotton yield in Brazil in 2006/2007 was 1.4 tons per hectare per year, while in the United States it was 0.9 tons per hectare per year.

The seven scientists thus conclude "temperatures higher than currently experienced in the US do not necessarily need to coincide with lower crop yields and … already existing technology and future advances (new varieties, optimized farm management, biotechnology, etc.) can overrule the negative effect of increasing temperatures on yield."

3.13.2 Grasslands

- As the air's CO_2 content rises, grassland plants likely will exhibit enhanced rates of photosynthesis and biomass production that will not be diminished by any global warming that might occur. If the ambient air temperature does rise, the growth-promoting effects of atmospheric CO_2 enrichment likely will rise also. Grasslands are likely to produce increasingly greater amounts of forage and perhaps reclaim areas of barren ground in certain environments.

As the atmosphere's CO_2 content rises, most plants, including those of various grassland ecosystems, will exhibit increased rates of photosynthesis and biomass production. This increase in productivity should increase the amount of forage available for grazing animals and possibly reduce the land area occupied by bare soil in certain environments. However, some researchers claim global warming will negate the growth-promoting effects of atmospheric CO_2 enrichment and cause the opposite to occur. This section reviews the results of experimental studies of the photosynthetic and growth responses of grassland plants to atmospheric CO_2 enrichment when exposed to higher-than normal-temperatures.

The optimum growth temperatures of many plants have been demonstrated to rise substantially with increasing concentrations of atmospheric CO_2 (Berry and Bjorkman, 1980; Stuhlfauth and Fock, 1990; McMurtrie *et al*., 1992; McMurtrie and Wang, 1993), as has been described in more detail by Long (1991), Idso and Idso (1994), and Cowling and Sykes (1999). These previously observed positive CO_2 x temperature interactions have continued to appear in more recent studies of the subject for grassland species.

Lilley *et al*. (2001) grew swards of subterranean clover (*Trifolium subterraneum*) at 380 and 690 ppm CO_2 in combination with simultaneous exposure to ambient and elevated (ambient plus 3.4°C) air temperatures. After one year of these treatments, they found elevated CO_2 increased foliage growth by 19% at ambient air temperatures. At elevated air temperatures, the CO_2-enriched plants displayed a growth enhancement of only 8%, but the plants grown at ambient CO_2 exhibited a 28% reduction in foliage growth. Similarly, Morgan *et al*. (2001) determined twice-ambient levels of atmospheric CO_2 increased aboveground biomass in native shortgrass steppe ecosystems by an average of 38%, despite an average

air temperature increase of 2.6°C. And when bahiagrass was grown across a temperature gradient of 4.5°C, Fritschi *et al*. (1999) found a 275 ppm increase in the air's CO_2 content boosted photosynthesis and aboveground biomass by 22 and 17%, respectively, independent of air temperature.

Greer *et al*. (2000) grew five pasture species at 18 and 28°C and found plants concomitantly exposed to 700 ppm CO_2 displayed average photosynthetic rates 36 and 70% greater, respectively, than average rates of control plants grown in air of ambient CO_2 concentration. The average CO_2-induced biomass increase for the five species rose dramatically with increasing air temperature, from only 8% at 18°C to 95% at 28°C.

Stirling *et al*. (1998) had found much the same thing. They nurtured five fast-growing native annual species in glasshouses maintained at two combinations of CO_2 (ambient and ambient plus 340 ppm) and temperature (ambient and ambient plus 3°C) for eight weeks, to assess their growth responses to elevated CO_2 and temperature. Elevated CO_2 significantly increased photosynthetic rates, by 18–36% for all species, independent of growth temperature, for the entire eight weeks of the experiment. The persistence of this photosynthetic enhancement led to total plant biomass increases for CO_2-enriched plants, on average, 25% greater than those of control plants grown in ambient-CO_2 air. And although elevated CO_2 and elevated temperature together had few significant interactive effects on the various metrics of growth, the overall CO_2 growth response was generally slightly larger at elevated than at ambient temperatures.

In a similar study with similar findings, Newman *et al*. (2001) grew two perennial grassland species (rhizoma peanut-*Arachis glabrata* and bahiagrass-*Paspalum notatum*) native to South America and common to Florida (USA) in greenhouses fumigated with air of either 360 or 700 ppm CO_2 for three full growing seasons. The C_3 and C_4 grasses were simultaneously exposed to air temperatures ranging from ambient to 4.5°C above ambient. Averaged across the three growing seasons, elevated CO_2 increased dry matter production in rhizoma peanut and bahiagrass by 25 and 15%, respectively. Here too, the researchers found no significant interactive effects of elevated CO_2 and temperature on dry mass production in these species, and on their own, air temperatures 4.5°C above ambient increased dry matter production in both species by an average of 13% across all three years.

Niklaus *et al*. (2001) established experimental plots in a nutrient-poor calcareous grassland in northwestern Switzerland that contained either 31, 12, or five species, removing selected species from some of the plots so the proportion of plant functional types in each of the plots remained unchanged (55% graminoids, 15% legumes, and 30% non-legume forbs). They fumigated the plots with air of either 360 or 600 ppm CO_2 for four years, to determine the ecological effects of elevated CO_2 across a biodiversity gradient in this grassland community. As plant community diversity decreased at ambient CO_2, soil nitrate concentrations increased, the scientists report. Elevated CO_2, however, reduced soil nitrate concentrations at all the studied levels of plant diversity. In addition, nitrification—a biological process that yields nitrate—increased with decreasing species diversity at ambient CO_2, and at elevated CO_2, rates of nitrification were 25% lower than those observed at ambient CO_2 at all levels of community diversity, suggesting a CO_2-enriched environment would reduce the risk of nitrate pollution of groundwater.

Hakala and Mela (1996) grew field-sown meadow fescue (*Festuca pratensis* cv. Kalevi) in open-top chambers and glasshouses maintained at atmospheric CO_2 concentrations of 350 and 700 ppm in combination with ambient and elevated (ambient plus 3°C) air temperatures for four consecutive years to determine the effects on aboveground biomass production in this important forage crop. They found elevated CO_2 significantly increased aboveground biomass by an average of 18% in each of the four study years, but the effect occurred only when plants were concomitantly exposed to elevated air temperatures.

Sinclair *et al*. (2007) note it has long been assumed global warming would be bad for plants that appear to be adapted to cool temperatures and typically exhibit reduced growth rates in warmer environments. Using climate-controlled mini-greenhouses, the five researchers tested this assumption by examining the interacting effects of air temperature and vapor pressure deficit (VPD) on the growth of tall fescue (*Festuca arundinacea* Schreb), a cool-season grass that from past studies was expected to show declining growth with warmer temperatures over the range of 18.5 to 27°C. They grew well-watered and -fertilized plants in two sets of six-week-long experiments, one in which air VPD was held constant at 1.2 kPa while air temperature was maintained at either 18.5, 21, 24, or 27°C, and one in

which air temperature was held constant at 22°C while air VPD was maintained at either 0.9, 1.2, 1.4, or 1.7 kPa.

In the experiment where the air VPD was held constant, they write, "in direct contrast to the anticipated results, the weekly growth of the tall fescue was substantially increased with increased temperature," as "growth at 24 and 27°C was about 2.3 times that at 18.5°C and 1.4 times that at 21°C." In the experiment where air temperature was held constant, "there was a strong, negative influence of increasing VPD on plant growth." In addition, "transpiration rates were similar across treatments," indicating "water movement through the plants did not increase in response to increasing VPD." This led them to conclude limitation of water movement through the plant "is likely a result of stomatal closure in response to elevated VPD (Bunce, 2006)." This phenomenon also would restrict the CO_2 diffusion pathway into the plants and result in a decrease in photosynthesis, which is likely what caused the decreased growth at increased VPD. Nonetheless, their results indicate as long as the air VPD does not rise concurrently, increasing temperatures do not lead to growth reductions in this cool-season plant. In fact, they observe just the opposite to be true—warming dramatically increased tall fescue growth.

Sinclair *et al*. note, "during the past 50 years, VPD has remained virtually constant (Szilagyi *et al*., 2001) due to an increase in atmospheric dew point temperature (Gaffen and Ross, 1999)," even in the face of what IPCC describes as unprecedented global warming. In a future warmer world, they conclude, "tall fescue, and perhaps other cool season species, could experience a substantial benefit with temperature increases expected in temperate zones if VPD were to remain unchanged."

Wolfe-Bellin *et al*. (2006) write, "nocturnal temperatures are predicted to increase more than diurnal temperatures," as has been observed in the real world over much of the twentieth century, and it might be expected "increased nocturnal temperature would increase dark respiration rate" and thereby "diminish the positive effects of elevated CO_2 on whole-plant growth, as measured by total biomass." In an experiment designed to explore this hypothesis, they grew the C_3 forb *Phytolacca americana* L. from the four-leaf stage to maturity under well-watered and well-fertilized conditions in 6.2-L containers filled with a general purpose growing medium in controlled-environment glass chambers maintained at either 370 or 740 ppm CO_2 at diurnal/nocturnal temperatures of either 26°/20°C or 26°/24°C. They periodically measured the plants' light-saturated photosynthetic rates and whole-plant biomass. They found "plant photosynthetic rate was greater under elevated CO_2 [+69% during the first part of the growing season], and dark respiration rate, predicted to increase under higher nocturnal temperatures, exhibited no response to the nocturnal temperature treatment." In contrast to their prediction, the forb they studied "exhibited no diminishment of total plant size in response to elevated nocturnal temperature," and "time to flowering decreased and biomass allocation to reproduction increased under conditions of elevated nocturnal temperatures." They conclude, "elevated CO_2 and high nocturnal temperatures of the future could have a neutral or even positive effect on the growth of northern *P. americana* populations," even to the extent of "increasing population sizes, at least for plants growing at the northern edge of the species' range."

Niu *et al*. (2010) note, "most modeling studies predict ecosystem carbon storage will decrease as respiration is stimulated more than photosynthesis by rising temperature, with a consequent positive feedback to climate warming." Working in a tallgrass prairie in McClain County, Oklahoma (USA) dominated by C_4 grasses and C_3 forbs that had not been grazed for the prior 40 years, they conducted a warming experiment in which they used infrared heaters to elevate soil temperature at a depth of 2.5 cm by an average of 1.96°C from 2000 to 2008, and "yearly biomass clipping mimicked hay or biofuel feedstock harvest."

They found the experimental warming "significantly stimulated carbon storage in aboveground plant, root, and litter pools by 17%, 38%, and 29%, respectively, averaged over the nine years," but it "did not change soil carbon content or nitrogen content in any pool." They conclude increased plant nitrogen use efficiency played a more important role than soil nitrogen availability in regulating carbon cycling in this ecosystem, as the tallgrass prairie experienced a significant increase in productivity caused solely by the warming of its soil and not promoted by any addition of nitrogen to it. They explain this result by stating, "increased inputs of more recalcitrant [higher carbon:nitrogen ratio] material into soil counterbalanced any direct warming stimulation of carbon release, leading to little change in soil carbon stock and no apparent feedback to climate warming."

Morgan *et al*. (2011) write, "global warming is

predicted to induce desiccation in many world regions through increases in evaporative demand," but "rising CO_2 may counter that trend by improving plant water-use efficiency." However, they note, "it is not clear how important this CO_2-enhanced water use efficiency might be in offsetting warming-induced desiccation because higher CO_2 also leads to higher plant biomass, and therefore greater transpirational surface."

Morgan *et al*. conducted a prairie heating and CO_2 enrichment (PHACE) experiment in which they evaluated the productivity of native mixed-grass prairie west of Cheyenne, Wyoming (USA) to two levels of atmospheric CO_2 concentration (385 and 600 ppm, supplied via standard FACE technology) and two temperature regimes—ambient and elevated (ambient plus 1.5/3.0°C warmer day/night temperatures) for three full growing seasons (2007–2009) by means of T-FACE technology (Kimball *et al*., 2008)—after first having measured grassland productivity under unmodified conditions for one growing season (2005) and with CO_2 enrichment alone for a second season (2006).

The 10 researchers report their warming treatment reduced annual soil water content by 13.1%, but their elevated CO_2 treatment increased annual soil water content by 17.3%, demonstrating "the water conservation effects of elevated CO_2 can completely cancel the desiccating effects of moderately warmer temperatures." In addition, they write, "exposure of the prairie to 600 ppm CO_2 increased peak total above-ground biomass by an average 33% in the first 3 years of the experiment when annual precipitation amounts were in 7% of the site's 132-year average of 388 mm," but "CO_2 enrichment had no effect on above-ground biomass in 2009," when "annual precipitation was 17% higher than the long-term mean." They speculate the "higher soil water content in 2009 minimized the potential water-relations benefit of CO_2 enrichment on plant productivity."

Morgan *et al*. write, "many believe that CO_2-induced reductions in transpiration at the leaf level will be largely offset at the canopy level by increases in leaf area," citing McNaughton and Jarvis (1991), Piao *et al*. (2007), Frelich and Reich (2010), and Seager and Vecchi (2010). They say their results "clearly illustrate the importance of compensating CO_2 and warming effects in semi-arid ecosystems" and "indicate that in a warmer, CO_2-enriched world, both soil water content and productivity in semi-arid grasslands may be higher than previously expected." In an accompanying commentary on their paper,

Baldocchi (2011) writes, "Morgan and colleagues provide one of the first and best views of how a mixed-grass ecosystem growing in a semi-arid climate will respond to future CO_2 and climatic conditions." Morgan *et al*.'s findings help explain the great CO_2-induced greening of the Earth phenomenon (see section 4.2, this volume), especially as manifested in semi-arid regions of the planet.

Even if the air's CO_2 content were to cease rising or have no effect on plants, it is still possible temperature increases alone would promote plant growth and development in some situations. Norton *et al*. (1999) found this to be the case. Elevated CO_2 had essentially no effect on the growth of the perennial grass *Agrostis curtisii* after two years of fumigation, whereas a 3°C increase in air temperature increased the growth of the species considerably.

The recent scientific literature indicates grassland plants likely will exhibit enhanced rates of photosynthesis and biomass production as the air's CO_2 content rises, and those benefits will not be diminished by any global warming that might occur. If the ambient air temperature does rise, the growth-promoting effects of atmospheric CO_2 enrichment likely will rise right along with it, becoming increasingly robust in agreement with the experimental observations reviewed by Idso and Idso (1994). As long as the air's CO_2 content continues to rise, grasslands will likely produce increasingly great amounts of forage, and perhaps reclaim areas of barren ground in certain environments.

3.13.3 Woody Plants

- As the air's CO_2 content rises, trees likely will exhibit enhanced rates of photosynthesis and biomass production that will not be counteracted by any global warming that might occur. If the ambient air temperature rises, the growth-promoting effects of atmospheric CO_2 enrichment likely will rise also. Trees are likely to produce greater amounts of biomass and, therefore, more timber products to meet the increasing needs of Earth's growing human population in the future.

As the air's CO_2 content rises, most trees likely will exhibit increased rates of photosynthesis and biomass production, which can help meet human demands for wood products. However, some researchers claim global warming will negate the growth-promoting effects of atmospheric CO_2 enrichment and actually reduce tree growth. To determine whether this claim has any validity, this section examines the results of several studies designed to reveal the net effect of both elevated CO_2 and air temperature on the growth of trees and other woody plants.

The optimum growth temperature for several plants already has been shown to rise substantially with increasing levels of atmospheric CO_2 (Berry and Bjorkman, 1980; Stuhlfauth and Fock, 1990; McMurtrie *et al.*, 1992; McMurtrie and Wang, 1993). Long (1991) described this phenomenon at length, having calculated from well-established plant physiological principles that most C_3 plants should increase their optimum growth temperature by approximately 5°C in response to a 300 ppm increase in the atmosphere's CO_2 concentration. In a subsequent review of the pertinent scientific literature, Cowling and Sykes (1999) demonstrated this was true for a number of plants. The photosynthetic rates of woody plants also are likely to rise in tandem with increases in the air's CO_2 concentration and temperature, as previously documented by Idso and Idso (1994) and by more recent studies for various trees and shrubs.

Kellomaki and Wang (2001) grew birch seedlings at atmospheric CO_2 concentrations of 350 and 700 ppm in combination with ambient and elevated (ambient plus 3°C) air temperatures. After five months, the photosynthetic rates of the CO_2-enriched seedlings were 21 and 28% greater than their ambient-grown counterparts at ambient and elevated air temperatures, respectively. Carter *et al.* (2000) report a 300 ppm increase in the air's CO_2 content allowed leaves of sugar maple seedlings to remain green and non-chlorotic when exposed to air temperatures 3°C above ambient air temperature, and seedlings fumigated with ambient air exhibited severe foliar chlorosis when exposed to the same elevated air temperatures. At elevated air temperatures, rates of photosynthesis are greater and foliar health is typically better in CO_2-enriched as opposed to ambient air.

Many other studies report similar results. Sheu *et al.* (1999), for example, grew a subtropical tree at day/night temperatures of 25/20 (ambient) and 30/25°C (elevated) for six months, reporting seedlings exposed to 720 ppm CO_2 displayed photosynthetic rates 20 and 40% higher, respectively, than those of their ambient-grown controls. The CO_2-induced increases in total dry weight for this species were 14 and 49%, respectively, at the ambient and elevated air temperatures. Similarly, Maherali *et al.* (2000) report a 5°C increase in ambient air temperature increased the CO_2-induced biomass enhancement resulting from a 750 ppm CO_2 enrichment of ponderosa pine seedlings from 42 to 62%. In addition, Wayne *et al.* (1998) observed that a 5°C increase in the optimal growth temperature of yellow birch seedlings fumigated with an extra 400 ppm of CO_2 increased the CO_2-induced increase in biomass from 60% to 227%. The beneficial effects of elevated CO_2 on tree photosynthesis and growth are often further enhanced by elevated air temperatures, a fact also observed during natural seasonal temperature changes, as documented by Hymus *et al.* (1999) for loblolly pine and Roden *et al.* (1999) for snow gum seedlings.

In some cases, however, there appear to be few interactive effects between elevated CO_2 and temperature on photosynthesis and growth in trees. For example, when Tjoelker *et al.* (1998a) grew seedlings of quaking aspen, paper birch, tamarack, black spruce, and jack pine at atmospheric CO_2 concentrations of 580 ppm, they reported an average increase in photosynthetic rates of 28%, irrespective of air temperature, which varied from 18 to 30°C. And after analyzing the CO_2-induced increases in dry mass for these seedlings, Tjoelker *et al.* (1998b) further reported dry mass values were about 50 and 20% greater for the deciduous and coniferous species, respectively, again irrespective of air temperature.

The list of recent studies of woody plants that experience a CO_2-induced enhancement of growth in response to environmental warming is extensive, starting with Hamerlynck *et al*. (2000), who grew seedlings of the evergreen perennial shrub *Larrea tridentata* in glasshouses maintained at atmospheric CO_2 concentrations of 360, 550, and 700 ppm for one year. The researchers withheld water from half of the seedlings for three months prior to a nine-day high-temperature treatment. Elevated CO_2 largely offset the detrimental effects of drought and high temperature on water relations and photosynthesis in this species. Averaged across the entire experiment, the photosynthetic rates of seedlings grown at 550 and 700 ppm CO_2 were 31 and 90% greater, respectively, than the rates of the ambient-grown control plants.

Usami *et al*. (2001) grew two-year-old saplings of *Quercus myrsinaefolia*, an evergreen broad-leaved oak species, in controlled-environment chambers having various atmospheric CO_2 concentrations and air temperatures for approximately one year, to study the interactive effects of elevated CO_2 and temperature on the development and growth of this important tree, which is widely distributed throughout Laos, Vietnam, China, Taiwan, South Korea, and southwestern Japan. In ambient air, 3 and 5°C increases in air temperature boosted final sapling biomass by 53 and 47%, respectively. At elevated CO_2 concentrations 1.5 or 2 times greater than the ambient CO_2 concentration, the same 3 and 5°C increases in air temperature enhanced final biomass by 110 and 140%, respectively.

Turbull *et al*. (2002) manipulated day/night air temperatures around 4-m-tall cottonwood (*Populus deltoides* Bartr. Ex Marsh) trees growing in large experimental enclosures, to study the effects of temperature on carbon relations. A 6°C increase in daytime temperature, coupled with a 10°C increase in nighttime temperature, enhanced rates of net photosynthesis by 64% and rates of dark respiration by 77%. On an absolute scale, the photosynthetic carbon gains due to the daytime temperature increase were nearly an order of magnitude greater than the nocturnal carbon losses caused by the greater increase in nighttime temperature. Consequently, if Earth were to begin to warm again, carbon uptake by cottonwood trees should increase significantly.

Peltola *et al*. (2003) constructed closed chambers around 20-year-old Scots pine (*Pinus sylvestris* L.) trees growing on a low-nitrogen-containing soil, and for three years thereafter they fumigated the trees in the chambers with air containing either 350 or 700 ppm CO_2 at either ambient or elevated air temperatures (about 4°C above ambient temperatures), to study the effects of elevated CO_2 and air temperature on stem development in this coniferous species when growing on a soil low in nitrogen. After three years, they found cumulative stem diameter growth in the CO_2-enriched trees grown at ambient air temperature was 57% greater than that of control trees grown at ambient CO_2 and ambient air temperature. The trees subjected to elevated CO_2 and elevated air temperature exhibited cumulative stem-diameter growth 67% greater than trees grown in ambient air at ambient air temperatures.

Sallas *et al*. (2003) grew seedlings of Scots pine and Norway spruce (*Picea abies* (L.) Karst.) for 50 days in computer-controlled environmental growth chambers in air of ambient or twice-ambient CO_2 concentration (normal or elevated (EC) treatments) at day/night temperature combinations of 19/12°C or 23/16°C (normal or elevated (ET) treatments), making a host of measurements. Seedlings of both species were shown to accumulate the most biomass in the combined EC + ET treatment.

Hymus *et al*. (2003) studied net ecosystem exchange (NEE) of CO_2 in a scrub-oak ecosystem—85–90% of the aboveground biomass of which was comprised of three oak species (*Quercus myrtifolia*, *Quercus geminate,* and *Quercus chapmanii*)—on Merritt Island in NASA's Kennedy Space Center on the coast of central Florida (USA). This ecosystem was completely burned in January 1996, after which 16 open-top chambers (OTCs) were placed on it in the spring of that year, half of which were maintained at the ambient atmospheric CO_2 concentration while the other half were maintained at ambient plus 350 ppm, with routine measurements being started in June 1999 and continuing for 25 months through July 2001. The scientists found the extra CO_2 supplied to the CO_2-enriched OTCs "increased maximum NEE and the apparent quantum yield of the NEE during the photoperiod," and the magnitude of the stimulation of maximum NEE, expressed per unit ground area, "was seasonal, rising from 50% in the winter to 180% in the summer," in accord with what is known about the interactive effects of atmospheric CO_2 enrichment and daily, seasonal, and multiyear warming.

Turnbull *et al*. (2004) studied four- to five-meter-tall cottonwood trees (*Populus deltoides* Bartr.) grown for three years in air of different CO_2 concentrations (420, 800, and 1,200 ppm) in the three bays of the Biosphere 2 facility near Tucson, Arizona (USA). They maintained the trees at three nocturnal

temperatures (15, 20, or 25°C) and a single constant daytime temperature (31 ± 1°C) in a short-term experiment in which they routinely measured maximum photosynthesis (Amax) rates at growth CO_2 concentrations. As nocturnal air temperature rose from 15 to 25°C, the researchers observed subsequent daytime Amax increased by 16% in air of 420 ppm CO_2, 12% in air of 800 ppm CO_2, and 4% in air of 1,200 ppm CO_2, leading them to conclude "at future elevated night temperatures suggested by global climate monitoring and modeling, net photosynthesis at elevated CO_2 may be increased." It appears the response could saturate at a CO_2 partial pressure of somewhat more than 1,200 ppm CO_2, but that value is far greater than anyone is suggesting will ever be reached as a consequence of mankind's burning of fossil fuels.

But what if air temperatures get *really* hot, for some as-yet-unknown reason? Idso *et al.* (1995) grew well-watered and -fertilized sour orange (*Citrus aurantium* L.) trees from the seedling stage out-of-doors at Phoenix, Arizona (USA) in clear-plastic-wall open-top chambers continuously maintained at mean atmospheric CO_2 concentrations of either approximately 400 or 700 ppm for 5.5 years. During the warmest parts of some of the hottest days of summer, the scientists measured the temperatures and rates of net photosynthesis of fully expanded outer-canopy sunlit leaves.

Figure 3.13.3.1 portrays the results of plotting their net photosynthesis measurements against leaf temperature. Based on the linear regression lines fit to the data, it can be determined the 75% increase in the air's CO_2 content led to a 75% enhancement of leaf net photosynthesis at a leaf temperature of 31°C, a 100% enhancement at a leaf temperature of 35°C, and a 200% enhancement at 42°C. At higher leaf temperatures, the net photosynthetic rate of the foliage growing in ambient air dropped to zero at
Figure 3.13.3.1. Leaf net photosynthetic rate vs. leaf temperature for the foliage of sour orange trees growing in air of either 400 or 700 ppm CO_2. Adapted from Idso *et al.* (1995).

47°C (making the CO_2-induced enhancement of photosynthesis at that point essentially infinite), and it became negative thereafter (which condition, if prolonged, would ultimately lead to plant death).

In the CO_2-enriched trees, by contrast, the net photosynthetic rate of the foliage was still substantial at 47°C, and the regression line for those trees suggests their mean rate of foliage net photosynthesis likely would not have declined to zero until leaf temperature reached 54°C, approximately 7°C above the upper-limiting temperature for positive net photosynthesis in the trees grown in ambient air.

These findings show if Earth's air temperature continues to rise significantly in the future, a concomitant rise in the air's CO_2 content would serve as a powerful antidote for the ill—and sometimes deadly—effects of temperature stress.

Lewis *et al.* (2001) reached somewhat similar conclusions when they grew Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco) seedlings in sunlit chambers programmed to track either ambient atmospheric CO_2 concentration or ambient + 200 ppm CO_2, as well as either ambient air temperature or ambient + 4°C, over a 21-month period, measuring

light-saturated rates of net photosynthesis at approximately monthly intervals. The extra CO_2 they supplied to the seedlings "increased net photosynthetic rates by an average of 21% across temperature treatments during both the 1996 hydrologic year, the third year of exposure, and the 1997 hydrologic year," and "elevated mean annual temperature increased net photosynthetic rates by an average of 33% across CO_2 treatments during both years." In addition, "between February and August 1996, the short-term temperature optima for photosynthesis shifted by approximately 10°C higher in both CO_2 treatments," and the elevated CO_2 treatment "increased the short-term (minutes to hours) temperature optima for photosynthesis, as has been observed in other tree species (Idso and Idso, 1994; Eamus *et al*., 1995)." The four researchers conclude "an increase of 200 ppm above current atmospheric CO_2 concentrations may shift temperature optima upward 3–4°C, paralleling the increase in mean annual temperatures predicted to occur during the next century," and "by shifting temperature optima upward, elevated CO_2 may 'acclimate' photosynthetic processes to future temperature regimes."

Huang *et al*. (2007) compared, synthesized, and evaluated the scientific literature to that point in time, describing atmospheric CO_2 enrichment experiments conducted on trees and empirical tree-ring studies designed to ascertain whether the growth-promoting effects of rising atmospheric CO_2 concentrations occur in natural forests. They found numerous CO_2-enrichment experiments have "demonstrated significantly positive physiological and growth responses of trees to CO_2, providing strong evidence to support the direct CO_2 fertilization effect (increased photosynthesis, water use efficiency, above- and below-ground growth) and thus allowing prediction of which ecosystems might be most responsive to CO_2." They suggest the latter will be "warm, moderately drought-stressed ecosystems with an ample nitrogen supply," because "drought-stressed trees could benefit from increased water use efficiency to enhance growth." They note tree-ring studies on the cold and arid Tibetan Plateau also "showed significant growth enhancements as well as increased water use efficiency (24.7% and 33.6% for each species, respectively) in Qilian juniper and Qinghai spruce since the 1850s," citing Zhang *et al*. (2003), Shao *et al*. (2005), Liang *et al*. (2006), Huang and Zhang (2007), and Zhang and Qiu (2007).

Hickler *et al*. (2008) evaluated the process-based LPJ-GUESS model of vegetation dynamics and biogeochemistry (Smith *et al*., 2001; Hickler *et al*., 2004) via a site-by-site comparison with the results of four temperate forest FACE experiments (Norby *et al*., 2005). After demonstrating the model simulations adequately reproduced the magnitude of the FACE site measurements—a mean model-derived net primary productivity (NPP) increase of 25.9% for CO_2 raised to a value of 550 ppm vs. a mean measured NPP increase of 27.8% for the same CO_2 increase—they conducted what they called a "global forest FACE experiment" to see what the reality-tested model suggested about CO_2 enrichment effects on the NPP of boreal and tropical forests, as well as its temperate forests.

For the world as a whole, the model suggests raising the air's CO_2 concentration to 550 ppm would increase the NPP of temperate forests by an average of 25.7%. The NPP of boreal forests would be raised by 15.1%, and tropical forests would experience an NPP increase of 35.1%. Hickler *et al*. note warming "is likely to increase NPP more in cold northern regions than close to the equator because of a greater proportional growing season extension in temperature-limited environments."

Martinez-Vilalta *et al*. (2008) describe their use of tree-ring data from the Catalan Ecological and Forest Inventory "to study the temporal variability of Scots pine stem radial growth (period 1901–1997) across a relatively large region (Catalonia, NE Spain) situated close to the southern limit of the distribution of the species." This inventory, they write, "included a total of 10,664 plots randomly distributed throughout the forested area of Catalonia," where Scots pine was present in 30.2% of the plots and dominant in 18.4% of them. They found "an overall increase of 84% in Scots pine BAI [basal area increment] during the 20th century, consistent with most previous studies for temperate forests." They state, "this trend was associated with increased atmospheric CO_2 concentration," which they interpret to be "a fertilization effect." Over the same period, the five researchers note, "there was also a marked increase in temperature across the study region (0.19°C per decade on average)," and "this warming had a negative impact on radial growth, particularly at the drier sites." They add "its magnitude was not enough to counteract the fertilization effect."

Darbah *et al*. (2010) measured the effects of a natural and prolonged heat wave on the photosynthetic rates of quaking aspen (*Populus tremuloides* Michx) and paper birch (*Betula papyrifera*) trees grown from the seedling stage for an additional nine

years in the free-air CO_2-enrichment (FACE) facility near Rhinelander, Wisconsin (USA), where from 0700 to 1900 hours each day throughout the growing season half of the trees were exposed to an extra ~190 ppm of CO_2. For the aspen trees, the heat wave produced "no visible symptoms of stress," but the birch trees exhibited "leaf curling and then yellowing of leaves and finally leaf shedding," with trees in the control treatment dropping 33% of their leaves and those in the CO_2-enriched treatment dropping 20%. Aspen clone 42E exhibited a 30% CO_2-induced increase in the rate of photosynthesis at saturating light intensities in the 32–35°C temperature range, and 218% in the 36–39°C range. Similarly, aspen clone 271 exhibited a 38% CO_2-induced increase in the 32–35°C range and a 199% increase in the 36–39°C range. The birch trees exhibited a 95% CO_2-induced increase in photosynthetic rates in the 32–35°C range and a 297% increase in the 36–39°C range.

The four researchers say their findings agree with those of Idso and Kimball (1992), who reported elevated CO_2 (ambient + 300 ppm) increased net photosynthetic rates in sour orange tree (*Citrus aurantium* L.) leaves exposed to full sunlight by 75, 100, and 200% compared to leaves in ambient CO_2 air at temperatures of 31, 35, and 42°C, respectively, suggesting "elevated CO_2 ameliorates heat stress in tree leaves." They also note their observations "agree with Veteli *et al*. (2007), who reported that elevated CO_2 ameliorated the negative effects of high temperature in three deciduous tree species," and "Wayne *et al*. (1998) reported that elevated CO_2 ameliorated high temperature stress in yellow birch trees (*Betula alleghaniensis*)." They conclude, "in the face of rising atmospheric CO_2 and temperature (global warming), trees will benefit from elevated CO_2 through increased thermotolerance."

Ghannoum, *et al*. (2010b) grew individual well-watered and -fertilized plants of two species of Australian eucalypts—faster-growing *Eucalyptus saligna* and slower-growing *E. sideroxylon*—from seed in 10-L pots filled with 9 kg of loamy sand in naturally lit glasshouse compartments maintained at either ambient or ambient + 4°C air temperature and three different CO_2 concentrations (280, 400, or 650 ppm) for 140 days, measuring various plant responses throughout the course of the experiment. They found light-saturated net photosynthesis (Asat) increased by ~50% with each step-increase in the air's CO_2 concentration—going from 280 to 400 ppm, and going from 400 to 650 ppm—and in the higher of the two temperature treatments the optimal temperature for Asat increased by 2–7°C across the three CO_2 treatments. They note these results "partly explain the strong growth responses to elevated CO_2 and temperature observed in a previous study with the same eucalypt seedlings," citing Ghannoum *et al*. (2010a).

Keenan *et al*. (2011) note climate models consistently project significant increases in temperature and decreases in precipitation in the Mediterranean basin, and they state these changes may have a large impact on current Mediterranean forests and the related ecosystem services they provide. They say niche-based models—also known as bioclimatic envelope models or habitat models—are the most commonly used method for predicting potential species distribution responses to future climatic changes, and they note these models typically predict significant negative consequences for terrestrial plants and animals in the face of increasing atmospheric CO_2 concentrations.

Keenan *et al*. say they prefer process-based models, which describe eco-physiological processes ranging from purely empirical relationships to mechanistic descriptions based on physical laws. These models, supported by experiments and growth and yield surveys, "suggest that global warming will have a positive impact on forest productivity (van der Meer *et al*., 2002; Nigh *et al*., 2004; Norby and Luo, 2004; Briceño-Elizondo *et al*., 2006; Gaucharel *et al*., 2008), due to the direct fertilization effect of increased CO_2 and indirect effects such as lengthening of the growing period." To elucidate the difference in results obtained by employing these two approaches, the five researchers assessed and compared the projections when applied to stands of three forest species (*Quercus ilex*, *Pinus halepensis,* and *Pinus sylvestris*) that have widely contrasting distributions in continental Spain.

Keenan *et al*. found CO_2 fertilization tends to show an increase in forest productivity in mechanistic process-based models (despite increased drought and presumed temperature stress) by up to three times the non-CO_2 fertilization scenario by the period 2050–2080, in stark contrast to projections of reduced habitat suitability based on niche-based models for the same period. Their results show "previous reports of species decline in continental Spain (e.g. Benito-Garzon *et al*., 2008) may be overestimated due to two reasons." One of these is the use of only one predictive niche-based model, and the other is the failure to account for positive effects of CO_2

fertilization in a warming world. They note similar studies in other regions that do not consider these two aspects are also potentially overestimating species decline due to climate change, because "niche-based model results also likely overestimate the decline in [habitat] suitability." They conclude, "an organism's niche must be modeled mechanistically if we are to fully explain distribution limits," citing Kearney (2006).

Osorio *et al*. (2011) investigated the impacts of drought and high-temperature stresses on photosynthesis, energy partitioning, and membrane lipids—as well as the potential ability of Carob or St. John's (*Ceratonia siliqua*) trees to attenuate oxidative damage. They studied seedlings growing in controlled-environment chambers and rooted in 3-dm^3 pots filled with a 2:1 mixture of a fertilized substrate and natural soil, maintained under two thermal regimes—low and high temperature (LT: 25/18°C; HT: 32/21°C)—and three soil water conditions (control, water stress, and rewetting), monitoring numerous physiological and biochemical plant properties and processes. The decrease in net photosynthesis (P_N) caused by drought was 33% in the LT chamber and 84% in the HT chamber. They note, "the negative effects of soil drying on P_N and stomatal conductance of HT plants were no longer detected 36 hours following rewatering." Also, "although *C. siliqua* seedlings exhibit clear signs of oxidative stress under drought and high temperature, they retain a remarkable ability to quickly restore normal physiological activity on rehydration." This ability was so strong the five Portuguese scientists say they "can state that although *C. siliqua* seedlings exhibit clear signs of oxidative stress under drought and high temperature, they retain a remarkable ability to quickly restore normal physiological activity on rehydration, which let us believe that they can satisfactorily deal with predicted climate warming and increased soil drying in the Mediterranean area."

Wertin *et al*. (2012) examined the influence of elevated temperature (ambient + 2°C) and atmospheric CO_2 concentration (700 ppm), applied singly and in combination, on biomass accumulation and the temperature response of net photosynthesis (Anet) and leaf respiration (Rd) of loblolly pine (*Pinus taeda* L.) seedlings grown simultaneously at a northern and a southern site in the species' range, where the long-term mean growing season temperature (from February through October) at the cool site was 15.2°C and at the warm site was 21.5°C. They grew the well-watered and -fertilized seedlings over two con-

secutive years in half-cylindrical polyfilm-enclosed chambers located in open fields.

Wertin *et al*. determined "biomass accumulation was substantially greater at the warmer site compared with the cooler site regardless of treatment," and "at each site, biomass accumulation was greater in the elevated temperature treatment compared with the ambient treatment." They also found "elevated CO_2 increased biomass accumulation and Anet at both sites and in both temperature treatments." The five University of Georgia (USA) researchers conclude their study "provides an indication that future projected increases in CO_2 and air temperature of 700 ppm and +2°C, respectively, are likely to increase loblolly pine growth in most, if not all, of its current range." And they state, "the large number of studies that have reported an increase in tree growth in elevated growth temperatures compared with current ambient temperature (Way and Oren, 2010) suggest that other species may respond similarly."

Ameye *et al*. (2012) note that in studies where the air's CO_2 content was doubled, "increases in net photosynthesis were reported ranging from 43% to 192% in *Pinus taeda* (Teskey, 1997; Tissue *et al*., 1997; Ellsworth, 1999; Wertin *et al*., 2010; Frenck *et al*., 2011) and from 30% to 256% in *Quercus rubra* (Kubiske and Pregitzer, 1996; Anderson and Tomlinson, 1998; Cavender-Bares *et al*., 2000)." Moreover, "generally, an increase in air temperature also has a positive effect on net photosynthesis and growth," citing Sage and Kubien (2007) and Way and Oren (2010).

Investigating how loblolly pine and northern red oak trees might respond to the extreme heat waves often predicted to occur in a future CO_2-enriched world, the scientists examined the most recent fully developed leaves of well-watered and -fertilized seedlings of *Pinus taeda* and *Quercus rubra* grown in 7.6-L pots out-of-doors at Athens, Georgia (USA) in polyethylene chambers maintained at ambient and elevated air temperatures (T_{amb} and T_{amb} + 3°C), as well as seven-day heat waves consisting of a biweekly +6°C heat wave or a monthly +12°C heat wave. These treatments were maintained throughout the growing season, and Ameye *et al*. measured rates of net photosynthesis before, during, and after the many midsummer heat waves they created. They report "an immediate and significant decline in net photosynthesis was observed in seedlings subjected to a +12°C heat wave, but not in seedlings subjected to a +6°C heat wave." They also state, "after the third day of the +12°C heat wave, net photosynthesis values

stabilized at positive values and did not show signs of further reduction, indicating that the photosynthetic apparatus did not accrue additional stress or damage as the heat wave continued." Therefore, they conclude, "if soil moisture is adequate, trees will experience negative effects in photosynthetic performance only with the occurrence of extreme heat waves." Also, as "elevated CO_2 diminished these negative effects," they conclude "the future climate may not be as detrimental to plant communities as previously assumed."

In concluding this literature review, it is instructive to consider the Paleocene-Eocene Thermal Maximum (PETM) of some 56 million years ago. According to Jaramillo *et al.* (2010), it "was one of the most abrupt global warming events of the past 65 million years (Kennett and Stott, 1991; Zachos *et al.*, 2003; Westerhold *et al.*, 2009)." It was presumed to have been driven, they write, by "a massive release of ^{13}C-depleted carbon (Pagani *et al.*, 2006; Zeebe *et al.*, 2009)" that led to "an approximate 5°C increase in mean global temperature in about 10,000 to 20,000 years (Zachos *et al.*, 2003)." Earth's tropical ecosystems "suffered extensively because mean temperatures are surmised to have exceeded the ecosystems' heat tolerance (Huber, 2008)," according to many scientists, Jaramillo *et al.* write.

To ascertain whether the ancient warming of the world truly constituted a major problem for the planet's rainforests, the 29 researchers from eight countries analyzed pollen and spore contents and the stable carbon isotopic composition of organic materials obtained from three tropical terrestrial PETM sites in eastern Colombia and western Venezuela. Contrary to the prevailing wisdom of the recent past, they found the onset of the PETM was "concomitant with an increase in diversity produced by the addition of many taxa (with some representing new families) to the stock of preexisting Paleocene taxa." They determined this increase in biodiversity "was permanent and not transient."

Jaramillo *et al.* write, "today, most tropical rainforests are found at mean annual temperatures below 27.5°C," and several scientists have argued "higher temperatures could be deleterious to the health of tropical ecosystems," citing Stoskopf (1981), Bassow *et al.* (1994), Lewis *et al.* (2004), Huber (2008, 2009), and Tewksbury *et al.* (2008). They report tropical warming during the PETM is actually thought to have produced intolerable conditions for tropical ecosystems, citing Huber (2008, 2009). Nevertheless, Jaramillo *et al.* reiterate

that at the sites that they studied, "tropical forests were maintained during the warmth of the PETM (~31° to 34°C)." Thus they conclude, "it is possible that higher Paleocene CO_2 levels (Royer, 2010) contributed to their success."

Their conclusion is supported by what is now the well-established fact that most woody plants tend to exhibit their greatest photosynthetic rates at increasingly warmer temperatures as the air's CO_2 content rises. It is becoming increasingly clear that greater warmth and atmospheric CO_2 concentrations are not as detrimental as IPCC and others typically make them out to be. Quite to the contrary, they are likely to make ecosystems both more stable and more productive.

The scientific literature of the past few decades indicates a continuing rise in the air's CO_2 content likely will lead to enhanced rates of photosynthesis and biomass production that will not be negated by any global warming that might occur. If the ambient air temperature rises, the growth-promoting effects of atmospheric CO_2 enrichment likely will rise right along with it. Trees are likely to produce greater amounts of biomass and, therefore, more timber products to meet the increasing needs of Earth's expanding human population.

3.14 UV-B Radiation Stress

- The rise in the air's CO_2 content is a powerful antidote to the deleterious biological impacts that might be caused by an increase in the flux of UV-B radiation at the surface of Earth due to depletion of the planet's stratospheric ozone layer.

Zhao *et al*. (2004) state "as a result of stratospheric ozone depletion, UV-B radiation (280–320 nm) levels are still high at the Earth's surface and are projected to increase in the near future (Madronich *et al*., 1998; McKenzie *et al*., 2003)," noting, "increased levels of UV-B radiation are known to affect plant growth, development and physiological processes (Dai *et al*., 1992; Nogues *et al*., 1999)." High UV-B levels often result in "inhibition of photosynthesis, degradation of protein and DNA, and increased oxidative stress (Jordan *et al*., 1992; Stapleton, 1992)." In light of these observations, it is only natural to wonder how the rise in the air's CO_2 content might affect the deleterious effects of UV-B radiation on vegetation.

Zhao *et al*. grew well-watered and -fertilized cotton plants in sunlit controlled-environment chambers maintained at atmospheric CO_2 concentrations of 360 or 720 ppm from emergence until three weeks past first-flower stage under three levels of UV-B radiation (0, 8, and 16 kJ m^{-2} d^{-1}). On five dates between 21 and 62 days after emergence, they measured a number of plant physiological processes and parameters. Over the course of the experiment, the mean net photosynthetic rate of the upper-canopy leaves in the CO_2-enriched chambers was increased relative to that in the ambient-air chambers by 38.3% in the low UV-B treatment (from 30.3 to 41.9 m m^{-2} s^{-1}), 41.1% in the medium UV-B treatment (from 28.7 to 40.5 m m^{-2} s^{-1}), and 51.5% in the high UV-B treatment (from 17.1 to 25.9 m m^{-2} s^{-1}).

In the medium UV-B treatment, the growth stimulation from the elevated CO_2 was sufficient to raise net photosynthesis rates 33.7% above the rates experienced in the ambient air and no UV-B treatment (from 30.3 to 40.5 m m^{-2} s^{-1}). In the high UV-B treatment, however, the radiation damage was so great the 51.5% increase in net photosynthesis provided by the doubled-CO_2 air could not prevent the destruction, and the mean net photosynthesis rate of the cotton leaves was 14.5% less than in the ambient air and no UV-B treatment (dropping from 30.3 to 25.9 m m^{-2} s^{-1}).

The medium UV-B treatment of this study was chosen to represent the intensity of UV-B radiation presently received on a clear summer day in the major cotton production region of Mississippi (USA) under current stratospheric ozone conditions, and the high UV-B treatment was chosen to represent what might be expected there following a 30% depletion of the ozone layer, which has been predicted to double the region's reception of UV-B radiation from 8 to 16 kJ m^{-2} d^{-1}. Thus doubling the current CO_2 concentration and current UV-B radiation level would reduce the net photosynthetic rate of cotton leaves by just under 10% (from 28.7 to 25.9 m m^{-2} s^{-1}), whereas in the absence of a doubling of the air's CO_2 content, a doubling of the UV-B radiation level would reduce cotton net photosynthesis by just over 40% (from 28.7 to 17.1 m m^{-2} s^{-1}). Doubling the current atmospheric CO_2 concentration thus would compensate for more than three-fourths of the loss of cotton photosynthetic capacity caused by a doubling of the current UV-B radiation intensity. And it might do even better than that: Zhao *et al*. (2003) reported both Adamse and Britz (1992) and Rozema *et al*. (1997) found a doubling of CO_2 fully compensated for the negative effects of equally high UV-B radiation.

Deckmyn *et al*. (2001) grew white clover plants for four months in four small greenhouses, in two of which they allowed 88% of the incoming UV-B radiation to pass through the roofs and walls and two of which allowed 82% to pass through. They maintained one of the two greenhouses in each of the UV-B treatments at ambient CO_2 (371 ppm) and the other at elevated CO_2 (521 ppm). At the midseason point of their study, the 40% increase in atmospheric CO_2 concentration stimulated the production of flowers in the low UV-B treatment by 22% and in the slightly higher UV-B treatment by 43%. At the end of the season, the extra CO_2 provided no stimulation of biomass production in the low UV-B treatment but stimulated biomass production by 16% in the high UV-B treatment.

The results of this study indicate the positive effects of atmospheric CO_2 enrichment on flower and biomass production in white clover are greater at more realistic or natural values of UV-B radiation than those found in many greenhouses. Deckmyn *et al*. state their results "clearly indicate the importance of using UV-B transmittant greenhouses or open-top chambers when conducting CO_2 studies," lest the results obtained significantly underestimate the

magnitude of the benefits provided by the rise in the air's CO_2 content.

Qaderi and Reid (2005) grew well-watered and well-fertilized canola plants (*Brassica napus*) from seed to maturity in pots in controlled-environment chambers maintained at either 370 or 740 ppm CO_2 with and without a daily dose of UV-B radiation in the amount of 4.2 kJ m^{-2}, measuring a number of plant parameters at various times throughout the growing season. The final seed yield was 0.98 g/plant in the control treatment (ambient CO_2, with UV-B). Doubling the CO_2 concentration increased yield by 25.5% to 1.23 g/plant, and removing the UV-B radiation flux increased yield by 91.8% to 1.88 g/plant. Doing both (doubling the CO_2 concentration while simultaneously removing the UV-B flux) increased final seed yield by 175.5% to 2.7 g/plant. Hence, doubling the air's CO_2 concentration in the presence of the UV-B radiation flux enhanced final seed yield by 25.5%, and doubling CO_2 in the absence of the UV-B radiation flux increased seed yield by 43.6%. Qaderi and Reid conclude, "elevated CO_2 may have a positive effect on plants by mitigating the detrimental effects caused by UV-B radiation."

In a follow-up paper, Qaderi *et al*. (2007) examined the effects of elevated CO_2 and UVB radiation on the photosynthetic rates and water use efficiency of the maturing husks (siliquas) that surround the canola plant's seeds. For the plants exposed to 4.2 kJ m^{-2} d^{-1} of UVB radiation, the experimental doubling of the air's CO_2 concentration led to a 29% increase in siliqua net photosynthesis, an 18% decrease in siliqua transpiration, and a 58% increase in siliqua water use efficiency. For the plants exposed to no UVB radiation, siliqua net photosynthesis was increased by 38%, transpiration was decreased by 22%, and water use efficiency was increased by 87% in the CO_2-enriched air.

Tohidimoghadam *et al*. (2011) grew two varieties (Okapi and Talaye) of canola out-of-doors over the 2008 and 2009 growing seasons beneath rigid frames covered with polyethylene plastic film in air maintained at ambient and elevated atmospheric CO_2 concentrations of 400 and 900 ppm, at ambient and elevated levels of UV radiation, and under well-watered and deficit-watered conditions, measuring numerous plant properties during and after the growing period. They found "water stress significantly decreased yield and yield components, oil yield, protein percentage, height, specific leaf area and the number of branches." Elevated CO_2

"increased the final yield, 1000-seed weight, oil percentage, oil yield, height, specific leaf area and number of branches." UV radiation "decreased the yield, yield components, oil and protein percentages and growth parameters." They also note "the highest seed weight was obtained from the 'Talaye' cultivar treated with compete irrigation and elevated CO_2 and grown under sunlight radiation," whereas "the seed weights of both cultivars visibly decreased due to UV-B, UV-C and water stress under an ambient CO_2 concentration." The three Iranian researchers who conducted the study state, "an increase in UV exposure deceases plant growth and development," but "elevated CO_2 ameliorate(s) the adverse effects of UV radiation in the final yield, seed weight, oil percentage, oil yield, plant height, specific leaf area and number of branches per plant." They conclude an increase in the atmosphere's CO_2 concentration "could improve yield, yield components and growth parameters for plants subjected to elevated levels of UV radiation."

In a study of UV-B and CO_2 effects on a natural ecosystem, conducted at the Abisko Scientific Research Station in Swedish Lapland, Johnson *et al*. (2002) studied plots of subarctic heath composed of open canopies of downy birch and dense dwarf-shrub layers containing herbs and grasses. For five years, they exposed the plots to factorial combinations of UV-B radiation (ambient and that expected to result from a 15% stratospheric ozone depletion) and atmospheric CO_2 concentration (ambient, around 365 ppm, and enriched, around 600 ppm), after which they determined the amounts of microbial carbon (C_{mic}) and nitrogen (N_{mic}) in the soils of the plots.

When the plots were exposed to the enhanced UV-B radiation, the amount of C_{mic} in the soil was reduced to only 37% of what it was at the ambient UV-B level when the air's CO_2 content was maintained at the ambient concentration. When the UV-B increase was accompanied by the CO_2 increase, however, there was no decrease in C_{mic} but an increase of 37%. When the plots were exposed to the enhanced level of UV-B radiation, the amount of N_{mic} in the soil showed a 69% increase when the air's CO_2 content was maintained at the ambient concentration, and when the UV-B increase was accompanied by the CO_2 increase, N_{mic} rose by 138%.

These findings, Johnson *et al*. write, "may have far-reaching implications ... because the productivity of many semi-natural ecosystems is limited by N (Ellenberg, 1988)." Thus, the 138% increase in soil microbial N observed in this study to accompany a

15% reduction in stratospheric ozone and a 64% increase in atmospheric CO_2 concentration should significantly enhance the input of plant litter to the soils of these ecosystems, which represents the first half of the carbon sequestration process—the carbon input stage.

As to the second stage—keeping as much of that carbon as possible in the soil—Johnson *et al.* note "the capacity for subarctic semi-natural heaths to act as major sinks for fossil fuel-derived carbon dioxide is [also] likely to be critically dependent on the supply of N," as indicated in the literature review of Berg and Matzner (1997). The latter report the presence of additional nitrogen in the soil significantly enhances the long-term storage of carbon, as more litter is chemically transformed into humic substances when nitrogen is more readily available, and these more recalcitrant carbon compounds can be successfully stored in the soil for many millennia.

Koti *et al.* (2007) investigated the interactive effects of elevated atmospheric CO_2 (720 vs. 360 ppm), UV-B radiation levels (0 vs. 10 kJ/m^2/day), and temperature (38/30°C vs. 30/22°C day/night) on the growth and development of six well-watered and well-fertilized soybean (*Glycine max* L.) genotypes. They found "elevated CO_2 partially compensated [for] the damaging effects on vegetative growth and physiology caused by negative stressors such as high temperatures and enhanced UV-B radiation levels in soybean." The authors note CO_2's positive influence on plant height, leaf area, total biomass, net photosynthesis, total chlorophyll content, phenolic content, and wax content, as well as relative plant injury. Thus, with respect to almost all of the ways high air temperatures and high UV-B radiation levels retard the growth and development of soybeans, elevated atmospheric CO_2 concentrations appear to provide significant ameliorative relief.

Estiarte *et al.* (1999) grew spring wheat in FACE plots in Arizona (USA) at atmospheric CO_2 concentrations of 370 and 550 ppm and two levels of soil moisture (50 and 100% of potential evapotranspiration). Under those conditions, leaves of plants growing in elevated CO_2 had 14% higher total flavonoid concentrations than those of plants grown in ambient air, and soil water content did not affect the relationship. One of the functions of flavonoids in plant leaves is to protect them against UV-B radiation. Hence, more studies of this nature should be conducted to see how general this beneficial response may be throughout the plant world.

These findings indicate the rise in the air's CO_2 content is a powerful counterbalance against the deleterious biological impacts that could be caused by an increase in the flux of UV-B radiation at the surface of Earth due to depletion of the planet's stratospheric ozone layer.

3.15 Water Stress

As the CO_2 content of the air rises, nearly all plants will exhibit increases in photosynthesis and biomass production, but some researchers claim water stress will negate these benefits. This section examines the results of several CO_2-enrichment studies designed to show the net effect of elevated CO_2 and water stress on the growth of Earth's vegetation.

3.15.1 Agricultural Crops

- The rise in the atmosphere's CO_2 content likely will lead to substantial increases in the photosynthetic rates and biomass production of the world's chief agricultural crops, even in stressful situations imposed by less-than-optimum soil moisture.

As the air's CO_2 content rises, nearly all plants will exhibit increases in photosynthesis and biomass production, but some researchers claim elevated concentrations of atmospheric CO_2 will lead to more droughty conditions in many parts of the world and thereby significantly reduce or totally negate these CO_2-induced benefits. This section reviews the results of numerous studies that show atmospheric CO_2 enrichment may help important food crops cope with periods of less-than-optimal water availability.

One way atmospheric CO_2 enrichment helps plants in this regard is by stimulating them to develop larger-than-usual and more robust root systems that enable them to probe greater volumes of soil for moisture. Wechsung *et al*. (1999), for example, observed a 70% increase in lateral root dry weights of water-stressed wheat grown at 550 ppm CO_2, and De Luis *et al*. (1999) reported a 269% increase in root-to-shoot ratio of water-stressed alfalfa growing at 700 ppm CO_2. Thus, elevated CO_2 may often elicit stronger-than-usual positive root responses in agricultural species under conditions of water stress.

Elevated levels of atmospheric CO_2 also tend to reduce the openness of stomatal pores on leaves, thus decreasing plant stomatal conductance. This phenomenon, in turn, reduces the amount of water lost to the atmosphere by transpiration and, consequently, lowers overall plant water use. Serraj *et al*. (1999), for example, reported water-stressed soybeans grown at 700 ppm CO_2 reduced their total seasonal water loss by 10% relative to water-stressed control plants grown at 360 ppm CO_2. And Conley *et al*. (2001) found a 200 ppm increase in the air's CO_2 concentration reduced cumulative evapotranspiration in water-stressed sorghum by about 4%.

Atmospheric CO_2 enrichment thus increases plant water acquisition by stimulating root growth, and it reduces plant water loss by constricting stomatal apertures. These two phenomena typically enhance plant water-use efficiency, even under conditions of less-than-optimal soil water content. They have other implications as well.

CO_2-induced increases in root development

together with CO_2-induced reductions in stomatal conductance often improve plant water status during times of drought. Sgherri *et al*. (1998), for example, found leaf water potential, which is a good indicator of overall plant water status, was 30% higher (less negative and therefore more favorable) in water-stressed alfalfa grown at an atmospheric CO_2 concentration of 600 ppm versus 340 ppm. Wall (2001) found leaf water potentials were similar in CO_2-enriched water-stressed plants and ambient-grown well-watered control plants, which implies a complete CO_2-induced amelioration of water stress in the CO_2-enriched plants. Lin and Wang (2002) demonstrated elevated CO_2 caused a several-day delay in the onset of the water stress-induced production of the highly reactive oxygenated compound H_2O_2 in spring wheat. Also, they found plants grown in elevated CO_2 maintained higher enzymatic activities of superoxide dismutase and catalase—two important antioxidants—relative to those observed in ambient-grown plants, following the induction of water stress.

If atmospheric CO_2 enrichment allows plants to maintain a better water status during times of water stress, it is only logical to surmise they would exhibit greater rates of photosynthesis than plants growing in similarly water-deficient soil in non-CO_2-enriched air. With the onset of experimentally induced water stress in India Mustard (*Brassica juncea*), Rabha and Uprety (1998) observed photosynthetic rates dropped by 40% in plants growing in ambient air, while plants growing in air containing 600 ppm CO_2 experienced only a 30% reduction in net photosynthesis. Ferris *et al*. (1998) imposed water-stress conditions on soybeans and allowed them to recover following complete rewetting of the soil, finding plants grown in air containing 700 ppm CO_2 reached pre-stressed rates of photosynthesis after six days, whereas plants grown in ambient air never recovered to pre-stressed photosynthetic rates.

Analogously, it is also to be expected that elevated CO_2 concentrations would enhance plant biomass production under drought conditions. Ferris *et al*. (1999) report water-stressed soybeans grown at 700 ppm CO_2 attained seed yields 24% greater than those of similarly water-stressed plants grown at ambient CO_2 concentrations, and Hudak *et al*. (1999) determined water stress had no detrimental effect on yield in CO_2-enriched spring wheat. Many studies have found the CO_2-induced biomass increase to be greater for water-stressed plants than for well-watered plants, as demonstrated in the review of the subject by Idso and Idso (1994).

Li *et al*. (2000), reported a 180 ppm increase in the air's CO_2 content increased final grain weights in the upper and lower sections of the main stems of the spring wheat they studied by 10 and 24%, respectively, under water-stressed conditions, but under well-watered conditions elevated CO_2 increased final grain weights only in the lower sections of the main stems and by only 14%. Thus elevated CO_2 had a greater positive impact on final grain weights of spring wheat under water-stressed field conditions than in non-water-stressed field conditions, once again demonstrating atmospheric CO_2 enrichment is often more important to stressed plants than to non-stressed plants.

Similarly, spring wheat grown in air containing an additional 280 ppm CO_2 exhibited 57 and 40% increases in grain yield under water-stressed and well-watered conditions, respectively (Schutz and Fangmeier, 2001). Ottman *et al*. (2001) found elevated CO_2 increased plant biomass in water-stressed sorghum by 15%, but no biomass increase occurred in well-watered sorghum. In predicting maize and winter wheat yields in Bulgaria under future scenarios of increased air temperature and decreased precipitation, Alexandrov and Hoogen-boom (2000) note yield losses were likely to occur if the air's CO_2 content remained unchanged, but if the atmospheric CO_2 concentration doubled, maize and winter wheat yields likely would increase, even under the combined stresses of elevated temperature and reduced rainfall.

Widodo *et al*. (2003) grew rice (*Oryza sativa* [L.] cv. IR-72) in eight outdoor, sunlit, controlled-environment chambers at daytime atmospheric CO_2 concentrations of 350 and 700 ppm for an entire season. In one pair of chambers the plants were continuously flooded, in a second pair drought stress was imposed during panicle initiation, in a third pair it was imposed during anthesis, and in a fourth pair it was imposed at both stages. In the elevated CO_2 treatment, midday leaf photosynthetic CO_2 exchange rates (CER) and chlorophyll concentrations were higher at most sampling dates. In addition, the CO_2-enriched plants exhibited enhanced midday leaf sucrose and starch accumulation during early reproductive phases.

Near the end of the imposed drought periods, water deficits caused substantial decreases in midday leaf CER and chlorophyll concentrations, along with concomitant reductions in the primary products of photosynthesis. These drought-induced effects,

Widodo *et al*. note, "were more severe for plants grown at ambient than at elevated CO_2." They report, for example, "plants grown under elevated CO_2 were able to maintain midday leaf photosynthesis, and to some extent other photosynthetic-related parameters, longer into the drought period than plants grown at ambient CO_2," as also has been observed for a number of other plants (Rogers *et al*., 1984; Jones *et al*., 1985; Idso, 1988; Bhattacharya *et al*., 1990; Chaves and Pereira, 1992; Clifford *et al*., 1993; Baker *et al*., 1997; Vu *et al*., 1998).

Recovery from drought-induced water stress was more rapid in the elevated CO_2 treatment. At panicle initiation, for example, Widodo *et al*. write, "as water was added back following a drought induction, it took more than 24 days for the ambient CO_2-[water] stressed plants to recuperate in midday leaf CER, compared with only 6–8 days for the elevated CO_2-[water] stressed plants." Similarly, they note, "for the drought imposed during anthesis, midday leaf CER of the elevated CO_2-[water] stressed plants was fully recovered after 16 days of re-watering, whereas those of the ambient CO_2-[water] stressed plants were still 21% lagging behind their unstressed controls at that date." The five researchers conclude, "rice grown under future rising atmospheric CO_2 should be better able to tolerate drought situations."

Triggs *et al*. (2004) grew sorghum (*Sorghum bicolor* (L.) Moench, a C_4 grain crop) for two full seasons in control CO_2 plots (about 370 ppm) and FACE plots (Control + 200 ppm) under both well-watered (Wet) and water-stressed (Dry, less than half the total water received by the Wet treatment via rainfall and irrigation) conditions near Maricopa, Arizona (USA). They assessed evapotranspiration (ET) on a continuous basis by means of micro-meteorological measurements designed to allow the calculation of all the other elements (net radiation, sensible heat flux, and soil surface heat flux) of the energy balance of the crop-soil interface with the atmosphere. Sorghum water use efficiency (WUE) was calculated using final grain yield data obtained by Ottman *et al*. (2001).

Triggs *et al*. write, "in the Wet treatments, a reduction in ET of about 19%, combined with only a slight increase in total biomass (+4%), resulted in a 28% increase in WUE in elevated CO_2 conditions," whereas "in the Dry treatments, the relatively large increase in total biomass (+16% for both years) more than compensated for the approximate 5% increase in total ET, giving the FACE-Dry treatments an increase in WUE of 16% over both seasons." They conclude,

"even if future climate change results in less water available for agriculture, higher atmospheric CO_2 concentrations will still benefit C_4 crops," although "in regions with ample precipitation or irrigation, C_3 crops with higher growth responses may be preferable."

Kaddour and Fuller (2004) grew three commercial cultivars of durum wheat (*Triticum durum* Desf.) registered in Syria (Cham 1, Cham 3, and Cham 5) from seed in 10-liter pots in different compartments of a phytotron. Half of the compartments were maintained at an atmospheric CO_2 concentration of approximately 400 ppm and half were maintained at a concentration of approximately 1,000 ppm. Half of each of these treatments were further subdivided into two soil water treatments: well-watered, where available water content (AWC) was replenished to 90% of full capacity when it dropped to 60%, and water-stressed, where AWC was replenished to 70% of full capacity when it dropped to 45%. Averaged over the three cultivars, the extra 600 ppm of CO_2 supplied to the CO_2-enriched compartments led to total plant biomass increases of 62% in the well-watered treatment and 60% in the water-stressed treatment. The extra CO_2 also led to increases in the nitrogen concentrations of stems and ears. Nitrogen concentration of the ears was increased by 22% in the well-watered plants and by 16% in the water-stressed plants.

Kaddour and Fuller write their results "have important implications for the production of durum wheat in the future." They state "yields can be expected to rise as atmospheric CO_2 levels rise," and "this increase in yield can be expected under both water restricted and well irrigated conditions." Therefore, "where water availability is a prime limiting economic resource, it can be distributed more effectively under higher CO_2 conditions," and "for countries such as Syria where average national production is well below the physiological maximum due largely to drought stress, the predicted rise in atmospheric CO_2 could have a positive effect on production."

Richter and Semenov (2005) note, "with global warming, evapotranspiration is likely to increase and, with more variable rainfall, droughts could occur more often." They evaluated the impact of potential climate change on drought indicators and yields of winter wheat in England and Wales using a crop simulation model (*Sirius*) that also incorporates the effects of elevated atmospheric CO_2 concentration and temperature on crop growth and development,

445

where the CO_2 scenario driving the model was of medium to high anthropogenic emissions that raise the air's CO_2 concentration from 334 ppm (the 1961–1990 baseline) to 554 ppm in the 2050s. Probability distributions derived from multiple simulations using representative weather, soil types, and sowing dates indicate maximum soil moisture deficit "is likely to increase in the future, especially on shallow soils, and the probability of potential yield reductions exceeding 25% will increase by 10% until the 2050s." Nevertheless, they write, "average wheat yields are likely to increase by 1.2 to 2 t/ha (15–23%) by the 2050s because of a CO_2-related increase in radiation use efficiency."

Bernacchi *et al.* (2006) grew soybeans (*Glycine max* (L.) Merr.) for three years at the SoyFACE facility of the University of Illinois at Urbana-Champaign, Illinois (USA) at atmospheric CO_2 concentrations of either 375 or 550 ppm under natural field conditions with and without a 23% increase in ambient atmospheric ozone concentration, measuring a number of weather and plant physiological parameters from pre-dawn to post-dusk on several days during the three growing seasons. They determined the mean daily integral of leaf-level net photosynthesis (A) was enhanced by nearly 25% in the CO_2-enriched air under ambient ozone concentrations, but by a slightly smaller 20% in the high-ozone air. In addition, "there was a strong positive correlation between daytime maximum temperatures and mean daily integrated A at elevated CO_2." From their graphical depiction of this relationship, it appears at a daily maximum temperature of approximately 26.5°C, A was stimulated by about 14%, and at a daily maximum temperature of approximately 34.5°C, it was stimulated by about 35%. The 11 researchers report "the effect of elevated CO_2 on photosynthesis tended to be greater under water stress conditions," rising from an approximate 17% enhancement of A at the most favorable soil moisture condition encountered to an enhancement close to 30% under the driest of the conditions experienced by the crop.

Robredo *et al.* (2007) grew well-watered and well-fertilized barley (*Hordeum vulgare* L.) seedlings (seven per each 2.5-liter pot filled with perlite and vermiculite) in controlled-environment chambers maintained at atmospheric CO_2 concentrations of either 350 or 700 ppm. At the conclusion of the 18th day after seedling emergence, the treatments were split, with one continuing to be watered three times a week and the other treatment receiving no further

water. At that time and on several following dates, researchers measured a number of soil and plant water parameters, along with rates of leaf transpiration and net photosynthesis. They found "during the period of drought, elevated CO_2 delayed by 3–4 days the depletion of soil water content," because of "the lower rates of transpiration in plants grown under CO_2 enrichment." As a result, "under elevated CO_2, plant water stress developed more slowly," thanks to "a slower rate of soil water depletion," They report "the stimulation of carbon assimilation by elevated CO_2 was even greater in droughted compared to well-watered plants," even though "elevated CO_2 caused stomata closure."

The seven Spanish researchers write, "exposure to high carbon dioxide concentration resulted in an increase in photosynthesis and in a reduction in whole plant transpiration, contributing to an increase in water use efficiency that was more noticeable when plants were subjected to elevated CO_2 in conjunction with drought." They conclude, "growing plants under [an] elevated CO_2 environment mitigates or delays the effects of water stress in barley."

Li *et al.* (2007) employed open-top chambers to determine net ecosystem CO_2 exchange (NEE) before, during, and after the severe Central Florida drought of 1998 in a scrub-oak ecosystem in ambient-CO_2 (AC) air and in elevated-CO_2 (EC) air enriched with an extra 350 ppm of CO_2 since May 1996. They focused on the ecosystem's dominant species (*Quercus myrtifolia* Willd.), for which they measured net photosynthetic rate (PN) throughout the daylight hours of several days. They found EC air generally increased PN, whereas drought decreased it. Under droughty conditions, PN peaked at around 0830 each day, after which it declined in a fairly steady fashion until solar noon and typically remained at a relatively low level throughout the remainder of the daylight hours. The scientists assessed the interactive impacts of elevated CO_2 and drought on tree PN by comparing the percentage reduction in PN from 0830 to 1230 in the two CO_2 treatments. They found in May 1998, PN was reduced by 77% from 0830 to 1230 at AC but by only 48% at EC, and in July 1998, when the drought had further intensified, PN was reduced by 82% at AC but by a lesser 69% at EC.

NEE responded in much the same way. In May and June 1998, for example, NEE's midday depression was 58% and 60% less at EC than at AC, and in July 1999 it was 66% less. In addition, Li *et al.* note, "the mitigation of the effects of water stress by EC was reflected in the aboveground biomass

growth," such that "the relative effect of EC on biomass accumulation of the dominant species *Q. myrtifolia* was higher during the drought year (210% for 1998) compared to the non-drought years (67% for 1997)."

Manderscheid and Weigel (2007) grew spring wheat (*Triticum aestivum* cv. Minaret) in open-top chambers on an experimental field of the Federal Agricultural Research Center in Braunschweig, Germany, in two growing seasons at either current or future (current + 280 ppm) atmospheric CO_2 concentrations and under sufficient-water-supply (WET) or drought-stress (DRY) conditions. They imposed the latter just after the crop first-node stage was reached (approximately 35 days after emergence), by halving the subsequent water supplied to the plants. The researchers found, "in both years, biomass and grain yield were decreased by drought and increased by CO_2 enrichment," with the positive CO_2 effect being greater under drought conditions. Averaged over both years, "CO_2 enrichment increased biomass and grain yield under WET conditions by <=10% and under DRY conditions by >=44%." The CO_2-induced increase in crop water-use efficiency was 20% in the sufficient-water-supply treatment and 43% in the drought-stress treatment.

Veisz *et al*. (2008) grew seven cereal grain crops—winter barley (*Hordeum vulgare*, cv. Petra), winter wheat (*Triticum aestivum*, cvs. Libellula, Mv Regiment, Mv Mambo), winter durum wheat (*Triticum durum*, cv. Mv Makaroni), spring wheat (*Triticum aestivum*, cv Lona), and spring oats (*Avena sativa*, cv. Mv Pehely)—in a phytotron at the Agricultural Research Institute of the Hungarian Academy of Sciences at ambient and enriched atmospheric CO_2 concentrations (380 and 750 ppm, respectively) under both well-watered and drought conditions. For the latter condition they withheld water beginning at the 10th day after heading, and soil volumetric water content dropped from approximately 25% to 6%. They measured a number of crop characteristics at harvest.

Under the experimental conditions, the plants grown in the CO_2-enriched air "produced more organic matter, being taller, with more spikes and a higher grain number per plant than those grown at the present CO_2 level," and "thanks to the more intensive incorporation of carbohydrate, there was an increase in the mean grain mass and in the grain yield per plant" in the CO_2-enriched air. However, there was a concomitant decrease in the protein concentration of the grains produced in the high-CO_2 treatment.

Nevertheless, the net effect was positive because, for the several cereal varieties averaged together, grain yield under the well-watered conditions rose by 12.37% (from 2.83 to 3.18 g/plant) in response to atmospheric CO_2 enrichment, and grain protein concentration dropped from 17.04% to 16.23%, resulting in a net increase of 7% in total grain protein production. Likewise, grain yield under the water-stressed conditions rose by 30.68% (from 1.76 to 2.30 g/plant) in response to atmospheric CO_2 enrichment, and the concentration of the grain protein dropped from 21.63% to 19.70%, leading to a net increase of 19% in total grain protein production.

Chun *et al*. (2011) grew corn plants from seed in naturally sunlit soil-plant-atmosphere-research (SPAR) units in which temperature, humidity, and CO_2 concentration were precisely controlled, the latter at either 400 ppm (ambient) or 800 ppm (elevated), beginning 21 days after emergence (DAE). These units were placed atop soil bins (2.0 m long by 0.5 m wide by 1.0 m deep) filled with a mixture of 75% coarse sand and 25% vermiculate, where soil water contents were monitored hourly by a time domain reflectometry (TDR) system that consisted of 15 TDR probes per chamber placed in three rows at depths of 0, 15, 30, 50, and 75 cm from the soil surface. By means of this system of soil water content assessment, combined with nightly "fertigation," Chun *et al*. were able to provide the plants with the nitrogen they needed while maintaining four soil water stress levels—control, mild, moderate, and severe—which were also initiated at 21 DAE. Thereafter, the height, number of leaves, leaf lengths, and growth states of the corn plants were determined twice weekly, and samples of the plants were collected, dried, and analyzed for biomass accumulation at 21 and 60 DAE (the beginning and end of the different CO_2 and soil water content treatments).

The five researchers did not find the elevated CO_2 treatment had a strong effect on plant height, leaf area, or above-ground biomass. But under both well-watered and water-stressed conditions, higher soil water contents were maintained in the elevated CO_2 treatment, even though 20–49% less water was applied to the soil of the elevated CO_2 treatment. The five researchers conclude, "under increased CO_2 concentrations as generally predicted in the future, less water will be required for corn plants than at present."

Robredo *et al*. (2011) write, "barley, an economically important and extensively cultivated

cereal worldwide, increases its yield in parallel with an increase in CO_2," but "responds to drought stress through altered nitrogen metabolism and reduced productivity." They explored these complexities by growing barley (*Hordeum vulgare* L. cv. Iranis) seedlings in 2.5-L pots containing a 3:1 mix of perlite:vermiculite in a controlled-environment growth chamber, first at ambient and then at elevated atmospheric CO_2 concentrations (350 and 700 ppm, respectively). Initially, they watered the pots twice a week with a complete Hoagland solution and with deionized water between each Hoagland solution application. They initiated drought when the seedlings were 18 days old, withholding water for intervals of 9, 13, and 16 days. They analyzed the effects of these actions at the end of each drought period and analyzed water recovery three days after rewatering the 13-day droughted plants, with each complete experiment being replicated three times.

The six Spanish scientists state their barley plants showed a reduction in water use, even though under elevated CO_2 the plants had a larger leaf area, much as others also have found (Owensby *et al*., 1997; Niklaus *et al*., 1998). In addition, "during the period of drought, the depletion of soil water content was delayed by 3–4 days in plants grown under elevated CO_2 conditions," and in the CO_2-enriched plants "water stress also developed more slowly than at ambient CO_2 because of a slower rate of water depletion." They report, "leaf water potential in plants subjected to drought but grown at elevated CO_2 was less negative than in their ambient CO_2 grown counterparts."

Robredo *et al*. also note "absolute values for nitrogen uptake by barley plants were higher under elevated CO_2 compared to ambient CO_2." In addition, they "observed high nitrate reductase activity in plants grown at elevated CO_2, which should parallel an increase in photosynthesis (Robredo *et al*., 2007) and sugar content (Perez-Lopez *et al*., 2010)." Also, "under ambient CO_2 conditions, protein content decreased as the water stress progressed," but "when plants grew under elevated CO_2 conditions, the rate of photosynthesis was higher [and] drought had less effect on the protein content." They report the barley plants "showed a greater content of proteins under elevated CO_2," in harmony with Geiger *et al*. (1999), who they say "reported a similar outcome in tobacco with the same supra-optimal nitrogen concentration." They further remark these findings also mesh with the results of studies reviewed by Idso and Idso (2001), who conclude any negative effects of elevated CO_2 on

crop protein content "could be ameliorated by increased use of nitrogen fertilizer." Robredo *et al*. conclude "elevated CO_2 mitigates many of the effects of drought on nitrogen metabolism and allows more rapid recovery following water stress."

Tohidimoghadam *et al*. (2011) grew two varieties (Okapi and Talaye) of canola (*Brassica napus* L.) plants over the 2008 and 2009 growing seasons out-of-doors at 35°59'N, 50°75'E beneath rigid frames covered with polyethylene plastic film in air maintained at ambient and elevated atmospheric CO_2 concentrations of 400 and 900 ppm, at ambient and elevated levels of UV radiation, and under well-watered and deficit-watered conditions, during and after which periods they measured numerous plant properties. They found "water stress significantly decreased yield and yield components, oil yield, protein percentage, height, specific leaf area and the number of branches," but elevated CO_2 "increased the final yield, 1000-seed weight, oil percentage, oil yield, height, specific leaf area and number of branches." They also found elevated UV radiation "decreased the yield, yield components, oil and protein percentages and growth parameters," but elevated CO_2 once again ameliorated "the adverse effects of UV radiation in the final yield, seed weight, oil percentage, oil yield, plant height, specific leaf area and number of branches per plant."

Varga *et al*. (2012) write, "as well as damaging numerous physiological functions, abiotic stress [such as drought] also leads to higher concentrations of reactive oxygen species, which are present in nature in all plants, but which may damage cell components and disturb metabolic processes when present in larger quantities," citing Omran (1980), Larson (1988), and Dat *et al*. (2000). They note, "many authors have demonstrated that the [atmosphere's] CO_2 concentration has a substantial influence on the stress sensitivity of plants via changes in antioxidant enzyme activity," citing Fernandez-Trujillo *et al*. (2007), Ali *et al*. (2008), and Varga and Bencze (2009).

In an experiment designed to explore this subject further, Varga *et al*. grew two varieties of winter wheat in phytotrons maintained at either 380 or 750 ppm CO_2, where the potted plants were watered daily and supplied with nutrient solution twice a week until the start of drought treatments. They induced drought in three phases—at first node appearance, heading, and grain filling—by completely with-holding water for seven days, which ultimately dropped the volumetric soil water content in the pots

from 20–25% to 3–5%. These actions, the four Hungarian researchers report, led to "changes in enzyme activity" that "indicated that enhanced CO_2 concentration delayed the development of drought stress up to first node appearance, and stimulated antioxidant enzyme activity when drought occurred during ripening, thus reducing the unfavorable effects of [drought] stress." They conclude the increases in the antioxidant enzymes they analyzed "may help to neutralize the reactive oxygen species induced by stress during various parts of the vegetation period," and this phenomenon should help crops cope with extremes of moisture insufficiency.

These peer-reviewed, scientific studies of the effects of water insufficiency on the productivity of the world's major agricultural crops strongly support the earlier work of Idso and Idso (1994), who concluded the rise in the air's CO_2 content likely will lead to substantial increases in the photosynthetic rates and biomass production of the world's major agricultural crops, even in less-than-optimum soil moisture conditions.

3.15.2 Grasslands

- The peer-reviewed scientific literature demonstrates the historical and still-ongoing rise in the air's CO_2 content has led and likely will continue to lead to substantial increases in the photosynthetic rates and biomass production of various grassland plants, even under stressful environmental conditions imposed by less-than-optimum soil moisture.

As the air's CO_2 content rises, nearly all plants should exhibit increases in photosynthesis and biomass production, but some researchers have claimed water stress will negate these benefits. In reviewing the scientific literature for 1983–1994, Idso and Idso (1994) concluded water stress will not in fact negate the CO_2-induced stimulation of plant productivity. They discovered the CO_2-induced percentage increase in plant productivity was nearly always greater under water-stressed conditions than when plants were well-watered. Seven years later, Poorter and Perez-Soba (2001) conducted a similar literature review and reached the same conclusion. This section provides background for this phenomenon and highlights some of the more important work that subsequently has been done in this area.

Elevated levels of atmospheric CO_2 tend to reduce the area of open stomatal pore space on leaf surfaces, thus reducing plant stomatal conductance. This phenomenon, in turn, effectively reduces the amount of water lost to the atmosphere via transpiration. Leymarie *et al*. (1999), for example, found twice-ambient levels of atmospheric CO_2 caused significant reductions in the stomatal conductance of water-stressed *Arabidopsis thaliana*. Similarly, Volk *et al*. (2000) reported several calcareous grassland species exposed to elevated atmospheric CO_2 concentrations (600 ppm) consistently exhibited reduced stomatal conductance, regardless of soil moisture availability.

In addition, CO_2-induced increases in root development and CO_2-induced reductions in leaf stomatal conductance often combine to maintain a more favorable plant water status during times of drought. In the case of four grassland species comprising a pasture characteristic of New Zealand, for example, Clark *et al*. (1999) report leaf water potential, a good indicator of plant water status, was consistently higher (less negative and, therefore, less stressful) under elevated atmospheric CO_2 concentrations. Leaf water potentials of the water-stressed C_4 grass *Panicum coloratum* grown at 1,000 ppm CO_2 were always higher than those of their water-stressed counterparts growing in ambient air (Seneweera *et al*., 2001). Seneweera *et al*. (1998) had earlier reported leaf water potentials observed in CO_2-enriched water-stressed plants were three-and-a-half times greater than those observed in control plants grown at 350 ppm during drought conditions (Seneweera *et al*., 1998).

If atmospheric CO_2 enrichment thus allows grassland plants to maintain better water status during times of water stress, it is logical to infer such plants will exhibit greater photosynthetic rates than similar

plants growing in ambient air. In a severe test of this concept, Ward *et al*. (1999) found extreme water stress caused 93 and 85% reductions in the photosynthetic rates of two CO_2-enriched grassland species, yet their rates of carbon fixation were still greater than those observed under ambient CO_2 conditions.

These observations demonstrate elevated CO_2 nearly always enhances photosynthetic rates during times of water stress. One thus would expect plant biomass production to be enhanced by elevated CO_2 concentrations under drought conditions.

On the American prairie, Owensby *et al*. (1999) observed tallgrass ecosystems exposed to twice-ambient concentrations of atmospheric CO_2 for eight years exhibited significant increases in above- and below-ground biomass only during years of less-than-average rainfall. Derner *et al*. (2001) observed a 150 ppm increase in the CO_2 content of the air increased shoot biomass in two C_4 grasses by 57%, regardless of soil water content. Seneweera *et al*. (2001) reported a 640 ppm increase in the air's CO_2 content increased shoot dry mass in a C_4 grass by 44 and 70% under well-watered and water-stressed conditions, respectively. Volk *et al*. (2000) grew calcareous grassland assemblages at 360 and 600 ppm CO_2 and documented 18 and 40% CO_2-induced increases in whole-community biomass under well-watered and water-stressed conditions, respectively.

Nelson *et al*. (2004) reported on a five-year study (1997–2001) conducted on the semi-arid shortgrass steppe (SGS) of Colorado (USA). Working at the USDA-ARS Central Plains Experimental Range in the northern portion of the SGS about 60 km northeast of Fort Collins, Colorado, they used large (15.5 m^2) open-top chambers to examine the effects of elevated CO_2 (720 vs. 360 ppm) on plant water relations, ecosystem water use efficiency, soil moisture dynamics, and root distributions of the ecosystem's dominant C_3 (*Pascopyrum smithii* and *Stipa comata*) and C_4 (*Bouteloua gracilis*) grasses.

The five Agricultural Research Service scientists and their collaborator from Colorado State University report "seasonal average soil moisture throughout the soil profile (0–15, 15–45, 45–75, 75–105 cm) was increased under elevated CO_2 compared to ambient CO_2 for much of the study period," with the greatest relative increase (16.4%) occurring in the 75–105 cm depth increment. This finding of "increased soil moisture under elevated CO_2 at the deepest soil depth suggests that water percolated deeper into the soil profile and that less moisture was lost to evapotranspiration under elevated CO_2." Noting "this

phenomenon enhances water storage in the deep fine sandy loam soils underlying large portions of the SGS," they state, "this increase in soil moisture has been shown to be the major controlling factor in improved carbon assimilation rates and increased total aboveground biomass in this system (LeCain *et al*., 2003) and will likely decrease the susceptibility of the SGS to drought."

The Colorado researchers also found, when averaged over the study period, "leaf water potential was enhanced 24–30% under elevated CO_2 in the major warm- and cool-season grass species of the SGS (*Bouteloua gracilis*, C_4, 28.5%; *Pascopyrum smithii*, C_3, 24.7%; *Stipa comata*, C_3, 30.4%)." They report these results are similar to those of "studies involving other C_3 and C_4 grass species (Owensby *et al*., 1993; Jackson *et al*., 1994)," and they say the enhanced leaf water potential—"which reflects improved plant water status and increased drought tolerance (Tyree and Alexander, 1993)"—may lead to increased leaf turgor and allow the grasses "to continue growth further into periods of drought." Averaged over the five years of the study, Nelson *et al*. report, "water-use efficiency (grams aboveground biomass harvested / kilogram water consumed) was 43% higher in elevated than ambient CO_2 plots."

Nelson *et al*. say their results "suggest that a future, elevated CO_2 environment may result not only in increased plant productivity due to improved water use efficiency, but also lead to increased water drainage and deep soil moisture storage in this semi-arid grassland ecosystem." They add, "this, along with the ability of the major grass species to maintain a favorable water status under elevated CO_2, should result in the SGS being less susceptible to prolonged periods of drought."

Nelson *et al*. note their findings are common, writing, "previous studies have reported increased soil moisture under elevated CO_2 in semi-arid C_3 annual grasslands in California (Fredeen *et al*., 1997), mesic C_3/C_4 perennial tallgrass prairie in Kansas (Owensby *et al*., 1993, 1999; Ham *et al*., 1995; Bremer *et al*., 1996), and mesic C_3 perennial grasslands in Switzerland (Niklaus *et al*., 1998) and Sweden (Sindhoj *et al*., 2000)." Taken together, these studies indicate the benefits of atmospheric CO_2 enrichment will apply to grasslands generally, as the air's CO_2 content rises to double-and-beyond its current concentration.

If air temperature rises concurrently, things could get even better. Nelson *et al*. note, for example, "air temperature was on average 2.6°C higher inside the

chambers than outside," and this warming "was implicated in the 36% enhanced biomass production observed in chambered-ambient compared to non-chambered plots." Consequently, since this already-enhanced biomass production was the starting point from which the 41% increase in biomass arising from the doubling of the air's CO_2 content was calculated, the increase in biomass caused by the concurrent actions of both factors (increasing air temperature and CO_2 concentration) could be on the order of 90%.

The 15-member team of Morgan *et al*. (2004) reviewed the scientific literature on the role of water relations in the response of grassland and desert ecosystems to elevated levels of atmospheric CO_2. They found it suggests "atmospheric CO_2 enrichment may stimulate plant growth either directly through (1) enhanced photosynthesis or indirectly through (2) reduced plant water consumption and hence slower soil moisture depletion, or the combination of both." They performed an analysis to determine "gas exchange, plant biomass and species responses of five native or semi-native temperate and Mediterranean grasslands and three semi-arid ecosystems to CO_2 enrichment, with an emphasis on water relations."

The team found "increasing CO_2 led to decreased leaf conductance for water vapor, improved plant water status, altered seasonal evapotranspiration dynamics, and in most cases, periodic increases in soil water content." As a result, "across the grasslands of the Kansas tallgrass prairie, Colorado shortgrass steppe and Swiss calcareous grassland, increases in aboveground biomass from CO_2 enrichment were relatively greater in dry years." In contrast, they report, "CO_2-induced aboveground biomass increase in the Texas C_3/C_4 grassland and the New Zealand pasture seemed little or only marginally influenced by yearly variation in soil water, and plant growth in the Mojave Desert was stimulated by CO_2 in a relatively wet year." In addition, "Mediterranean grasslands sometimes failed to respond to CO_2-related increased late-season water, whereas semiarid Negev grassland assemblages profited."

Although they state "vegetative and reproductive responses to CO_2 were highly varied among species and ecosystems, and did not generally follow any predictable pattern in regard to function groups," considered in their entirety, they conclude the literature results they reviewed (many of which they themselves had been instrumental in collecting) "suggest that the indirect effects of CO_2 on plant and soil water relations may contribute substantially to experimentally induced CO_2-effects."

Lazzarotto *et al*. (2010) write, "white clover (*Trifolium repens* L.) is the most important pasture legume grown in temperate climates in association with a variety of grasses, notably perennial ryegrass (*Lolium perenne* L.)," adding, "white clover improves the nutritional quality and digestibility of the herbage" and "contributes substantially to the nitrogen status of the sward through biological nitrogen fixation." They note some researchers have expressed concern future drought, such as is predicted by climate models to occur in tandem with CO_2-induced global warming, will damage clover more than the grass with which it is intermingled, thereby degrading the nutritional quality and digestibility of pasture swards.

Lazzarotto *et al*. conducted a study in which "mechanisms controlling transient responses to elevated CO_2 concentration and climate change in an unfertilized grassland on the Swiss Plateau were examined in light of simulations with PROGRASS." They used a process-based model of grass-clover interactions developed by Lazzarotto *et al*. (2009), in which "daily weather for a series of transient climate scenarios spanning the 21st century were developed for the study site with the help of the LARS-WG weather generator," as described by Semenov and Barrow (1997) and Semenov *et al*. (1998), and "changes in the length of dry and wet spells, temperature, precipitation and solar radiation defining the scenarios were obtained from regional climate simulations carried out in the framework of the PRUDENCE project," as described by Christensen and Christensen (2007).

"Compared to 1961–1990," the Swiss and UK scientists write, the climate scenarios they developed for a CO_2 increase from 370 to 860 ppm "indicated that for 2071–2100 there would be a noticeable increase in temperature (roughly 3°C in winter and 5°C in summer), a significant drop in summer precipitation (of the order of -30%) and a nearly 2-fold increase in the length of dry spells." They report "clover abundance did not decline even in the absence of CO_2 stimulation." When the atmospheric CO_2 concentration was programmed to gradually rise from an initial value of 370 ppm to a final value of 860 ppm, "clover development benefited from the overall positive effects of CO_2 on nitrogen acquisition," which they note was "the reason for increasing productivity of the [entire] sward."

These findings indicate the rather large increases in temperature and decreases in precipitation projected for the remainder of the twenty-first

century, even if they come to pass, will not have much of an effect on Swiss grass-clover swards, but the concomitant increase in the air's CO_2 content will benefit them considerably. Lazzarotto *et al.* opine it is likely "technical progress in the management of grasslands and pastures," which will surely occur, will help such pastures even more.

Noting "grassland communities constitute an important fraction of the green surface of the Earth, and are worldwide an important source of cattle-food (Carlier *et al.*, 2009; Ciais *et al.*, 2011)," Farfan-Vignolo and Asard (2012) investigated several physiological and molecular (antioxidant) responses to water deficit in two major grassland species (*Lolium perenne* L. and *Medicago lupulina* L.) under current ambient (A) and future elevated (E) atmospheric CO_2 concentrations and air temperatures (T), where $ECO_2 = ACO_2 + 375$ ppm, and $ET = AT + 3°C$. The researchers found "drought caused significant increases in oxidative damage, i.e., in protein oxidation and lipid peroxidation levels." They also report, "in both species the impact of drought on protein oxidation was reduced in future climate conditions [ECO_2 and ET]." As to the stress-reducing effect of ECO_2, they state "this 'CO_2-protection effect' is reported for a variety of abiotic stress conditions and species," citing Schwanz and Polle (1998), Sgherri *et al.* (2000), Geissler *et al.* (2009), Perez-Lopez *et al.* (2009), Vurro *et al.* (2009), and Salazar-Parra *et al.* (2012). They say they too "find support for this effect at the level of oxidative cell damage and protein oxidation in water-deficit responses of *L. perenne* and *M. lupulina*." Even under drought stress, they note, "elevated CO_2 significantly affected shoot production in *L. perenne* (increase by 27–32%)," and "also in *M. lupulina* a biomass increase was observed (26–38%)."

Thus the conclusions of Idso and Idso (1994), based on the pre-1994 literature, are well supported by the subsequent peer-reviewed scientific literature, which indicates the rise in the air's CO_2 content likely will lead to substantial increases in plant photosynthetic rates and biomass production, even with stressful environmental conditions imposed by less-than-optimum soil moisture conditions.

3.15.3 Woody Plants

- The rise in the air's CO_2 concentration likely will lead to substantial increases in the photosynthetic rates and biomass production of trees and shrubs, even with stressful environmental conditions imposed by suboptimal soil moisture availability.

It is widely acknowledged that as the CO_2 content of the air rises, nearly all plant types will exhibit increases in photosynthesis and biomass production, but some researchers claim future water stress will negate these benefits of atmospheric CO_2 enrichment. Much of the pertinent scientific literature of the 10-year period 1983–1994, reviewed by Idso and Idso (1994), calls that claim into question, showing water stress will generally not negate the CO_2-induced stimulation of plant growth. Idso and Idso's literature review found the CO_2-induced percentage increase in plant productivity was nearly always greater under water-stressed conditions than when plants were well-watered. This section discusses subsequent relevant literature as it pertains to woody species.

It is well-known that during times of water stress, atmospheric CO_2 enrichment often stimulates the development of larger-than-usual and more robust root systems in woody plants, enabling them to probe greater volumes of soil for scarce and much-needed moisture. Tomlinson and Anderson (1998), for example, found greater root development in water-stressed red oak seedlings grown at 700 ppm CO_2 helped them effectively deal with the reduced availability of moisture, and these trees eventually produced just as much biomass as well-watered controls exposed to air containing 400 ppm CO_2. Polley *et al.* (1999) report water-stressed honey mesquite trees exposed to an atmospheric CO_2 concentration of 700 ppm produced 37% more root biomass than water-stressed seedlings in air of 370 ppm.

Elevated levels of atmospheric CO_2 also tend to reduce the area of open stomatal pore space on leaf surfaces, thus reducing plant stomatal conductance. This phenomenon, in turn, reduces the amount of water lost to the atmosphere via transpiration. Tognetti *et al.* (1998) determined the stomatal conductances of mature oak trees growing near natural CO_2 springs in central Italy were significantly lower than those of similar trees growing farther away from the springs during periods of severe summer drought, which allowed the CO_2-enriched trees to better conserve what little water was available to them.

Working together, CO_2-induced increases in root development and CO_2-induced reductions in stomatal conductance often contribute to the maintenance of a more favorable plant water status during times of drought. In the case of three Mediterranean shrubs, for example, Tognetti *et al.* (2002) found leaf water potential, a good indicator of plant water status, was consistently higher (less negative and, hence, less stressful) under twice-ambient CO_2 concentrations. Polley *et al.* (1999) observed leaf water potentials of water-stressed mesquite seedlings grown at 700 ppm CO_2 were 40% higher than those of their water-stressed counterparts growing in ambient air, comparable to the values of -5.9 and -3.4 MPa observed in water-stressed evergreen shrubs (*Larrea tridentata*) exposed to 360 and 700 ppm CO_2, respectively, as documented by Hamerlynck *et al.* (2000).

If atmospheric CO_2 enrichment allows plants to maintain a better water status during times of water stress, it is only logical to surmise plants growing under such conditions will exhibit CO_2-induced increases in photosynthesis. Palanisamy (1999) found water-stressed Eucalyptus seedlings grown at 800 ppm CO_2 had greater net photosynthetic rates than their ambient-grown and water-stressed counterparts. Runion *et al.* (1999) found the CO_2-induced photosynthetic stimulation of water-stressed pine seedlings grown at 730 ppm CO_2 was nearly 50% greater than similar water-stressed pine seedlings grown at 365 ppm CO_2. Similarly, Centritto *et al.* (1999a) report water-stressed cherry trees grown at 700 ppm CO_2 displayed net photosynthetic rates 44% greater than those of water-stressed trees grown at 350 ppm CO_2. And Anderson and Tomlinson (1998) determined a 300-ppm increase in the air's CO_2 concentration boosted photosynthetic rates in well-watered and water-stressed red oak seedlings by 34 and 69%, respectively, demonstrating the CO_2-induced enhancement in net photosynthesis in this species was essentially twice as great in water-stressed seedlings as in well-watered ones.

Nevertheless, plants sometimes suffer drastically when subjected to extreme water stress, but the addition of CO_2 to the air often induces plants to react better to stress than plants growing in normal air. Tuba *et al.* (1998), for example, reported leaves of a water-stressed woody shrub exposed to an atmospheric CO_2 concentration of 700 ppm continued to maintain positive rates of net carbon fixation for a period that lasted three times longer than did leaves of

equally water-stressed control plants growing in ambient air. Fernandez *et al*. (1998) discovered herb and tree species growing near natural CO_2 vents in Venezuela continued to maintain positive rates of net photosynthesis during that location's dry season, and the same species growing some distance away from the CO_2 source displayed net losses of carbon during this stressful time. Likewise, Fernandez *et al*. (1999) note that after four weeks of drought, the deciduous Venezuelan shrub *Ipomoea carnea* continued to exhibit positive carbon gains under elevated CO_2 conditions, whereas ambient-growing plants display-ed net carbon losses. Polley *et al*. (2002) reported seedlings of five woody species grown at twice-ambient CO_2 concentrations survived 11 days longer (on average) than control seedlings when subjected to maximum drought conditions.

Since elevated CO_2 enhances photosynthetic rates during times of water stress, one would expect tree and shrub biomass production to be enhanced by elevated CO_2 concentrations under drought conditions. That was demonstrated by Arp *et al*. (1998), who reported six perennial plants common to the Netherlands increased their biomass under CO_2-enriched conditions even when suffering from lack of water. In some cases, the CO_2-induced percentage biomass increase is greater for water-stressed plants than for well-watered plants. Catovsky and Bazzaz (1999), for example, reported the CO_2-induced biomass increase for paper birch was 27% and 130% for well-watered and water-stressed seedlings, respectively. Schulte *et al*. (1998) noted the CO_2-induced biomass increase of oak seedlings was greater under water-limiting conditions than under well-watered conditions (128% vs. 92%), as did Centritto *et al*. (1999b) for basal trunk area in cherry seedlings (69% vs. 22%).

Knapp *et al*. (2001) developed tree-ring index chronologies from western juniper stands in Oregon (USA), finding the trees recovered better from the effects of drought in the 1990s, when the air's CO_2 concentration was around 340 ppm, than they did in 1900–1930, when the atmospheric CO_2 concentration was around 300 ppm.

In a loosely related study, Osborne *et al*. (2000) looked at the warming and reduced precipitation experienced in Mediterranean shrublands over the last century and concluded primary productivity should have been negatively impacted in those areas. However, when the concurrent increase in atmos-pheric CO_2 concentration was factored into their mechanistic model, a 25% increase in primary productivity was projected.

Centritto (2002) grew peach seedlings for two growing seasons in pots in open-top chambers of either ambient or CO_2-enriched air (350 or 700 ppm, respectively) inside a glasshouse, where all plants were continuously maintained at optimum soil fertility and, for the entire first growing season, at optimum soil water availability. In the second growing season, half of the seedlings had water withheld from them for four weeks. At the end of the study, there was no evidence of any downward acclimation of photosynthesis in the seedlings grown at elevated CO_2, nor was there any downward acclimation in rubisco carboxylation efficiency or in the maximum RuBP regeneration capacity mediated by electron transport.

Xiao *et al*. (2005) experimented with *Caragana intermedia* Kuanget H.C. Fu, a deciduous shrub of semi-arid northern China that occurs primarily in the country's Maowusu sandland as well as parts of Inner Mongolia, where they state it is "used by local people as feed for livestock, and as shelter for protection of soils (Zhang, 1994)," noting "it is one of the dominant shrubs that fix soil and reduce wind speed, thus actively mitigating desertification." The five Chinese scientists grew seedlings of this species for 3.5 months in 10-cm-diameter by 10-cm-deep pots filled with sand and maintained at three water regimes—well-watered (60–70% field capacity), moderate-watered (45–55% field capacity), and drought-stressed (30–40% field capacity)—in greenhouse compartments maintained at atmospheric CO_2 concentrations of either 350 or 700 ppm. Near the end of this period, they measured leaf water potentials and several plant growth parameters.

Xiao *et al*. found, "elevated CO_2 significantly increased leaf water potential" while also increasing tree height, basal diameter, shoot biomass, root biomass, and total biomass, which was increased by 79% under the well-watered condition, by 61% under the moderate-watered condition, and by 53% under the drought-stressed condition. They report the Canopy Productivity Index (CPI, total growth per unit leaf area) was also "significantly increased by elevated CO_2, and the increase in CPI became stronger as the level of drought stress increased." They conclude their study "confirmed the beneficial effects of elevated CO_2 on *C. intermedia* seedlings exposed to drought-stressed conditions," and these findings "suggest that elevated CO_2 may enhance drought avoidance and improved water relations, thus weakening the effect of drought stress on growth of

C. intermedia seedlings."

Soule and Knapp (2006) write, "two major environmental issues have arisen regarding the increasingly CO_2-rich world of the late 20th and early 21st centuries: climatic change, and plant responses to the environment," and they note, "while the implications of atmospheric CO_2 for potential climatic change have received the majority of attention, the potential role of atmospheric CO_2 fertilization in plant growth and subsequent ecosystem dynamics may be equally important." They studied ponderosa pine trees growing at eight sites in the Pacific Northwest of the United States to see how they may have responded to the increase in the atmosphere's CO_2 concentration that occurred after 1950.

The two geographers say they chose study sites that "fit several criteria designed to limit potential confounding influences associated with anthropogenic disturbance," with "a variety of climatic and topo-edaphic conditions, ranging from extremely water-limiting environments ... to areas where soil moisture should be a limiting factor for growth only during extreme drought years." They note all their study sites were located in areas "where ozone concentrations and nitrogen deposition are typically low."

At each of the eight sites, Soule and Knapp obtained core samples from about 40 mature trees that included "the potentially oldest trees on each site," so their results would indicate "the response of mature, naturally occurring ponderosa pine trees that germinated before anthropogenically elevated CO_2 levels, but where growth, particularly post-1950, has occurred under increasing and substantially higher atmospheric CO_2 concentrations." Utilizing meteorological evaluations of the Palmer Drought Severity Index, they compared ponderosa pine (*Pinus ponderosa* Laws. var. *ponderosa*) radial growth rates during matched wet and dry years pre- and post-1950.

The two researchers report finding a post-1950 radial growth enhancement "more pronounced during drought years compared with wet years," and they add, "the greatest response occurred at the most stressed site." They write, "the relative change in growth [was] upward at seven of our [eight] sites, ranging from 11 to 133%."

Soule and Knapp state their results, "showing that radial growth has increased in the post-1950s period ... while climatic conditions have generally been unchanged, suggest that nonclimatic driving forces are operative." In addition, "these radial growth responses are generally consistent with what has been

shown in long-term open-top chamber (Idso and Kimball, 2001) and FACE studies (Ainsworth and Long, 2005)." They state their findings suggest "elevated levels of atmospheric CO_2 are acting as a driving force for increased radial growth of ponderosa pine, but that the overall influence of this effect may be enhanced, reduced or obviated by site-specific conditions."

Soule and Knapp recount how they "hypothesized that ponderosa pine ... would respond to gradual increases in atmospheric CO_2 over the past 50 years, and that these effects would be most apparent during drought stress and on environmentally harsh sites," and in the following sentence they state their results "support these hypotheses." They conclude it is likely "an atmospheric CO_2-driven growth-enhancement effect exists for ponderosa pine growing under specific natural conditions in the [USA's] interior Pacific Northwest."

Wang *et al*. (2006) conducted a similar study, seeking to ascertain how the historical increase in atmospheric CO_2 concentration had affected the growth of trees in the real world rather than experimental settings. They examined ring-width development in cohorts of young and old white spruce (*Picea glauca*) trees in a mixed grass-prairie ecosystem in southwestern Manitoba, Canada, where a 1997 wildfire killed most of the older trees growing in high-density spruce islands, but where younger trees slightly removed from the islands were not affected by the flames. "Within each of a total of 24 burned islands," the three researchers write, "the largest dominant tree (dead) was cut down and a disc was then sampled from the stump height," and "adjacent to each sampled island, a smaller, younger tree (live) was also cut down, and a disc was sampled from the stump height."

After removing size-, age-, and climate-related trends in radial growth from the ring-width histories of the trees, Wang *et al*. plotted the residuals as functions of time for the 30-year periods for which both the old and young trees would have been approximately the same age: 1900–1929 for the old trees and 1970–1999 for the young trees. During the first of these periods, the atmosphere's CO_2 concentration averaged 299 ppm, and during the second it averaged 346 ppm. The mean rate-of-rise of the atmosphere's CO_2 concentration was 0.37 ppm/year for the first period and 1.43 ppm/year for the second.

In comparison to the 1900–1929 period, the slope of the linear regression describing the rate-of-growth of the ring-width residuals for the 1970–1999 period

(when the air's CO_2 concentration was 15% greater and its rate-of-rise was 285% greater) was more than twice the linear regression describing the rate-of-growth of the ring-width residuals for the 1900–1929 period. As the researchers observe, these results show "at the same developmental stage, a greater growth response occurred in the late period when atmospheric CO_2 concentration and the rate of atmospheric CO_2 increase were both relatively high," and "these results are consistent with expectations for CO_2-fertilization effects." They write, "the response of the studied young trees can be taken as strong circumstantial evidence for the atmospheric CO_2-fertilization effect."

Wang *et al.* also learned "postdrought growth response was much stronger for young trees (1970–1999) compared with old trees at the same development stage (1900–1929)." They add, "higher atmospheric CO_2 concentration in the period from 1970–1999 may have helped white spruce recover from severe drought." Similarly, young trees showed a weaker relationship to precipitation than did old trees, noting "more CO_2 would lead to greater water-use efficiency, which may be dampening the precipitation signal in young trees." Wang *et al.*'s unique study provides an exciting real-world example of the benefits the historical rise in the air's CO_2 content likely has conferred on long-lived woody species.

Davi *et al.* (2006) used a meteorological model following "a moderate CO_2 emission scenario" (B2 of IPCC) to calculate a 1960–2100 average temperature increase of 3.1°C and a mean summer rainfall decrease of 27%, which they used as input to a physiologically based multilayer process-based ecosystem productivity model (which contained a carbon allocation sub-model coupled with a soil model) to evaluate net productivity changes of six French forest ecosystems representative of oceanic, continental, and Mediterranean climates dominated, respectively, by deciduous species (*Fagus sylvatica*, *Quercus robur*), coniferous species (*Pinus pinaster*, *Pinus sylvestris*), and sclerophyllous evergreen species (*Quercus ilex*). These ecosystems, they write, "are representative of a significant proportion of forests in western Europe."

"By comparing runs with and without CO_2 effects," according to the researchers, they found "CO_2 fertilization is responsible from 1960 to 2100 for an NEP [net ecosystem productivity] enhancement of about 427 g(C) on average for all sites (= 3.05 g(C) m^{-2} year^{-1})," and "the CO_2 fertilization effect" turns a

warming- and drying-induced "decrease of NEP into an increase." In addition, they report, "no saturation of this effect on NEP is found because the differences between the simulations with and without CO_2 fertilization continuously increase with time." Consequently, the real-world physiological effects of atmospheric CO_2 enrichment included in the ecosystem productivity model employed by Davi *et al.* are able to more than compensate for the deleterious effects of the dramatic climate-change scenario on the productivity of major European forests.

Pardos *et al.* (2006) grew seedlings of cork oak (*Quercus suber* L., which they describe as "a typical Mediterranean species") germinated from acorns they collected from trees near Toledo, Spain, and maintained for five months, one per each 3-L pot filled with a mixture of fine sand and peat. The seedlings were maintained at either high (83%) or low (32–34%) growing medium moisture, under either high (600 μmol m^{-2} s^{-1}) or low (60 μmol m^{-2} s^{-1}) light intensity, in growth chambers maintained at either ambient (360 ppm) or elevated (700 ppm) atmospheric CO_2 concentrations. The four Spanish researchers state "elevated CO_2 caused the cork oak seedlings to improve their performance in dry and high light environments to a greater extent than under well-irrigated and low-light conditions, thus ameliorating the effects of soil water stress and high light loads on growth." Consequently, and because they assume these latter two stressful conditions are what "global change is likely to produce in the Mediterranean basin in the next decades," the rise in the air's CO_2 concentration should help the cork oak species deal successfully with those stresses, if and when they occur.

Saleska *et al.* (2007) note "large-scale numerical models that simulate the interactions between changing global climate and terrestrial vegetation predict substantial carbon loss from tropical ecosystems, including the drought-induced collapse of the Amazon forest and conversion to savanna." They used Terra satellite data—Enhanced Vegetation Index (EVI) derived from the Moderate Resolution Imaging Spectroradiometer (MODIS)—to determine whether the widespread Amazon drought of 2005, which peaked during the dry season onset (July–September), did indeed reduce whole-canopy forest photosynthesis as predicted, which they said "should have been especially observable during this period, when anomalous interannual drought coincided with the already seasonally low precipitation."

Strongly contradicting the model predictions, the

four researchers found intact forest "greenness" in the region was "dominated by a significant increase (P<0.0001), not a decline." They say the trees of the Amazon forest may be utilizing deep roots to "access and sustain" water availability during drought. Another possibility is the historical increase in the air's CO_2 content has significantly enhanced the trees' water use efficiency, enabling them to produce considerably more biomass per unit of water transpired and thereby conserve water. And yet another possibility is the phenomenon described in Soule and Knapp (2006), Wang *et al*. (2006), Davi *et al*. (2006), and Pardos *et al*. (2006), discussed above.

Huang *et al*. (2007) compared, synthesized, and evaluated the scientific literature describing atmospheric CO_2 enrichment experiments conducted on trees and empirical tree-ring studies designed to ascertain whether the growth-promoting effects of rising atmospheric CO_2 concentrations occur in natural forests. They found numerous CO_2-enrichment experiments have "demonstrated significantly positive physiological and growth responses of trees to CO_2, providing strong evidence to support the direct CO_2 fertilization effect (increased photosynthesis, water use efficiency, above- and below-ground growth) and thus allowing prediction of which ecosystems might be most responsive to CO_2." They conclude the latter will be "warm, moderately drought-stressed ecosystems with an ample nitrogen supply," because "drought-stressed trees could benefit from increased water use efficiency to enhance growth." They also note tree-ring studies on the cold and arid Tibetan Plateau "showed significant growth enhancements as well as increased water use efficiency (24.7% and 33.6% for each species, respectively) in Qilian juniper and Qinghai spruce since the 1850s," citing Zhang *et al*. (2003), Shao *et al*. (2005), Liang *et al*. (2006), Huang and Zhang (2007), and Zhang and Qiu (2007).

Wyckoff and Bowers (2010) note, "with continued increases in global greenhouse gas emissions, climate models predict that, by the end of the 21st century, Minnesota [USA] summer temperature will increase by 4–9°C and summer precipitation will slightly decrease," citing Kling *et al*. (2003) and Christensen *et al*. (2007). They state certain "forest models and extrapolations from the paleoecological record suggest that, in response to increased temperature and/or drought, forests may retreat to the extreme north-eastern parts of the state," citing Pastor and Post (1998), Hamilton and Johnson (2002), and Galatowitsch *et al*. (2009). Working with bur oak

(*Quercus macrocarpa*) trees, Wyckoff and Bowers explored the likelihood of this scenario by: "(i) using tree rings to establish the relationship between drought and *Q. macrocarpa* growth for three sites along Minnesota's prairie-forest border, (ii) calculating the current relationship between growth and mortality for adult *Q. macrocarpa* and (iii) using the distributions of current growth rates for *Q. macrocarpa* to predict the susceptibility of current populations to droughts of varying strength." In addition, they looked for "temporal trends in the correlation between *Q. macrocarpa* growth and climate, hypothesizing that increases in CO_2 may lead to weaker relationships between drought and tree growth over time," because atmospheric CO_2 enrichment typically leads to increases in plant water use efficiency, which generally makes them less susceptible to the deleterious impact of drought on growth.

The two University of Minnesota researchers report "the sensitivity of annual growth rates to drought has steadily declined over time as evidenced by increasing growth residuals and higher growth rates for a given PDSI [Palmer Drought Severity Index] value after 1950 [when the atmosphere's CO_2 concentration rose by 57 ppm from 1950 to 2000] compared with the first half of the century [when the CO_2 increase was only 10 ppm]." They state "for *Q. macrocarpa*, declining sensitivity of growth to drought translates into lower predicted mortality rates at all sites," and at one such site, "declining moisture sensitivity yields a 49% lower predicted mortality from a severe drought (PDSI = -8, on a par with the worst 1930s 'American Dust Bowl' droughts)." Wyckoff and Bowers conclude "the decreasing drought sensitivity of established trees may act as a buffer and delay the movement of the prairie-forest ecotone for many decades even in the face of climate change."

Noting climate models "consistently project significant increases in temperature and decreases in precipitation in the Mediterranean basin," Keenan *et al*. (2011) report these changes may have a large impact on current Mediterranean forests and the related ecosystem services they provide. They note niche-based models—also known as bioclimatic envelope models or habitat models—are the most commonly used method for predicting potential species distribution responses to future climatic changes. These models typically predict significant negative consequences for terrestrial plants and animals in the face of continued increases in

atmospheric CO_2 concentrations.

Keenan *et al.* say they preferred process-based models, which describe eco-physiological processes ranging from purely empirical relationships to mechanistic descriptions based on physical laws. These models—supported by experiments and growth and yield surveys—"suggest that global warming will have a positive impact on forest productivity (van der Meer *et al.*, 2002; Nigh *et al.*, 2004; Norby and Luo, 2004; Briceño-Elizondo *et al.*, 2006; Gaucharel *et al.*, 2008), due to the direct fertilization effect of increased CO_2 and indirect effects such as lengthening of the growing period."

To demonstrate the difference in results obtained by these two approaches to forecasting, the five researchers assessed and compared the projections of each when applied to stands of three common forest species (*Quercus ilex*, *Pinus halepensis,* and *Pinus sylvestris*) with widely contrasting distributions in continental Spain. This procedure revealed, they write, "CO_2 fertilization through projected increased atmospheric CO_2 concentrations is shown to increase forest productivity in the mechanistic process-based model (despite increased drought stress) by up to three times the non-CO_2 fertilization scenario by the period 2050–2080, which is in stark contrast to projections of reduced habitat suitability from the niche-based models by the same period."

Thus the Spanish and U.S. scientists write, "previous reports of species decline in continental Spain (e.g. Benito-Garzon *et al.*, 2008) may be overestimated due to two reasons: the use of only one predictive niche-based model, and the failure to account for possible effects of CO_2 fertilization." They add, "similar studies in other regions, which do not consider these two aspects, are also potentially overestimating species decline due to climate change." They note, "niche-based model results also likely overestimate the decline in [habitat] suitability," and they therefore conclude "an organism's niche must be modeled mechanistically if we are to fully explain distribution limits," citing Kearney (2006).

Osorio *et al.* (2011) write, "water deficits and high temperature are major abiotic stress factors restricting plant growth and productivity in many regions," and "the impact of climate change on temperature and rainfall patterns is of great importance in determining the future response of tree crops to new environmental conditions." They studied the Carob or St. John's tree (*Ceratonia siliqua*), which grows in the Mediterranean, where they

contend water stress will be the most important factor limiting plant growth throughout the remainder of this century. They investigated the impacts of drought and high-temperature stresses on photosynthesis, energy partitioning, and membrane lipids, as well as the potential ability of Carob trees to attenuate oxidative damage, in young seedlings growing in controlled-environment chambers. They rooted the plants in 3-dm^3 pots filled with a 2:1 mixture of a fertilized substrate and natural soil and maintained them under two thermal regimes—low and high temperature (LT: 25/18°C; HT: 32/21°C)—and three soil water conditions (control, water stress, and rewetting), monitoring numerous physiological and biochemical plant properties and processes.

Osorio *et al.* report the decrease in net photosynthesis (*P*N) caused by drought was 33% in the LT chamber and 84% in the HT chamber. They say "the negative effects of soil drying on *P*N and stomatal conductance of HT plants were no longer detected 36 hours following rewatering." The five Portuguese scientists remark, "although *C. siliqua* seedlings exhibit clear signs of oxidative stress under drought and high temperature, they retain a remarkable ability to quickly restore normal physiological activity on rehydration, which let us believe that they can satisfactorily deal with predicted climate warming and increased soil drying in the Mediterranean area."

Soule and Knapp (2011) write, "in 2008, atmospheric CO_2 concentrations from the Mauna Loa, Hawaii, Observatory records exceeded 385 ppm, representing a 22% increase since 1959." They note, "as CO_2 has increased, most tree species have been able to use water more efficiently" as their "leaf stomatal apertures narrow during photosynthesis," resulting in "less transpirational water loss per biomass gained." The parameter representing this phenomenon is referred to as intrinsic water-use efficiency (iWUE), defined as the ratio of net CO_2 assimilation to stomatal conductance, and it has been documented, they write, "for various tree species in many parts of the world," citing Bert *et al.* (1997), Feng (1999), Tang *et al.* (1999), Arneth *et al.* (2002), Saurer *et al.* (2004), Waterhouse *et al.* (2004), and Liu *et al.* (2007).

They examined changes in, and relationships between, radial growth rates and the iWUE of ponderosa pine (*Pinus ponderosa*) trees, climate, and atmospheric CO_2 concentration in the western United States since the mid-nineteenth century, developing tree-ring chronologies for eight sites in three climate

regions, and using carbon isotope data to calculate pentadal values of iWUE. They examined relationships among radial growth, climate, iWUE, and CO_2 via correlation and regression analyses.

Soule and Knapp report finding significant upward trends in iWUE at all sites, and they state "despite an absence of climate changes that would favor growth," upward radial growth trends occurred at five sites. The highest iWUE values "were recorded in the last pentad at six of eight sites and follow a positive quadratic progression at all sites, suggesting that future increases in iWUE are likely for ponderosa pine within our study regions as CO_2 levels increase." They also found "significant improvements in radial growth rates during drought years after 1950," when the air's CO_2 content rose at an accelerating rate.

The two researchers say their findings suggest "increased iWUE associated with rising CO_2 can positively impact tree growth rates in the western United States and are thus an evolving component of forest ecosystem processes." They conclude, "if potential climate changes lead to increasing aridity in the western United States, additional increases in iWUE associated with future increases in CO_2 might ameliorate growth declines associated with drought conditions."

The peer-reviewed scientific studies described in this section support the earlier conclusions of Idso and Idso (1994), who found the rise in the air's CO_2 content likely will lead to substantial increases in photosynthetic rates and biomass production in Earth's many woody species, even under stressful conditions imposed by suboptimal soil moisture.

3.16 Weeds

Some researchers suggest weeds will become more aggressive as the air's CO$_2$ content climbs, making them greater threats to the wellbeing of natural ecosystems and farming operations. The subsections below investigate the merits of this claim regarding non-parasitic and parasitic weeds.

3.16.1 Non-Parasitic

- Non-parasitic weeds likely will be no more competitive in a high-CO_2 environment than they are today, and many could become less competitive. Atmospheric CO_2 enrichment may provide non-weeds with greater protection against weed-induced decreases in productivity, thereby increasing the competitiveness of non-weeds over weeds. And although atmospheric CO_2 enrichment increases the growth of many weeds, the fraction helped is probably not as large as non-weeds.

3.16.1.1 Competitiveness

- Non-parasitic weeds likely will be no more competitive in a high-CO_2 environment than they are today, and many could become less competitive.

Wayne *et al*. (1999) grew a common agricultural weed (field mustard) at six densities in pots exposed to atmospheric CO_2 concentrations of 350 and 700 ppm, sequentially harvesting them during the growing season. Early in stand development, the extra CO_2 increased above-ground biomass in a density-dependent manner; with the greatest stimulation (141%) occurring at the lowest weed density (20 plants per square meter) and the smallest stimulation (59%) occurring at the highest weed density (652 plants per square meter), the authors report. As the stands matured, the density-dependence of the growth response disappeared, and the CO_2-enriched weeds exhibited an average above-ground biomass 34% greater than those grown in ambient air. That response is similar to those of most herbaceous plants (a 30 to 50% increase for a doubling of the air's CO_2 content) and less than those of most woody species (50% and up). Consequently, in currently farmed or abandoned agricultural fields, as well as in regenerating forests, it is unlikely field mustard plants will benefit relative to other plants from Earth's rising atmospheric CO_2 concentration.

Caporn *et al*. (1999) grew bracken—a serious weed and potential threat to human health in the United Kingdom and elsewhere—for 19 months in controlled-environment chambers maintained at atmospheric CO_2 concentrations of 370 and 570 ppm and normal or high levels of fertilization. They found the extra 200 ppm of CO_2 increased rates of net photosynthesis by 30 to 70%, depending on soil fertility and time of year. The elevated CO_2 did not increase total plant biomass, nor did it increase the biomass of any plant organs, including rhizomes, roots, and fronds. The only significant effect of elevated CO_2 on plant growth was observed in the normal nutrient regime, where it reduced average frond area.

Gavazzi *et al*. (2000) grew one-year-old loblolly pine seedlings for four months in pots seeded with a variety of C_3 and C_4 weeds and maintained at adequate and inadequate levels of soil moisture in growth chambers maintained at atmospheric CO_2 concentrations of 360 and 660 ppm. The elevated CO_2 increased pine seedling biomass by 22%, decreased total weed biomass by 22%, and reduced the percentage of weed biomass composed of C_4 species from 53 to 35%. The additional CO_2 induced an increase in root-to-shoot ratio under water-stressed conditions in the pine seedlings, which Gavazzi *et al*. opine could "contribute to an improved ability of loblolly pine to compete against weeds on dry sites under elevated CO_2 levels."

Ziska (2003) grew Canada thistle, "the most frequently listed noxious weed species in surveys of the continental United States and southern Canada," in pots watered to the drip point daily with one of three complete nutrient solutions that differed only in nitrogen (N) concentration (3.0, 6.0, or 14.5 mM) in controlled-environment chambers maintained at 287 and 373 ppm CO_2 from seeding until flowering, which occurred at 77 days after seeding (DAS). He reports, "N supply did not affect the relative response to CO_2 for any measured vegetative parameter up to 77 DAS." Averaged across the three nitrogen treatments, the 86 ppm increase in atmospheric CO_2 concentration increased total plant biomass by 65.5%, which for the full 100 ppm CO_2 increase experienced over the course of the Industrial Revolution (initial value ~275 ppm, current value ~375 ppm) translates into an approximate 76% biomass increase.

To assess the significance of this CO_2-induced increase in weed biomass, it is necessary to compare it with what would have been expected for crops with which Canada thistle competes. Mayeux *et al*. (1997) obtained data indicating the 100-ppm increase in atmospheric CO_2 concentration experienced over the course of the Industrial Revolution should have produced yield increases of 70 and 74% in the two wheat varieties they studied when grown under well-watered conditions comparable to those studied by Ziska. In addition, based on the voluminous data Idso

and Idso (2000) summarized, we can scale these results to derive comparable CO_2-induced growth enhancements of 84% for other C_3 cereals, 74% for legumes, and 80% for root and tuber crops. Thus the CO_2-induced growth enhancement likely experienced by Canada thistle over the course of the Industrial Revolution was not much different from the growth enhancements of most of the crops with which it competes, suggesting the competitive ability of this noxious weed against these crops has remained largely unaffected by the historical increase in the air's CO_2 content.

Ziska and Goins (2006) grew genetically modified (Round-up Ready) soybean plants in the field in aluminum chambers maintained at ambient and ambient + 250 ppm atmospheric CO_2 concentrations for two full growing seasons under conditions allowing a variety of different weed densities to develop among the soybeans. The elevated CO_2 conditions advanced soybean seed yields by 25, 33, 50, 90, and 250% when chamber weed biomass densities were 0, 200, 400, 600, and 800 gm^{-2}, respectively. Soybean seed yield in the ambient-air treatment fell to a value of zero at a weed density of approximately 920 gm^{-2}, whereas calculations reveal it would not drop that far in the CO_2-enriched treatment until a weed density of approximately 1,250 gm^{-2} was reached. Consequently, the atmospheric CO_2 enrichment of this study boosted crop yield by an increasing percentage as the stress of the expanding weed population grew larger, benefiting the soybean plants most when they needed it most. This phenomenon also has been shown to be true of other environmental stressors, such as plant diseases, lack of water, and high temperatures.

Kao-Kniffin and Balser (2007) grew invasive reed canary grass from seed for four months in well-watered mesocosms located in greenhouses maintained at atmospheric CO_2 concentrations of either 365 or 600 ppm in soils of either low or high nitrogen (N) supply (5 mg N l^{-1} or 30 mg N l^{-1}) under conditions where the invading species was either dominant (high invasion: >90% cover) or subdominant (low invasion: <50% cover), and where the remaining surface portions of the mesocosms were covered with native graminoids (grasses, sedges, and bulrushes) and native forbs also grown from seed. Elevating the air's CO_2 content increased belowground biomass only in the plant communities moderately invaded by reed canary grass, and the only plants to show a significant increase in aboveground biomass were the native graminoids in the moderately invaded low N treatment. The scientists conclude, "when CO_2 concentrations rise in the future, wetland plant communities comprised of native graminoids may be better able to hinder reed canary grass invasion, particularly under low N environments."

Williams *et al.* (2007) studied the impacts of a 170 ppm increase in atmospheric CO_2 concentration and a 2°C rise in air temperature at the Tasmanian free-air CO_2 enrichment (TasFACE) facility, located in a native lowland grassland in the southern midlands region of Tasmania, Australia. Between spring 2003 and summer 2006, they documented annual seed production, seedling emergence, seedling survival, and adult survival of four abundant perennial species, including the two most dominant invading weeds: *Hypochaeris radicata* L. and *Leontodon taraxacoides* (Vill.) Merat, members of the Asteraceae family. They found no significant CO_2-induced differences in the population growth rates of either weed species, but the population growth rates of both "were substantially reduced by warming." The six researchers conclude "global warming may be a more important determinant of the success of invasive species than CO_2 concentration," and both the invading weed species they studied "are likely to be excluded from the grassland community by increasing temperatures."

McPeek and Wang (2007) collected seeds from a single dandelion plant in Speedway, Indiana (USA), which they allowed to sprout and grow until reaching reproductive maturity in pots placed in each of two controlled-environment chambers, one continually flushed with ambient air of 370 ppm CO_2 and the other maintained at an elevated atmospheric CO_2 concentration of 730 ppm. After harvesting the plants and measuring numerous parameters of reproductive fitness, the two scientists conducted a second experiment in which they measured various parameters of the germination of the seeds produced in the two CO_2 treatments, along with the physical characteristics of the second-generation plants 35 days after planting.

McPeek and Wang state the dandelion plants "produced 83% more inflorescences and 32% more achenes, i.e., single-seed fruits, per plant at elevated than at ambient CO_2," and the "seeds from elevated CO_2-grown plants were significantly heavier and had a higher germination percentage, leading to larger seedlings and earlier establishment in the subsequent generation." Furthermore, "achenes from plants grown at elevated CO_2 had characteristics, such as higher stalks at seed maturity, longer beaks, and

larger pappi, which would increase the distance of seed dispersal by wind."

The two researchers conclude "dandelion can potentially become more widespread and noxious as atmospheric CO_2 continues to rise."

3.16.1.2 Biodiversity Impacts

- Rising atmospheric CO_2 concentrations will not favor the growth of non-parasitic weeds over crops and native plants. A CO_2 increase may provide the latter with greater protection against weed-induced decreases in productivity, thereby increasing the competitiveness of non-weeds over weeds.

Elevated CO_2 typically stimulates the growth of nearly all plant species in monoculture, including weeds. Consequently, it is important to determine how future increases in the air's CO_2 content may influence relationships between weeds and non-weeds when they grow competitively in mixed-species stands.

Dukes (2002) grew model serpentine grasslands common to California (USA) in competition with the invasive forb *Centaurea solstitialis* at atmospheric CO_2 concentrations of 350 and 700 ppm for one year. They found elevated CO_2 increased the biomass proportion of this weedy species in the community by 1.2%, while total community biomass increased by 28%. Similarly, Gavazzi *et al*. (2000) grew loblolly pine seedlings for four months in competition with C_3 and C_4 weeds at atmospheric CO_2 concentrations of 260 and 660 ppm, reporting elevated CO_2 increased pine biomass by 22% while eliciting no response from either type of weed. In a study of pasture ecosystems near Montreal, Canada, Taylor and Potvin (1997) determined elevated CO_2 concentrations did not influence the number of native species returning after their removal (to simulate disturbance), even in the face of the introduced presence of the C_3 weed *Chenopodium album*, which normally competes quite effectively with several slower-growing crops in ambient air. Atmospheric CO_2 enrichment did not impact the growth of this weed in any measurable way.

Ziska *et al*. (1999) studied the C_3 weed *C. album*, along with the C_4 weed *Amaranthus retroflexus*, in glasshouses maintained at atmospheric CO_2 concentrations of 360 and 720 ppm. Elevated CO_2 significantly increased the photosynthetic rate and total dry weight of the C_3 weed but had no effect on the C_4 weed. They report the growth response of the C_3 weed to a doubling of the air's CO_2 content was approximately 51%, about the same as the average 52% growth response tabulated by Idso (1992) and by Poorter (1993) for rapidly growing wild C_3 species (54%), suggesting a CO_2-enriched environment does not cause enhanced dominance of the C_3 weed over

other C_3 plants.

Wayne *et al*. (1999) studied another agricultural weed, field mustard (*Brassica kaber*), which they sowed in pots at six densities, placed in atmospheric CO_2 concentrations of 350 and 700 ppm, and sequentially harvested during the growing season. Early in stand development, elevated CO_2 increased aboveground weed biomass in a density-dependent manner, with the greatest stimulation (141%) occurring at the lowest density (20 plants per square meter) and the smallest stimulation (59%) occurring at the highest density (652 plants per square meter). As these stands matured, the density-dependence of the CO_2-induced growth response disappeared, and CO_2-enriched plants exhibited an average above-ground biomass 34% greater than ambient-grown plants across a broad range of plant densities. This final growth stimulation was similar to those of most other herbaceous plants exposed to atmospheric CO_2 enrichment (30 to 50% biomass increases for a doubling of the air's CO_2 content), demonstrating atmospheric CO_2 enrichment confers no undue advantage on weeds at the expense of other plants.

In a study of a weed that affects both plants and animals, Caporn *et al*. (1999) examined bracken (*Pteridium aquilinum*), which poses a serious weed problem and potential threat to human health in the United Kingdom and other regions, growing specimens for 19 months in controlled-environment chambers maintained at atmospheric CO_2 concentrations of 370 and 570 ppm and normal or high levels of soil fertility. The high-CO_2 treatment consistently increased rates of net photosynthesis by 30 to 70%, depending on soil fertility and time of year. Elevated CO_2 did not increase total plant dry mass or the dry mass of any plant organ, including rhizomes, roots, and fronds. The only significant effect of elevated CO_2 on bracken growth was observed in the normal nutrient regime, where elevated CO_2 reduced mean frond area.

These studies suggest atmospheric CO_2 enrichment will not favor the growth of non-parasitic weeds over crops and native plants.

3.16.1.3 Miscellaneous Weeds

- Atmospheric CO_2 enrichment tends to increase the growth of many weeds, but possibly not by quite as great a percentage as it does for non-weeds.

Lewis *et al*. (2002) grew the common cocklebur (*Xanthium strumarium* L.) in controlled-environment growth chambers maintained at atmospheric CO_2 concentrations of 365 and 730 ppm for 70 days post-emergence. During the weed's vegetative growth phase, the photosynthetic rates of the CO_2-enriched plants were 30% greater than those of the plants growing in ambient air. During the flowering period that ensued shortly thereafter, this stimulation was reduced to 10%, after which it rose to 20% during the weed's fruiting period.

Gibeaut *et al*. (2001) grew the common weed *Arabidopsis thaliana* for seven weeks in controlled-environment chambers maintained at atmospheric CO_2 concentrations of 360 and 1,000 ppm, finding the 640 ppm increase in the air's CO_2 concentration increased the relative growth rate of the plants by about 20% during the first three weeks of the study. The extra CO_2 also increased the activity of the enzyme UDP-glucose dehydrogenase (an important enzyme involved in cell wall biosynthesis) by approximately 25%. Thereafter, relative growth rates were the same in both CO_2 treatments. Nevertheless, by the end of the study the CO_2-enriched plants had produced 2.3 times more biomass than the ambient-grown plants.

Ziska (2002) grew Canadian thistle (*Cirsium arvense* L. Scop.) plants in controlled-environment chambers maintained at atmospheric CO_2 concentrations of 280, 380, and 720 ppm for about two months. They determined the first increment of extra CO_2 enhanced photosynthesis rates and total plant biomass production by 45 and 126%, respectively, and the second CO_2 increment enhanced these two parameters by 49 and 69%.

Leishman *et al*. (1999) grew four weedy C_3 plants common to European grasslands (*Cardamine hirsute*, *Spergula arvensis*, *Senecio vulgaris*, and *Poa annua*) from seed to senescence in glasshouses maintained at atmospheric CO_2 concentrations of 350 and 550 ppm at two light intensities: full light and 67% of full light. The extra 200 ppm of CO_2 did not significantly impact vegetative growth in three of the species. For *Spergula arvensis*, it increased maximum leaf length by an average of 15%, regardless of light treatment, and total dry weight by 20 and 68% at full and reduced light levels, respectively. It significantly enhanced reproductive success in only one of the species, increasing the number of seeds in *Poa annua* by 50 and 26% at full and reduced light levels, respectively.

Nagashima *et al*. (2003) established even-aged stands of the summer annual *Chenopodium album* (a weed commonly found in open habitats, such as abandoned fields and flood plains) at ambient and twice-ambient atmospheric CO_2 concentrations and low and high levels of soil nutrient availability in open-top chambers in the experimental garden of Tohoku University, Sendai, Japan. They monitored the growth of individual plants every week until flowering. At the conclusion of the experiment, they could detect no significant effect of elevated CO_2 on aboveground biomass in the low nutrient regime; in the high nutrient regime, the extra CO_2 increased aboveground biomass by 50%. The CO_2-induced enhancement of growth in the high nutrient regime gradually waned and ultimately disappeared altogether in smaller subordinate individuals but continued in larger dominants throughout the experiment.

Ziska and Bunce (1999) grew four C_4 plants in controlled-environment chambers maintained continuously at atmospheric CO_2 concentrations of 350 and 700 ppm or at a nocturnal CO_2 concentration of 700 ppm and 350 ppm during the day for approximately three weeks. They found continuous CO_2 enrichment caused a significant increase in photosynthesis (+13%) and total dry mass (+21%) in only one of the four species, *Amaranthus retroflexus*. Nocturnal CO_2 enrichment provided no significant effects in this species, indicating the CO_2-induced increase in biomass was not facilitated by a reduction in dark respiration rate. Plants exposed to continuous CO_2 enrichment did not increase their biomass due to improved internal water balance, as leaf water potentials were not significantly different among plants of any CO_2 treatment.

Ziska *et al*. (1999) grew broad-leaved C_3 (*Chenopodium album*) and C_4 (*Amaranthus retroflexus*) weeds in glasshouses maintained at atmospheric CO_2 concentrations of 360 and 720 ppm. Both young and mature plants of each species were sprayed with one-tenth and full-strength solutions of the chemical glyphosate ("Roundup"). The elevated CO_2 significantly increased the photosynthetic rate and total dry weight (by 51%) of the unsprayed C_3 weed, regardless of maturity stage, but it had no effect on these parameters in the case of the C_4 weed. Spraying both young and mature *A. retroflexus* plants with full-strength herbicide resulted in their death, regardless of atmospheric CO_2 concentration; spraying *C. album* plants with full-strength glyphosate severely reduced, but did not eliminate, growth in the elevated-CO_2 air, whereas chemically treated plants died in ambient CO_2 air. Consequently, farmers who use glyphosate to control *A. retroflexus* should not have to modify their current chemical practices in the future, but better control of *C. album* may require application of glyphosate earlier in the season when the weeds are smaller or, if applied later, at higher concentrations, as elevated CO_2 slightly increases the glyphosate tolerance of this particular C_3 weed.

These studies suggest although atmospheric CO_2 enrichment tends to increase the growth of many weeds, it may not do so by as great a percentage as for non-weeds. (See, for example, the results of the

many non-weed plants listed in Tables 1.1.1 and 1.1.2 in Appendices 3 and 4.)

3.16.2 Parasitic

- Rising atmospheric CO_2 concentrations appear to reduce the negative effects of parasitic weed infection so infected host plants continue to exhibit positive (but somewhat reduced) growth responses to elevated CO_2.

Parasitic plants obtain energy, water, and nutrients from their host plants and cause widespread reductions in harvestable yields. This brief section examines how increasing atmospheric CO_2 concentrations may impact the growth of parasitic weeds and the relationships that exist between them and their host plants.

Dale and Press (1999) infected white clover (*Trifolium repens*) plants with *Orobanche minor*, a parasitic weed that primarily infects leguminous crops in the United Kingdom and the Middle East, and exposed them to atmospheric CO_2 concentrations of either 360 or 550 ppm for 75 days in controlled-environment growth cabinets. The elevated CO_2 had no effect on the total biomass of parasite per host plant, nor did it affect the number of parasites per host plant or the time to parasitic attachment to host roots. While infected host plants growing in ambient air produced 47% less biomass than uninfected plants growing in ambient air, infected plants growing at 550 ppm CO_2 exhibited final dry weights only 20% less than those of uninfected plants growing in the CO_2-enriched air, indicating a significant CO_2-induced partial alleviation of parasite-induced biomass reductions in the white clover host plants.

Watling and Press (1997) infected several C_4 sorghum plants with *Striga hermonthica* and *Striga asiatica* (parasitic C_3 weeds of the semi-arid tropics that infest many grain crops) and grew them, along with uninfected control plants, for approximately two months in controlled-environment cabinets maintained at atmospheric CO_2 concentrations of 350 and 700 ppm. In the absence of parasite infection, the extra 350 ppm of CO_2 increased sorghum biomass by approximately 36%. When infected with *S. hermonthica*, the sorghum plants grown at ambient and elevated CO_2 concentrations produced only 32 and 43% of the biomass displayed by their respective uninfected controls. Infection with *S. asiatica* was somewhat less stressful and led to host biomass production of about half that of uninfected controls in both ambient and CO_2-enriched air. Therefore, the doubling of the air's CO_2 content employed in this study increased sorghum biomass by 79% and 35% in the C_4 sorghum plants infected with *S. hermonthica* and *S. asiatica*, respectively.

Watling and Press (2000) grew upland rice (*Oryza sativa* L.) in pots in controlled-environment chambers maintained at 350 and 700 ppm CO_2 in either the presence or absence of the root parasite *S. hermonthica* for 80 days after sowing, after which they harvested and weighed the plants. In ambient air, the presence of the parasite reduced the biomass of the rice to only 35% of what it was in the absence of the parasite. In air enriched with CO_2 the presence of the parasite reduced the biomass of infected plants to 73% of what it was in the absence of the parasite.

These few observations suggest rising atmospheric CO_2 concentrations generally tend to reduce the negative effects of parasitic weed infection so

infected host plants continue to exhibit positive growth responses to elevated CO_2. It is likely host plants infected by parasitic weeds will fare better under higher atmospheric CO_2 conditions than they do currently.

    4.5.3 Temperature Induced
    4.5.4 Drought Induced

Key Findings

The key findings of this chapter are listed below.

- Rising atmospheric CO_2 and warming temperatures, both of which IPCC claims constitute a significant threat to the biosphere, benefited agriculture in the ancient past and in the twentieth century.

- Empirical studies suggest a future warming of the climate coupled with rising atmospheric CO_2 levels will boost global agricultural production and help meet the food needs of the planet's growing population.

- When model-based studies fully account for the growth-enhancing and water-conserving benefits of atmospheric CO_2 enrichment, they project significant gains for future agricultural production.

- The vigor of the terrestrial biosphere has been increasing with time, revealing a great greening of the planet that extends across the globe.

- Satellite-based analyses of net terrestrial primary productivity (NPP) reveal an increase of around 6–13% since the 1980s.

- There is no empirical evidence to support the model-based claim that future carbon uptake will

diminish on a global scale due to rising temperatures.

- Earth's land surfaces were a net *source* of CO_2-carbon to the atmosphere until about 1940. From 1940 onward, the terrestrial biosphere has become, in the mean, an increasingly greater *sink* for CO_2-carbon.

- Over the past 50 years, global carbon uptake has doubled from 2.4 ± 0.8 billion tons in 1960 to 5.0 ± 0.9 billion tons in 2010.

- The observed greening of the Earth has occurred in spite of the many real and imagined assaults on the planet's vegetation over this time period, including fires, disease, outbreaks of pests, deforestation, and climatic changes (primarily in temperature and precipitation).

- The atmosphere's rising CO_2 content—which IPCC considers to be the chief culprit behind its concerns about the future of the biosphere—is most likely the primary cause of the observed greening trends.

- In the future, plants should be able to adjust their physiology to accommodate a warming of the magnitude and rate of rise typically predicted by climate models to accompany the projected future increase in atmospheric CO_2 content.

- The rise in the air's CO_2 concentration and its anti-transpiration effect, which improves plant water-use efficiency, are enhancing and will continue to enhance the vegetative productivity of Africa.

- The rise of the air's CO_2 concentration and temperature to their highest values of the past century enhanced the terrestrial vegetative productivity of all parts of Asia, including deserts, forests, grasslands, and the Tibetan Plateau.

- Evergreen vegetation, woody plants, and other plant life have increased across Australia over the past 200 years as a result of CO_2 enrichment.

- Over the last two decades of the twentieth century, Europe as a whole became greener and much of it is seeing an increase in woodlands due to the recent rise in atmospheric CO_2, which has tended to offset the detrimental effects of climate change in the region.

- Opposite the forecasts promulgated by the models used by IPCC, land-based plants of the Arctic and near-Arctic regions of North America are thriving, thanks in large part to the ongoing rise in the atmosphere's CO_2 concentration and global warming.

- Late twentieth-century increases in air temperature and atmospheric CO_2 concentration did not negatively affect plant communities in the eastern United States. Rather, the temperature and CO_2 increases significantly enhanced local and regional productivity, and there is little reason to think such enhancements will not continue throughout the foreseeable future.

- The late twentieth-century rise in temperature and atmospheric CO_2 concentrations improved the productivity of plant communities in the central region of the United States, notwithstanding model-based concerns to the contrary.

- The late twentieth-century rise in temperature and atmospheric CO_2 improved the productivity of plant communities in the western region of the United States, notwithstanding model-based projections of unprecedented ecological disaster due to rising temperatures and drought.

- Warmer temperatures and higher CO_2 concentrations are resulting in net primary productivity increasing across tropical South America, overcoming the effects of deforestation, forest fires, and incursions by human civilization into natural areas.

- It is likely the greening of the planet will continue in the future, even if the largest temperature increases predicted by the models occur, because the optimum temperature for plant growth and development typically rises with increasing levels of atmospheric CO_2. This response, coupled with expected increases in plant photosynthetic rates from the rise in the air's CO_2 concentration, is more than enough to compensate for any temperature-induced plant stress caused by global warming.

- Real-world observations reveal plants have many ways of adjusting to changes in climate in addition to their ability to spread from places of rising warmth to cooler habitats, and these observations suggest the planet's current assemblage of plants

is likely to be around a good deal longer than many theoretical models have predicted.

- A major cause of biodiversity reductions is not rising atmospheric CO_2 concentrations, but instead the direct encroachment of man upon the world of nature. Anthropogenic global warming, to whatever extent it exists, is helping plants overcome these assaults and thrive despite the growing human presence.

- As good as things currently are for world agriculture, and as much better as they are expected to become as the atmospheric CO_2 content continues to rise, there may be additional substantial room for both natural selection and bioengineering to remove the constraints of low CO_2 adaptation in several important agricultural crops and thereby create novel genotypes able to exploit high CO_2 conditions to their—and our—advantage.

- The ongoing rise in atmospheric CO_2 content is likely exerting significant selection pressure on Earth's naturally occurring terrestrial plants, which should improve their performance in the face of various environmental stressors via the process of microevolution. Plants may be much better prepared than most scientists once thought to meet whatever climatic challenges, including global warming, the future may pose for them.

- Evidence continues to accumulate for substantial heritable variation of ecologically important plant traits, including root allocation, drought tolerance, and nutrient plasticity, which suggests rapid evolution based on epigenetic variation alone should be possible.

Introduction

A remarkable global phenomenon occurred throughout much of the twentieth century that the authors of IPCC's reports pretend never occurred despite hundreds of scholarly studies documenting its extent, causes, and consequences. The phenomenon is a gradual yet dramatic increase in biospheric productivity, or more simply, the greening of the Earth. According to IPCC's assumptions, theories, and models, this should not be occurring, indeed *cannot* be occurring. And yet, as this chapter will document, the evidence is overwhelming.

The aerial fertilization effect caused by the rise in

CO_2 following the last deglaciation, combined with its transpiration-reducing effect that in turn led to a large increase in the water use efficiencies of the world's major C_4 founder crops, was the global trigger that made human agriculture possible. By dramatically increasing the yields of the first crops, that natural rise in CO_2 made modern civilization possible. Far from being a crisis, it was a miracle.

Fast-forward to the modern era and we are witnessing a rise in CO_2 levels similar to what occurred some 22,000 to 7,000 years ago. Once again, agricultural production is increasing throughout the world and across all types of landscapes, including plants and areas where improvements in human cultivation techniques cannot explain the improvement. Could global warming be good? In China, home to a fifth of all of humanity, Liu *et al.* (2004) report "all of China would benefit from climate change in most scenarios." Julien *et al.* (2006) say of the last two decades of the twentieth century, "Europe as a whole has a tendency to greening," and much of it is "seeing an increase in its wood land proportion." Extensive research has found the benefits of global warming on agriculture are occurring globally, across Asia, North America, and South America.

Nor is there evidence this greening is soon to end. Ballantyne *et al.* (2012) conclude, "although present predictions indicate diminished C uptake by the land and oceans in the coming century, with potentially serious consequences for the global climate, as of 2010 there is no empirical evidence that C uptake has started to diminish on the global scale." Their results clearly indicate just the opposite appears to be the case, with global carbon uptake doubling over the past half-century. Their research refutes the hypothesis of Canadell *et al.* (2007) and Raupach *et al.* (2008), who claimed to have detected a decreasing trend in the efficiency of the planet's carbon sinks, and it vindicates the many studies revealing an increasing greening of planet Earth.

IPCC feigns ignorance of this reality. Its authors seem still to be in the thrall of two authors who, two decades ago, wrote CO_2-induced changes in global climate were expected to occur "too fast for evolutionary processes such as natural selection to keep pace," and this phenomenon "could substantially enhance the probability of extinction of numerous species" (Root and Schneider (1993)).This famous but unsubstantiated declaration has pervaded the publications of IPCC ever since … but it never has been proven correct. It is more likely to be incorrect.

This chapter begins, in Section 4.1, with a

discussion of how the rise in CO_2 levels boosted food production globally in the past and how models that include the fertilizing effects of CO_2 suggest a future warming of the climate coupled with rising CO_2 levels will boost future global agricultural production, helping to meet the food needs of the planet's growing population. Section 4.2 surveys the extensive literature on the greening of the Earth, first presenting global studies and then studies focusing on specific continents, and finally studies that ask whether rising temperatures could check or offset the greening trend.

Section 4.3 reviews evidence on the impact of the rise in CO_2 levels on biodiversity and finds that impact to be positive. Similarly, Section 4.4. looks at the impact of the rise in CO_2 levels on plant extinctions and finds CO_2 makes extinctions less likely to occur. Finally, Section 4.5 asks whether plants can in fact evolve fast enough to adapt to a world with higher levels of CO_2, higher temperatures, and more drought. The evidence is clear that many plant species can make significant adaptations to changes in their environment in just a few generations.

4.1 Agricultural and Food Production

According to IPCC, over the past century or so the atmosphere's temperature and CO_2 concentration have risen at rates (and to levels) not seen for millennia in the case of temperature and millions of years in the case of CO_2. Section 4.1.1 examines how the modern increase in temperature and CO_2 affected agriculture and food production in the past, and Section 4.1.2 provides an appraisal of how they might affect them in the future.

4.1.1 The Past

- Rising atmospheric CO_2 and warming temperatures, both of which IPCC claims constitute a significant threat to the biosphere, benefited agriculture in the ancient past and in the twentieth century.

According to Cunniff *et al.* (2008), "early agriculture was characterized by sets of primary domesticates or 'founder crops' that were adopted in several independent centers of origin," all at about the same time, and "this synchronicity suggests the involvement of a global trigger." Further noting Sage (1995) saw a causal link between this development and the rise in atmospheric CO_2 concentration that followed deglaciation (a jump from about 180 to 270 ppm), they hypothesized the aerial fertilization effect caused by the rise in CO_2 combined with its transpiration-reducing effect led to a large increase in the water use efficiencies of the world's major C_4 founder crops, and that this development was the global trigger that launched the agricultural enterprise.

To test this hypothesis, Cunniff *et al.* designed "a controlled environment experiment using five modern day representatives of wild C_4 crop progenitors, all 'founder crops' from a variety of independent centers." The five C_4 crops employed in their study were *Setaria viridis*, *Panicum miliaceum* var. *ruderale*, *Pennisetum violaceum*, *Sorghum arundinaceum*, and *Zea mays* subsp. *parviglumis*. They were grown individually in small pots filled with a 1:1 mix of washed sand and vermiculite for 40–50 days in growth chambers maintained at atmospheric CO_2 concentrations of either 180, 280, or 380 ppm, characteristic of glacial, post-glacial, and modern times, respectively.

Cunniff *et al.* report the "increase in CO_2 from glacial to postglacial levels [180 to 280 ppm] caused a significant gain in vegetative biomass of up to 40%," together with "a reduction in the transpiration rate via

decreases in stomatal conductance of ~35%," which led to "a 70% increase in water use efficiency, and a much greater productivity potential in water-limited conditions." The five researchers write, "these key physiological changes could have greatly enhanced the productivity of wild crop progenitors after deglaciation ... improving the productivity and survival of these wild C_4 crop progenitors in early agricultural systems." They further note "the lowered water requirements of C_4 crop progenitors under increased CO_2 would have been particularly beneficial in the arid climatic regions where these plants were domesticated."

Expanding on their work two years later, Cunniff et al. (2010) conducted a second set of experiments designed to further study the physiological and yield responses to glacial and post-glacial atmospheric CO_2 concentrations of modern representatives of the wild crop progenitors, but this time they included an analysis of C_3 and C_4 cereals. Once again, their experimental work was conducted in the laboratory in controlled-environment chambers maintained at atmospheric CO_2 concentrations of either 180 or 280 ppm. Cunniff et al. report "both the C_3 and C_4 species responded positively to rising CO_2 from the glacial to post-glacial level," with vegetative biomass near-doubling and yield rising by 50% in the C_3 species, consistent with the findings of Polley et al. (1992) and Dippery et al. (1995), and with a 10–15% yield enhancement under well-watered conditions in the C_4 species, consistent with the findings of Polley et al. (1996), Ziska and Bunce (1997), and Ward et al. (1999). In the case of the C_4 species, which typically are found in semi-arid environments, they discovered the transpiration-reducing effect of atmospheric CO_2 enrichment had a considerably larger positive impact on plant growth and yield. They write, "this stronger response of photosynthesis to soil drying in the C_4 species could represent an important route for rising CO_2 to stimulate biomass accumulation in a semi-arid environment," citing Cunniff (2009).

Cunniff et al. state the data described in their paper "provide experimental support for Sage's CO_2 limitation hypothesis, showing that atmospheric conditions of the last glacial period would have placed direct and indirect limitations on the productivity of crop progenitors." Although they also note the hypothesis does not explain why the domestication of crops occurred, they opine "it does offer evidence-based explanations of why agriculture did not begin earlier." It is logical to conclude civilizations of the past, which could not have existed without agriculture, were largely made possible by the increase in the atmospheric CO_2 content that accompanied deglaciation, and that people of today are likewise indebted to this phenomenon as well as to the additional 100 ppm of CO_2 the atmosphere has subsequently acquired.

A number of studies reveal the important role of temperature in agricultural production. Following the centuries-long cold period of the Little Ice Age (sixteenth through nineteenth centuries), global agriculture production has benefited from the warmer climate of the twentieth and twenty-first centuries.

Shen et al. (2005), for example, derived and analyzed long-term (1901–2002) temporal trends in the agroclimate of Alberta, Canada, reporting "an earlier last spring frost, a later first fall frost, and a longer frost-free period are obvious all over the province." They also say May–August precipitation in Alberta increased 14% from 1901 to 2002, and annual precipitation exhibited a similar increasing trend, with most of the increase coming in the form of low-intensity events. They note "the area with sufficient corn heat units for corn production, calculated according to the 1973–2002 normal, had extended to the north by about 200–300 km, when compared with the 1913–32 normal, and by about 50–100 km, when compared with the 1943–72 normal."

These changes, Shen et al. write, "imply that Alberta agriculture has benefited from the last century's climate change" and "the potential exists to grow crops and raise livestock in more regions of Alberta than was possible in the past." They also state the increase in the length of the frost-free period "can greatly reduce the frost risks to crops and bring economic benefits to Alberta agricultural producers." In addition, they note the northward extension of the corn heat unit boundary sufficient for corn production "implies that Alberta farmers now have a larger variety of crops to choose from than were available previously." Shen et al. say "there is no hesitation for us to conclude that the warming climate and increased precipitation benefit agriculture in Alberta."

Qian et al. (2010) derived a set of agroclimatic indices representing Canadian climatic conditions, which they analyzed for trends sure to prove useful for agricultural production planning for many years to come. They used a homogenized temperature dataset consisting of daily maximum and minimum air temperatures obtained from 210 meteorological stations distributed across Canada that cover the period 1895–2007, along with an adjusted precipitation dataset developed at the Climate Research Division of Environment Canada. They found "a significant lengthening of the growing season due to a sig-

nificantly earlier start and a significantly later end of the growing season," adding, "significant positive trends are also observed for effective growing degree-days and crop heat units at most locations across the country." Qian *et al.* report "the occurrence of extremely low temperatures had become less frequent during the non-growing season, implying a more favorable climate for overwinter survival," and "the total numbers of cool days, frost days, and killing-frost days within a growing season had a decreasing trend," so "crops may also be less vulnerable to cold stress and injury during the growing season." Their work revealed "extreme daily precipitation amounts and 10-day precipitation totals during the growing season have been increasing" and "significant trends associated with increased availability of water during the growing season are identified."

Clearly, the global warming that brought an end to the debilitating cold of the Little Ice Age and ushered the planet into the Current Warm Period is proving to be a benefit to Canada.

Hicke and Lobell (2004) calculated cropland net primary production (NPP) in the central part of the United States (South Dakota, Nebraska, Kansas, Missouri, Iowa, Minnesota, Wisconsin, and Illinois) using U.S. Department of Agriculture information together with crop-specific parameters that convert agronomic data into carbon fluxes for the period 1972–2001. Total cropland area exhibited no temporal trend over the study period, but "both NPP (flux per unit area) and P (spatially aggregated flux) increased during the study period (46 and 51%, respectively)."

These results indicate agricultural productivity in the central United States increased, and dramatically so, over the last three decades of the twentieth century, contrary to frequent claims that rising air temperatures and CO_2 concentrations will have negative effects on agriculture. Possible drivers of this increased agricultural productivity, according to Hicke and Lobell, include "improved cultivars, better fertilizer and pest management, more favorable climate, shifts to productive crop types, and economic influences (Duvick and Cassman, 1999; Evans, 1997; Lobell and Asner, 2003)."

Moonen *et al.* (2002) studied agriculturally important data collected from 1878 to 1999 on the outskirts of Pisa, Italy. Meteorological parameters routinely measured over this period were daily maximum, minimum, and mean air temperature plus daily rainfall. Agrometeorological parameters included the date of first autumn frost, date of last spring frost, length of growing season, number of

frost days, lengths of dry spells, potential evapotranspiration, reference evapotranspiration, soil moisture surplus, theoretical irrigation requirement, number of days with soil moisture surplus, and number of days with soil moisture deficit.

Moonen *et al.*'s analysis found "extremely cold temperature events have decreased and extremely warm temperature events have remained unchanged." They suggest these observations may be attributed to the increase in cloud cover that would be expected to occur in a warming world, since more clouds would reduce midday heating and thereby offset much, if not all, of the impetus for global warming during the hottest part of the day. At night, the increased cloud cover would enhance the atmosphere's greenhouse effect, thereby adding to the long-term warming trend. Moonen *et al.* conclude, "no negative effects can be expected on crop production from this point of view." They found a real "silver lining" in the latter of these cloud feedback phenomena: "the number of frost days per year had decreased significantly resulting in a decrease in risk of crop damage." Hence, they say the time of planting spring crops could be safely advanced by many days, noting the length of the growing season increased by fully 47 days during the period they studied.

With respect to rainfall, Moonen *et al.* found a somewhat analogous situation. On an annual basis, the incidence of extremely high rainfall events did not appear to have changed, but there was an increase in the incidence of very low rainfall events. The one exception to this rule on a seasonal basis was a decrease in high rainfall events in the spring, which might be expected to increase drought risk at that time of year. However, when the maximum length of dry spells was assessed on a seasonal basis, the only significant change observed was a lengthening of this parameter in the autumn. Autumn is the wettest season of the year in Pisa, Italy; the researchers conclude "no increased drought risk is to be expected."

The bottom line with respect to water in agriculture is the balance between what is received via rainfall and what is lost via evapotranspiration, as this difference is what determines the soil moisture balance. Although there was a downward trend in yearly rainfall at Pisa over the past 122 years (due to the decrease of high rainfall events in the spring), there also was a nearly offsetting downward trend in evapotranspiration (possibly induced by enhanced daytime cloud cover), so there were "no significant changes in soil water surplus or deficit on an annual basis." The scientists noted a significant decrease in

the number of surplus soil moisture days in the autumn, but because autumn is the wettest season of the year, they write, "this indicates a reduced flooding risk in autumn, which could have positive effects on workability of the soil and imply a reduction of erosion."

Thus Moonen *et al.* conclude, concomitant with the warming of the Northern Hemisphere over the past 122 years, "extreme events in Pisa have not changed in a way that is likely to negatively affect crop production." More often than not, the changes demonstrated to have occurred seem to have had positive impacts on agriculture. Moonen *et al.* say "there is no doubt regarding the reality of the observed changes."

Fengjin and Lianchun (2011) write, "the damage from extreme low temperature events during the warm season in Northeast China is one of the major disasters that affect agriculture in China," noting "rice, sorghum, corn, soybeans, and other major crops are all vulnerable to low-temperature damage." They computed temporal trends in the frequency of occurrence of extreme minimum temperatures during Northeast China's warm season (May to September) during the years 1956–2005, concurrently calculating trends in the region's annual average near-surface air temperature, after which they compared the former dependent trend with the latter independent trend.

The two Beijing Climate Center researchers found for the 1956–2005 period, the overall rate of increase in the annual average temperature was 0.32°C per decade. But from 1970 to 2005 it was 0.49°C per decade, and "from 1990, the increasing trend in the annual average temperature has become much more significant." They further report, "the average number of extreme minimum temperature days during the warm season in the 1950s was 15.8 days; in the 1960s, the average was 16.5 days; in the 1970s, the average increased to 17.3 days, and this was similar in the 1980s." In the 1990s, the average number of extreme minimum temperature days "decreased sharply to 13.3 days," and since 2000 the number of extreme minimum temperature days has been "decreasing constantly with an average of 11.4 days."

As warming accelerated across Northeast China over the latter part of the past half-century, there was a concomitant decrease in the number of extreme minimum temperature events during that region's warm season. Fengjin and Lianchun state a "decreased frequency of extreme low temperatures over the past few decades has also been reported in other regions, e.g., Australia and New Zealand

(Salinger *et al.*, 2000; Stone *et al.*, 1996)." The two Chinese scientists say the decrease in extreme minimum temperature events in response to the warmer temperatures of the past few decades has enabled farmers in Northeast China to harvest greater amounts of rice, sorghum, corn, soybeans, and other major crops than would otherwise have been possible.

Chen *et al.* (2011) report corn acreage in Northeast China—specifically Heilongjiang, Jilin, and Liaoning provinces—"accounts for 26.3% of the corn area in the country and accounts for about 29.4% of Chinese total corn grain production." They note the corn production of this region "plays a significant role in ensuring Chinese food security," and "knowledge of the potential effects of climate change on corn production in Northeast China will be highly valuable, not only for China but also for the world." Chen *et al.* "performed a multiple regression analysis to study the relationship between corn growth and the key climatic factors of temperature and precipitation during the crop growing season and during specific months in Northeast China from 1965 to 2008," to learn "which variables of climate change and which month in the crop growing season were associated with yield variability over this 44-year period."

The six scientists determined the major climatic factor affecting corn yield in Northeast China is daily minimum temperature, particularly in the months of May and September. They found a warming of 1.0°C in the mean daily minimum temperature of either of these months may enhance corn yield by 303 kg/ha (May) or 284 kg/ha (September). They report growth duration—defined as the period from sowing to harvest (days to maturity)—rose by six days in Liaoning province and by seven days in Jilin and Heilongjiang provinces during the years 1950–2008, which encompassed the period of 1965–2008, when daily minimum temperature rose at a rate of 0.44°C per decade. They conclude, "in order to fully exploit the positive effects of global warming on corn production, new varieties should be adapted to the longer growing season." This adjustment could be described as a good example of man and nature working together to ensure maximum food security for a significant portion of humanity.

Magrin *et al.* (2005) evaluated twentieth-century changes in climate and the yields of the chief crops (soybean, wheat, maize, and sunflower) of nine areas of contrasting environment in Argentina's Pampas region, which accounts for more than 90% of the country's grain production. After determining low-frequency upward trends in yield due to improvements in crop genetics and management techniques,

as well as the aerial fertilization effect of the historical increase in the air's CO_2 concentration, they used annual yield anomalies and concomitant climatic anomalies to develop relations describing the effects of precipitation, temperature, and solar radiation on crop yields, to determine the effects of long-term changes in these climatic parameters on Argentina's agriculture.

Although noting "technological improvements account for most of the observed changes in crop yields during the second part of the 20th century"—which totaled 110% for maize, 56% for wheat, and 102% for sunflower—Magrin *et al.* report changes in climate between the periods 1950–1970 and 1970–1999 led to yield increases of 38% in soybean, 18% in maize, 13% in wheat, and 12% in sunflower.

These studies suggest rising atmospheric CO_2 concentrations and warmer temperatures—both of which IPCC claims to constitute significant threats to the biosphere, having reached levels IPCC describes as unprecedented over the past one to two millennia—were far from problematic for agriculture.

4.1.2 The Future

Several researchers have expressed concerns about a looming food production crisis on the horizon, suggesting just a few decades from now the ever-growing human population of the planet will need a near-doubling of present-day agricultural production. One example is the brief Perspective article published in *Science*, where Running (2012) resurrected shades of Meadows *et al.*'s 1972 treatise on *The Limits to Growth*.

Noting "terrestrial plant production is the foundation of the biospheric carbon cycle" and that "water and atmospheric CO_2 are transformed into plant carbohydrate matter with the help of solar energy," Running states this plant matter "sustains the global food web and becomes the source of food, fiber and fuel for humanity." A problem Running sees, however, is that for more than 30 years, global net primary production (NPP) has "stayed near 53.6 Pg per year, with only ~1 Pg of inter-annual variability," citing two studies of which he was a coauthor (Nemani *et al.*, 2003; Zhao and Running, 2010). He thus speculates, "if global NPP is fixed by planetary constraints, then no substantial increase in plant growth may be possible."

If true, this would indeed have catastrophic consequences, for it is almost universally agreed, as Running writes, "the projected 40% increase in human population by 2050 CE, combined with goals to substantially improve standards of living for the poorest 5 billion people on Earth, implies at least a doubling of future resource demand by 2050." The most important of these resources is food.

But is a doubling of food production by mid-century realistic? Agriculture already consumes 38% of the world's land surface, and Running notes "many analyses now conclude that freshwater use for irrigation has already reached a planetary boundary." Furthermore, with "massive river pollution and ocean anaerobic dead zones," he states, "if anything, future increases in NPP must be achieved with less, not more, irrigation and fertilizer use." Others have noted additional challenges, such as Tilman *et al.* (2009)

noting "land previously allocated to food production is transformed to bioenergy production, raising food prices for the people who can least afford it."

Has the planet reached a limit to its growth? In a 2012 paper published in *Nature,* titled "Increase in observed net carbon dioxide uptake by land and oceans during the past 50 years," Ballantyne *et al.* (2012) suggest it has not. The five U.S. scientists state their mass balance analysis shows "net global carbon uptake has increased significantly by about 0.05 billion tonnes of carbon per year and that global carbon uptake doubled, from 2.4 ± 0.8 to 5.0 ± 0.9 billion tonnes per year, between 1960 and 2010." They conclude, "there is no empirical evidence that carbon uptake has started to diminish on the global scale." In fact, as their results indicate, just the opposite appears to be the case, with global carbon uptake actually *doubling* over the past half-century.

There are many reasons why this doubling has occurred: breeding of better crop varieties that are higher-yielding, more competitive with weeds, less tasty to insect pests, more nutritious, and more drought-resistant, as well as smarter ways of farming, improved technologies, and the worldwide aerial fertilization and transpiration-reducing effects of the historical and still-ongoing rise in the atmosphere's CO_2 content. The latter two phenomena benefit agriculture and nature simultaneously.

Also concerned about adequately meeting the food needs of a growing world population, Parry and Hawkesford (2010) note "food production needs to increase 50% by 2030 and double by 2050 to meet projected demands." They say while the demand for food is increasing, production is progressively being limited by "non-food uses of crops and cropland," such as the production of biofuels. In their UK homeland, for example, they note, "by 2015 more than a quarter of wheat grain may be destined for bioenergy production," which is both sad and puzzling, as they also point out "currently, at least one billion people are chronically malnourished and the situation is deteriorating," with more people "hungrier now than at the start of the millennium."

The two researchers turn their discussion to photosynthesis, the all-important process by which plants "convert light energy into chemical energy, which is used in the assimilation of atmospheric CO_2 and the formation of sugars that fuel growth and yield." These phenomena make this natural and life-sustaining process "a major target for improving crop productivity both via conventional breeding and biotechnology," they write.

Next to a plant's need for carbon dioxide is its

need for water, the availability of which, in the words of Parry and Hawkesford, "is the major constraint on world crop productivity." They state, "since more than 80% of the [world's] available water is used for agricultural production, there is little opportunity to use additional water for crop production," because as populations increase, "the demand to use water for other activities also increases." Hence they conclude, "a real and immediate challenge for agriculture is to increase crop production with less available water."

They provide an example of a success story: the Australian wheat variety Drysdale, which gained fame "because it uses water more efficiently." This valued characteristic was achieved "by slightly restricting stomatal aperture and thereby the loss of water from the leaves." They note this ability "reduces photosynthetic performance slightly under ideal conditions," but it enables plants to "have access to water later in the growing season thereby increasing total photosynthesis over the life of the crop."

Of course, Drysdale is but one variety of one crop, and the ideal goal would be to get nearly all varieties of all crops to use water more efficiently. That goal in fact can be reached without doing anything new, because allowing atmospheric CO_2 concentrations to rise will cause the vast majority of plants to reduce the apertures of their stomata and thereby lower the rate at which water vapor escapes from them into the air. The result is even better than that produced by the breeding of Drysdale, because the extra CO_2 in the air more than overcomes the photosynthetic reduction that results from the partial closure of plant stomatal apertures, allowing even more yield to be produced per unit of water transpired in the process.

Human ingenuity can make the situation better still, by breeding and selecting crop varieties that perform better under higher atmospheric CO_2 concentrations than the varieties people currently rely upon, and by employing various technological means of altering them. Humanity can succeed even though "the United Nations Millennium Development Goal of substantially reducing the world's hungry by 2015 will not be met," as Parry and Hawkesford conclude. This truly seems to be the path to take, as they write "at least one billion people are chronically malnourished and the situation is deteriorating," with more people "hungrier now than at the start of the millennium."

Ainsworth *et al*. (2008) argue for breeding major crop varieties upon which the world depends for food to best take advantage of the ongoing rise in the atmospheric CO_2 content. The international consortium of 32 scientists from 12 countries notes, "the growing world population, increasing demands for grains for animal feeds, land loss to urban expansion and demand for bioenergy production are exerting more and more pressure on global agricultural productivity." They state, "a major challenge for plant biologists, agronomists and breeders will be to provide germplasm and seed material that maximize future crop production," particularly in the context of rising atmospheric CO_2 concentrations that provide "a unique opportunity to increase the productivity of C_3 crops." They say "only a fraction of available germplasm of crops has been tested for CO_2 responsiveness," and "further research is needed to elucidate the mechanisms of yield response to CO_2, to assess the genetic diversity available for improving responsiveness and to devise efficient schemes for selection for adaptation to rising ambient CO_2, whether based on conventional plant breeding or systems biology approaches for selecting and engineering improved genetics."

The first step in meeting these objectives, according to the researchers, "is to create facilities for field screening the yield response to elevated CO_2 across a wide range of germplasm," and doing so under "conditions and management that reflect dominant agronomic practices and provide as natural an environment as possible." They recommend free air CO_2 enrichment (FACE) experimentation, which these scientists say meets many of these criteria and presents a minimally obtrusive interaction with the natural environment.

Although FACE systems are often considered expensive to construct and operate, Ainsworth *et al*. note "the net cost is compensated for by economies of scale, and the cost per unit ground area is considerably less than alternative systems." This is very important, as they explain, because "the new research requires investigating large numbers of genotypes," and "to investigate the association of CO_2 responsiveness with a single quantitative trait locus mapping population, approximately 150 inbred lines would need to be investigated."

The world-renowned group of scientists concludes, "because it may take 10–15 years to move from discovery of new advantaged genetics to commercial cultivars of annual grain crops, developing a robust strategy and supporting the planned work with the best possible facilities should be an urgent priority."

Zhu *et al*. (2010) embrace an alternative strategy for boosting agricultural production. They say meeting the global increase in agricultural demand

during this century "is predicted to require a doubling of global production," but "the world has limited capacity to sustainably expand cropland," and this capacity is actually "shrinking in many developed countries." The three researchers contend, "meeting future increases in demand will have to come from a near doubling of productivity on a land area basis." They suggest "a large contribution will have to come from improved photosynthetic conversion efficiency," for which they estimate "at least a 50% improvement will be required to double global production."

The researchers focus on photosynthetic conversion efficiency because experimental evidence has found increases in the atmosphere's CO_2 concentration boost the photosynthetic rates of nearly all plants, and those rate increases generally lead to equivalent increases in plant productivity on a land-area basis. They examined the prospects for boosting photosynthetic conversion efficiency in an entirely different way: genetically, without increasing the atmosphere's CO_2 content.

The three scientists write, "Improving photosynthetic conversion efficiency will require a full suite of tools including breeding, gene transfer, and synthetic biology in bringing about the designed alteration to photosynthesis." For some of these "near-term" endeavors, they write, "implementation is limited by technical issues that can be overcome by sufficient investment." But a number of "mid-term" goals could take 20 years to achieve, and "even when these improvements are achieved, it may take an additional 10–20 years to bring such innovations to farms in commercial cultivars at adequate scale." And they write of still longer-term goals for which "too little of the science has been undertaken to identify what needs to be altered to effect an increase in yield." They acknowledge some of what they envision may not even be possible, such as developing a form of rubisco that exhibits a significant decrease in oxygenation activity, or designing C_3 crops to utilize the C_4 form of photosynthetic metabolism. The focus of Ainsworth *et al.* (2008) appears to be a far better path to pursue: conducting research to "elucidate the mechanisms of yield response to CO_2, to assess the genetic diversity available for improving responsiveness and to devise efficient schemes for selection for adaptation to rising ambient CO_2, whether based on conventional plant breeding or systems biology approaches for selecting and engineering improved genetics."

Godfray *et al.* (2010) note, "more than one in seven people today still do not have access to sufficient protein and energy from their diet and even more suffer some form of micronutrient malnourishment," citing the FAO (2009). They write, although "increases in production will have an important part to play" in correcting this problem and keeping it from worsening in the future, mankind "will be constrained by the finite resources provided by the Earth's lands, oceans and atmosphere." This set of difficulties they describe at the end of their review as a "perfect storm."

The first question they ask in regard to how mankind might successfully navigate this highly restricted terrain is: "How can more food be produced sustainably?" They say the primary solution to food shortages of the past had been "to bring more land into agriculture and to exploit new fish stocks," but they quickly note there is precious little remaining of either of these resources. They conclude, "the most likely scenario is that more food will need to be produced from the same or less land," because "we must avoid the temptation to sacrifice further the Earth's already hugely depleted biodiversity for easy gains in food production, not only because biodiversity provides many of the public goods upon which mankind relies, but also because we do not have the right to deprive future generations of its economic and cultural benefits."

The key to meeting these diverse requirements simultaneously is in Godfray *et al.*'s statement, "greater water and nutrient use efficiency, as well as tolerance of abiotic stress, are likely to become of increasing importance." As discussed previously, rising carbon dioxide can bring about all of these changes in mankind's crops. Rising concentrations of atmospheric CO_2 increase the photosynthetic prowess of essentially all plants, while generally reducing the rate at which they transfer water from the soil to the air. In addition, an increase of CO_2 in the atmosphere tends to enhance the efficiency with which plants utilize nutrients in constructing their tissues and producing the edible portions that essentially all of Earth's animals and humans depend on.

Each of the important benefits noted above has been discussed in great detail in the preceding chapters of this volume. In the material that follows, we limit our discussion to studies that directly imply general trends regarding these global benefits. Section 4.1.2.1 examines the findings of several empirical studies from which trends in future agricultural production can be inferred, and Section 4.1.2.2 presents a review of several model-based studies that shed additional light on the subject.

4.1.2.1 Empirical Studies

- Empirical studies suggest a future warming of the climate coupled with rising atmospheric CO_2 levels will boost global agricultural production and help meet the food needs of the planet's growing population.

As discussed in the preceding chapters of this volume, numerous studies attest to the growth-enhancing, water-conserving, and stress-alleviating benefits of CO_2 enrichment for plants. In the present subsection, therefore, we limit our discussion to studies from which we can infer general trends in future agricultural production.

According to Tian *et al.* (2012), "more than 20% of the world's food consumers depend on wheat (*Triticum aestivum* L.), which is produced on an area of over 200 million hectares worldwide (Ortiz *et al.*, 2008)." They note "winter wheat area accounts for more than 80% of this total," and "it is typically grown in the seasons of winter and spring where warming is mainly anticipated." China, the writers note, is the world's largest producer of winter wheat, and more than 70% of the crop is sown in the country's eastern provinces on the Yangtze Delta Plain.

Tian *et al.* "conducted a five-year field warming experiment since 2004 with a facility of Free Air Temperature Increase (FATI) in Nanjing, Jiangsu province," in which their objectives were "to investigate the actual responses of winter wheat phenophase, biomass production and grain yield to anticipated warming [~1.5°C] under field conditions" where "there were no water and nitrogen limitations for winter wheat growth, which is common in East China." They studied *Triticum aestivum* L. cv Yangmai 11, a local cultivar having a "high yield potential."

The 1.5°C increase in temperature significantly advanced crop phenophases, leading to a reduction in the length of the entire growth period of about 10 days, with the result that grain yields rose due to "the mitigation of low temperature limitation during the pre-anthesis phase and to the avoidance of hot-dry stress during the post-anthesis phase." The researchers found the areas of flag leaves and total green leaves at anthesis, as well as the 1,000-grain weight of the plants, were 36.0, 19.2, and 5.9% higher in the warmed plots than in the unaltered control, respectively. The net effect of these warmth-induced changes was a mean grain yield increase of 16.3%, and they therefore conclude "anticipated warming

may facilitate winter wheat production in East China."

Ortiz *et al*. (2008) reviewed some of the approaches for ameliorating the oft-predicted negative impacts climate change may have on wheat production in some of the most important wheat growing areas of the world. They write, "to adapt and mitigate the climate change effects on wheat supplies for the poor, germplasm scientists and agronomists are developing heat-tolerant wheat germplasm, as well as cultivars better adapted to conservation agriculture," noting these encouraging results include "identifying sources of alleles for heat tolerance and their introgression into breeding populations through conventional methods and biotechnology." They report "wheat geneticists and physiologists are also assessing wild relatives of wheat as potential sources of genes with inhibitory effects on soil nitrification." This activity could lead to significantly reduced emissions of nitrous oxide from agricultural soils and thereby shrink the impetus for global warming provided by this powerful trace greenhouse gas, which molecule-for-molecule is about 300 times more radiatively active than CO_2. Ortiz *et al*. conclude important technology and knowledge will ultimately flow to farmers and enable them "to face the risks associated with climate change."

Bunce (2008) grew adequately fertilized plants of four varieties of the common garden bean (*Phaseolus vulgaris*)—Matterhorn (a great northern bean), Jaguar (a black bean), Red Hawk (a kidney bean), and Brown Beauty (a snap bean)—from seed to maturity under standard field conditions at Beltsville, Maryland (USA) in open-top chambers. They made photosynthetic measurements of mature upper-canopy leaves in full sunlight at midday during the pod-filling stages of four growing seasons and determined final seed yields and other plant characteristics at harvest. They found an extra 180 ppm of CO_2 in the CO_2-enriched chambers (a concentration increase of close to 50% during daylight hours) resulted in a mean long-term stimulation of midday net photosynthesis of approximately 18% in the Matterhorn and Jaguar bean varieties, and an increase of twice that much (36%) in the Red Hawk and Brown Beauty cultivars. In terms of dry mass seed yield, the Matterhorn variety experienced a CO_2-induced increase of about 39%, followed by Red Hawk at 21%, Brown Beauty at 18%, and Jaguar with a 10% decline in seed yield. As Bunce reports, "the highest yielding variety at ambient CO_2 [Jaguar] was out-yielded by a different variety at elevated CO_2 [Matterhorn]."

These observations make it clear there is

significant variability in seed yield response to atmospheric CO_2 enrichment among the four bean varieties tested by Bunce. In addition, it is equally clear there was no *a priori* way of knowing which of the four cultivars would respond best to an increase in atmospheric CO_2 concentration, or that one would actually respond negatively. Bunce's experiment demonstrates the great need to perform a host of such studies on the planet's most important crop plants, to identify which of their many varieties should be selected for additional crop breeding work. That is the only way to take full advantage of the significant increase in the atmosphere's CO_2 concentration that will occur over the next several decades.

In a standard paddy-culture FACE experiment conducted at Yangzhou, Jiangsu, China, during the years 2004–2006, Yang *et al*. (2009) grew a two-line inter-subspecific hybrid rice variety (Liangyoupeijiu) at ambient and elevated atmospheric CO_2 concentrations of 376 and 568 ppm, respectively, at two levels of field nitrogen (N) application—low N (12.5 g N m^{-2}) and high N (25 g N m^{-2})—while measuring numerous aspects of crop growth, development, and final yield. The eight Chinese scientists found the 51% increase in atmospheric CO_2 concentration increased the final grain yield of the low N rice crop by 28% and that of the high N rice crop by 32%. As a result, and in light of the findings of two prior rice FACE experiments (Kim *et al*., 2003; Yang *et al*., 2006), they conclude "hybrid rice appears to profit much more from CO_2 enrichment than inbred rice cultivars (c. +13%)." Yang *et al*. describe Liangyoupeijiu as "one of the most popular 'super' hybrid rice varieties in China (Peng *et al*., 2004)."

Shimono *et al*. (2007) say lodging—the environmental beating down of a crop—"can occur under heavy rains and strong winds," and this phenomenon "decreases canopy photosynthesis due to self-shading (Setter *et al*., 1997) and disturbs the translocation of carbon and nutrients to the rice grains (Hitaka and Kobayashi, 1961), resulting in lower yield and poor grain quality." They note Setter *et al*. (1997) found a moderate degree of lodging reduced canopy height by 35% and decreased yield by about 20%, whereas severe lodging reduced canopy height by 75% and decreased yield by up to 50%.

Shimono *et al*. designed a free-air CO_2-enrichment experiment to determine what effect the ongoing rise in the atmosphere's CO_2 content might have on lodging in rice plants, growing the cultivar Akitakomachi in paddy fields under three nitrogen (N) fertilization regimes—low N (6 g N m^{-2}), medium N (9 g N m^{-2}), and high N (15 g N m^{-2})—at two

season-long 24-hour mean CO_2 concentrations—375 ppm (ambient) and 562 ppm (enriched)—measuring the degree of naturally occurring lodging at the time of grain maturity on a scale of 0–5, based on the bending angles of the stems at 18° intervals, where 0 = 0° from the vertical, 1 = 1°–18°, 2 = 19°–36°, 3 = 37°–54°, 4 = 55°–72°, and 5 = 73°–90°.

The six scientists report lodging was significantly higher under high N than under medium and low N. The lodging experienced in the high N treatment "was alleviated by elevated CO_2," because the lowest internodes of the rice stems "became significantly shorter and thicker under elevated CO_2," which likely "strengthened the rice culms against the increased lodging that occurred under high N." They note the reduced lodging experienced under elevated CO_2 in the high N treatment increased the grain-ripening percentage of the rice by 4.5% per one-unit decrease in lodging score.

Shimono *et al*. note there is concern that in order "to increase rice yield under projected future CO_2 levels, N fertilization must be increased to meet increased plant demand for this nutrient as a result of increased growth rates," but greater N fertilization might enhance lodging, thereby defeating the purpose of the fertilization. Their study found "elevated CO_2 could significantly decrease lodging under high N fertilization, thereby increasing the ripening percentage and grain yield," in what amounts to another CO_2-induced success story for what the researchers called "the most important crop for feeding the world's population."

Lou *et al*. (2008) note there is a pressing need to identify genotypes that produce maximum grain yields under projected future atmospheric CO_2 levels. They grew four different rice cultivars—Dular (a traditional indica variety), IR72 (an improved indica variety), Koshihikari (a temperate japonica variety), and IR65598 (a new variety not yet released to farmers at that time)—in Japan in growth chambers in submerged pots filled with a fertilized soil at two atmospheric CO_2 concentrations: ambient (~370 ppm) and elevated (~570 ppm). They found the extra 200 ppm of CO_2 reduced the ultimate grain yield of Dular (by 0.7%) and increased it for IR72 (by 8.0%), Koshihikari (by 13.4%), and IR65598 (by 17.7%).

Roy *et al*. (2012) write "an average annual increase in grain production of 44 million metric tons is required to meet the food demands of the world by 2050," citing Tester and Langridge (2010), and they note "the predicted 2.0°C increase in air temperature by the end of 2050 (IPCC, 2007) might lead to a 20–40% decrease in cereal yields," citing Lele (2010). To assess this situation from an experiment-based perspective, the five researchers from the Central Rice Research Institute of India conducted a three-year open-top-chamber field study to observe the effects of elevated atmospheric CO_2 concentration (550 vs. ambient 390 ppm), as well as elevated temperature (T, 2°C above ambient temperature), on dry matter production, carbon (C), and nitrogen (N) concentrations and their allocation in a tropical rice cultivar (cv. *Naveen*).

In the elevated CO_2/normal temperature treatment, their experiment revealed: dry matter accumulation in the aboveground portion of the rice plants was enhanced by 17.7% at maturity; root biomass, leaf area index, and net carbon assimilation rates increased by 28, 19, and 40%, respectively; grain yield was significantly higher (22.6%); the net carbon yield increased by 23.3%; and nitrogen allocation increased significantly in leaf (13%), stem (14%), and panicle (17%) at maturity.

In the elevated CO_2/elevated temperature treatment, the found: dry matter accumulation in the aboveground portion of the rice plants was enhanced by 18.1% at maturity; root biomass, leaf area index, and net carbon assimilation rates also increased significantly; grain yield was significantly higher (19.6%); the net carbon yield increased by 24.2%; and nitrogen allocation increased significantly in leaf (13%), stem (14%), and panicle (17%) at maturity.

Jin *et al*. (2009) conducted a CO_2 enrichment study in three pairs of greenhouses placed over a uniform soil surface, in which they planted celery (*Apium graveolens* L.), leaf lettuce (*Lactuca virosa* L.), stem lettuce (*Lactuca saiva* L.), oily sowthistle (*Sonchus oleraceus* L.), and Chinese cabbage (*Brassica chinensis* L.). In response to a slightly more-than-doubling of atmospheric CO_2 content, "the average percentage of yield increases of all three sites were 270%, 257%, 87%, 140% and 227% for celery, leaf lettuce, stem lettuce, oily sowthistle, and Chinese cabbage, respectively." The extra CO_2 also increased the concentration of vitamin C in all five species, "by 13%, 39%, 25%, 72%, and 37% for celery, leaf lettuce, stem lettuce, oily sowthistle, and Chinese cabbage, respectively."

Vanaja *et al*. (2010) write, "food grain requirements of India (both human and cattle) are estimated at 300 Mt in 2020," citing Sinha *et al*. (1998), and they note "grain legumes are one of the mainstays of the drylands, as these crops provide much needed nutritional security in the form of proteins to the predominant vegetarian populations of India and also the world." They further state legumes—of which

pigeon peas are an important example—"have the potential to maximize the benefit of elevated CO_2 by matching [CO_2-]stimulated photosynthesis with increased N_2 fixation," citing Rogers *et al*. (2009).

Vanaja *et al*. grew pigeon peas (*Cajanus cajan* L. Millsp.) from seed to maturity out-of-doors at Hyderabad (India) in open-top chambers maintained at atmospheric CO_2 concentrations of either 370 or 700 ppm (ambient or enriched, respectively), after which they harvested them and measured a number of pertinent productivity parameters. The team of nine Indian scientists from the country's Central Research Institute for Dryland Agriculture report "total biomass recorded an improvement of 91.3%, grain yield 150.1% and fodder yield 67.1%." They write, "the major contributing components for improved grain yield under elevated CO_2 were number of pods, number of seeds and test weight," which exhibited increases of 97.9%, 119.5%, and 7.2%, respectively. In addition, the found "a significant positive increase of harvest index at elevated CO_2 with an increment of 30.7% over ambient values," which they attribute to the crop's "improved pod set and seed yield under enhanced CO_2 concentration." These findings, Vanaja *et al*. conclude, illustrate the importance of pigeon peas for "sustained food with nutritional security under a climate change scenario."

Rosenthal *et al*. (2012) write, "given the projections that future food production will need to double to meet the global demand by 2050 (Lobell *et al*., 2008; Godfray *et al*., 2010; Tilman *et al*., 2011), there is an urgent need to assess the impact of climate drivers on crops of food insecure regions." They note, "more than 900 million people are undernourished and nearly 90% live in Sub-Saharan Africa, Asia, and the Pacific," citing the United Nations Food and Agriculture Organization (FAO, 2010). The eight researchers also write, "in Sub-Saharan Africa, the starchy root tuber crop cassava accounts for almost two-thirds of the direct human caloric intake," and in areas where drought is recurrent, "cassava is harvested when other crops fail (FAO, 2005)," adding, cassava "provides food security during armed conflicts when above-ground crops are destroyed, as the cassava tuber remains viable below ground for up to three years (Cock, 1982; Lebot, 2009)."

Rosenthal *et al*. report a recent greenhouse study on cassava found decreased yields at elevated CO_2, and the smaller yields were accompanied by increases in leaf, but not tuber, cyanide content (Gleadow *et al*., 2009). This finding alarmed them because, they write, "cassava leaves are eaten for their protein, and a higher leaf cyanide content suggests increased

toxicity at elevated CO_2." But since this study was conducted in a greenhouse, they opted to conduct a study to determine whether increases in cassava biomass or leaf toxicity would occur in plants grown under natural field conditions, employing free-air CO_2 enrichment (FACE) technology at the SoyFACE facility located at the Experimental Research Station of the University of Illinois in Urbana-Champaign (USA), where the air of four plots was enriched with CO_2 to approximately 200 ppm above what was measured in four ambient-treatment plots.

The U.S. and Australian researchers report, after three-and-a-half months of growth at elevated CO_2, the above-ground biomass of cassava was 30% greater and cassava tuber dry mass was more than 100% greater than in plants grown in ambient air. This result, they write, "surpasses all other C_3 crops and thus exceeds expectations." In contrast to the greenhouse study they cited, they find "no evidence" of increased leaf or total cyanide concentrations in the plants grown in the elevated CO_2 plots.

Vanuytrecht *et al*. (2012) acquired peer-reviewed publications reporting the results of free-air CO_2-enrichment (FACE) studies via searches of the ISI Web of Science citation database (Thomson) and the ScienceDirect citation database (Elsevier BV). They conducted a meta-analysis of 529 independent observations of various plant growth responses to elevated CO_2 obtained from 53 papers containing relevant data in graphical or numerical format pertaining to wheat (*Triticum aestivum* L.), barley (*Hordeum vulgare* L.), rice (*Oryza sativa* L.), soybean (*Glycine max* L.), potato (*Solanum tuberosum* L.), sugar beet (*Beta vulgaris* L.), cotton (*Gossypium hirsutum* L.), maize (*Zea mays* L.), and sorghum (*Sorghum bicolor* L.), as well as the two major pasture species of perennial ryegrass (*Lolium perenne* L.) and white clover (*Trifolium repens* L.).

Considered *en masse*, Vanuytrecht *et al*. report an approximate 200 ppm increase in the air's CO_2 concentration (the mean enhancement employed in the studies they analyzed) led to water productivity improvements of 23% in terms of aboveground biomass production per unit of water lost to evapotranspiration, and 27% in terms of aboveground yield produced per unit of water lost to evapo-transpiration. These two productivity increases would roughly correspond to enhancements of 34% and 40% for a 300 ppm increase in the air's CO_2 concentration.

Although "the FACE technique avoids the potential limitations of (semi-) closed systems by studying the influence of elevated CO_2 on crop growth in the field without chamber enclosure," the

team of Belgian researchers writes, other studies have demonstrated a significant problem caused by the rapid (sub-minute) fluctuations of CO_2 concentration about a target mean common to most FACE experiments, as described by Bunce (2011, 2012). The latter found total shoot biomass of vegetative cotton plants in a typical FACE study averaged 30% less than in a constantly elevated CO_2 treatment at 27 days after planting, and wheat grain yields were 12% less in a fluctuating CO_2 treatment compared with a constant elevated CO_2 concentration treatment.

The results of the empirical studies described above suggest a future warming of the climate, coupled with rising atmospheric CO_2 levels, will boost global agricultural production and help to meet the food needs of the planet's growing population.

4.1.2.2 Model-based Studies

- When model-based studies fully account for the growth-enhancing and water-conserving benefits of atmospheric CO_2 enrichment, they project

significant gains for future agricultural production.

Bootsma *et al*. (2005) derived relationships between agroclimatic indices and average grain yields of corn, soybeans, and barley obtained from field trials conducted in the eastern part of Canada and used them to estimate the impacts of projected climate change scenarios on the yields of these commodities for the years 2040–2069. Based on a range of heat units projected by multiple climate model simulations, they report average yields achievable in field trials could increase by 40–115% for corn and 21–50% for soybeans by 2040–2069, "not including the direct effect of increased atmospheric CO_2 concentrations." Adding the expected CO_2 increase into the mix, along with gains in yield anticipated to be achieved through breeding and improved technology, these numbers rose to 114–186% for corn and 117–157% for soybeans.

Initial yields of barley, in contrast, were projected to decline, by as much as 25% in areas with significant water deficits, but after reviewing the scientific literature on the subject, the Canadian researchers conclude the direct effect of increased CO_2 alone "would more than offset the yield reductions anticipated due to effects of rising temperature and changes in water deficit." All things considered, they conclude, "barley yields would increase by an average of about 15% under this scenario." Bootsma *et al*. predict a "switch to high-energy and high-protein-content crops (corn and soybeans) better adapted to the warmer climate," but say "there will likely still be a considerable area of land seeded to barley and other small grain cereals, as these are very desirable in rotation with potatoes."

Liu *et al*. (2004) made detailed calculations of the economic impact of predicted climate changes for the year 2050 (a mean countrywide temperature increase of 3.0°C and a mean precipitation increase of 3.9%) on agriculture in China, using the methodology of Mendelsohn *et al*. (1994) and agricultural, climate, social, economic, and edaphic data for 1,275 agricultural counties for the period 1985–1991. In the mean, Liu *et al*. report "all of China would benefit from climate change in most scenarios." In addition, they write, "the effects of CO_2 fertilization should be included, for some studies indicate that this may produce a significant increase in yield," an increase that is well-established (see Chapter 1, this volume) and was not included in their analysis. Liu *et al*. note "China's agriculture has to feed more than one-fifth of the world's population, and, historically, China has been famine prone," noting, "as recently as the late

1950s and early 1960s a great famine claimed about thirty million lives (Ashton *et al*., 1984; Cambridge History of China, 1987)."

Chavas *et al*. (2009) also showed the importance of including the effects of CO_2 fertilization in projecting agricultural trends, studying potential climate change impacts on the productivity of five major crops (canola, corn, potato, rice, and winter wheat) of eastern China (30 to 42°N, 108 to 123°E). They conducted full-domain simulations of the EPIC agro-ecosystem model for the baseline period 1961–1990 and the future period 2071–2100 under IPCC's A2 scenario for projected atmospheric CO_2 concentrations and accompanying climate change. They found, "without the enhanced CO_2-fertilization effect, potential productivity declines in all cases ranging from 2.5 to 12%." When the CO_2-fertilization effect was included, "aggregate potential productivity (i.e. if the crop is grown everywhere) increases 6.5% for rice, 8.3% for canola, 18.6% for corn, 22.9% for potato, and 24.9% for winter wheat." In addition, "similar results are reported at the national scale in the work of Lin *et al*. (2005) using alternative RCM output and the CERES crop simulation model."

Thus, despite the supposedly deleterious climate changes predicted to occur over the rest of the twenty-first century, when the seven scientists factored into the yield model the aerial fertilization effect of the projected increase in atmospheric CO_2, they found the net productivities of all five crops rose over the entire study region.

Noting "rice is an essential component of the diet in more than half the world's population" and "the most socially and economically important crop in China," where it "contributes 43.7% of total national grain production," Xiong *et al*. (2009) assessed the effect of greenhouse gas-induced climate change and the direct fertilization effect of CO_2 on rice yields and production in China by coupling "the regional climate model PRECIS (Providing Regional Climates for Impacts Studies) with the CERES (Crop Environment Resources Synthesis) rice crop model to simulate current (1961–1990) and future (2011–2100) rice yields and production under [IPCC's] A2 and B2 climate change scenarios."

They found "single rice cropping may expand further north in China, and double rice cropping may move to the northern portion of the Yangtze River basin." In addition, "the national mean rice production is estimated to increase by 2.7 to 19.2% considering the combined effects of climate change, CO_2 and shifting rice-producing areas." Consequently, even considering the inflated temperature

increases predicted by IPCC, the estimated net effect of global warming and concomitant growth in anthropogenic CO_2 emissions results in a significant increase in rice production in the world's most populous country, where it is the people's most important food source.

Tao *et al*. (2013) introduce their work by writing "future climate change is projected to be one of the major challenges for regional agricultural production in broad regions of the world," noting Tao *et al*. (2009a,b) and Tao and Zhang (2010) developed "a new process-based Model to capture the Crop-Weather relationship over a Large Area (MCWLA) and a new super-ensemble-based probabilistic projection (Super EPPS) to account for the uncertainties not only from greenhouse gas emission scenarios and climate change scenarios but also from biophysical processes in crop models, and to assess the impacts of climate change (variability) on regional crop productivity and water use in a probabilistic framework." These model projections "have been demonstrated," they continue, "in addressing the probabilistic responses and adaptations of maize production to climate change in the North China Plain (NCP)."

Tao and Zhang state the crop model MCWLA-Wheat was first developed "by adapting the process-based general crop model, MCWLA, to winter wheat," after which "Bayesian probability inversion and a Markov chain Monte Carlo (MCMC) technique were applied to the MCWLA-Wheat to analyze uncertainties in parameter estimations, and to optimize parameters." Ensemble hindcasts show "the MCWLA-Wheat could capture the inter-annual variability of detrended historical yield series fairly well, especially over a large area." Based on the MCWLA-Wheat, they developed a Super EPPS and applied it to project the probabilistic responses of wheat productivity and water use in the NCP to future climate change. The scientists used 10 climate scenarios "consisting of the combinations of five global climate models and two greenhouse gases emission scenarios (A1F1 and B1), the corresponding atmospheric CO_2 concentration range, and multiple sets of crop model parameters representing the biophysical uncertainties from crop models."

The Chinese researchers found a high probability that future climate change would increase winter wheat yields in the NCP during the 2020s, 2050s, and 2080s, with (and without) CO_2 fertilization effects and relative to 1961–1990 levels, by, on average, 37.3% (18.6%), 67.8% (23.1%), and 87.2% (34.4%), respectively, over 80% of the study area.

These findings are encouraging in light of the analysis of Schmidhuber and Tubiello (2007), who suggest global food production may need to rise by as much as 70% by the year 2050 in order to adequately feed the nine billion people (compared to today's seven billion) they project to be inhabiting the planet at that midcentury point.

Trnka *et al*. (2004) used the crop growth model CERES-Barley version 2.1 (Otter-Nacke *et al*., 1991) to assess the direct biological effect of a doubling of the air's CO_2 concentration (from 350 to 700 ppm) on the growth and yield of spring barley in the Czech Republic, along with the indirect effect on growth and yield produced by the climate changes predicted to accompany such a CO_2 increase, as simulated by several GCMs, including ECHAM4, HadCM2, NCAR-DOE, and seven other GCMs available from IPCC. They report the indirect effect on spring barley yield caused by changed weather conditions was mostly negative, ranging from -19% to +5% for the several climate scenarios applied to three different production regions of the Czech Republic.

CO2 enrichment made a positive difference in these results. Trnka *et al*. write, "the magnitude of the direct [and positive] effect of doubled CO_2 on the stressed yields for the three test sites is 35–55% in the present climate and 25–65% in the 2 x CO_2 climates," and "the stressed yields would increase in 2 x CO_2 conditions by 13–52% when both direct [biological] and indirect [climatic] effects were considered." In addition, "the decrease of the mean yields due to the indirect [climatic] effect of doubled CO_2 may be reduced, and it might be even turned to increase, if the spring barley is planted 45–60 days sooner." They conclude, "application of the earlier planting date would result thus in an additional 15–22% increase of the yields in 2 x CO_2 conditions." They conclude, "the positive direct effect of doubled CO_2 dominates over the negative effect of changed weather conditions," and they note the results they obtained "might be applied to vast regions of Central Europe with similar environmental characteristics."

Kvalvik *et al*. (2011) state the consequences of predicted climate change "are not straightforward, but dependent on the interaction between different weather and biological elements, as well as political, economic and social conditions." In their inter-disciplinary study of this complex situation, the six Norwegian scientists "assessed biological and agronomic effects of climate change, and their interaction with political, economic and social factors to identify farmers' vulnerability and adaptive capacity to climate change," based on "downscaled climate change scenarios and interviews with local farmers in the three northernmost counties in Northern Norway (latitude 65.5° to 70°N)."

The scientists found "the farmers themselves are willing to use the opportunities afforded by a more favorable climate," and "a warmer climate is generally regarded as favorable by the farmers in our study region." However, they report their study of farmers in northern Norway shows they are "vulnerable to a changing climate, not because of the direct effect of changing growing conditions, but because these changes are an added factor to an already tenuous situation created by Norwegian agricultural policy and the socio-economic develop-ment in general," which "poses a greater challenge to farming and is likely to reduce the farmers' adaptive capacity."

Kvalvik *et al*. conclude farmers in northern Norway "are highly adaptive, to both changing growing conditions and changing agricultural policies." They note "changes in policy are currently a greater challenge to farmers than climate change," and "such changes are therefore a more salient driver of vulnerability," implying the Norwegian govern-ment's presumptive cure for the disease of global warming (which is described in some detail in their paper) is probably no cure at all, and possibly worse than the disease itself.

Cullen *et al*. (2012) introduce their study by noting "climate change projections for southern Australia indicate the region is likely to become warmer and drier," noting "there is considerable variation in the projections from different climate models and emission pathways." They point out "there is some uncertainty about how rapidly warming will occur" and "projections for rainfall change vary widely." Given the large uncertainty in climate change projections from global circulation models, Cullen *et al*. conclude an alternative approach would be "to explore the sensitivity of agricultural systems to a range of likely future temperature, carbon dioxide and rainfall combinations, thereby creating a three-dimensional surface of response."

The three Australian researchers report the simulated changes in pasture production and the approach adopted in their study highlight when and where possible adaptation options may be required, adding this approach "clearly demonstrates the resistance of pasture production over a range of climate changes." Cullen *et al*. conclude that for south-eastern Australia, "annual pasture production is resistant to climatic changes of up to 2°C warming," thanks to the collective wisdom of farmers, who

learned from experience how to cope with various degrees of temperature and precipitation change, and of scientists who had studied the subject in considerable detail.

Marin *et al*. (2013) evaluated the effects of climate change on sugarcane yield, water use efficiency, and irrigation needs in southern Brazil, based on downscaled outputs of two general circulation models (PRECIS and CSIRO) and a sugarcane growth model (DSSAT/CANEGRO) calibrated for the main cultivar currently grown in Brazil. They used data from five field experiments conducted under several soil and climate conditions, analyzing the sensitivities of simulated stalk fresh mass (SFM) to air temperature, CO_2 concentration, and rainfall, to identify increases in simulated SFM and water use efficiency (WUE) for all scenarios investigated.

On average, this analysis revealed, "for the current sugarcane area in the State of Sao Paulo, SFM would increase 24% and WUE 34% for rain-fed sugarcane." The authors write, "considering the current technological improvement rate, projected yields for 2050 ranged from 96 to 129 tons per hectare, which are respectively 15 and 59% higher than the current state average yield." They say their simulations suggest "the WUE increase due to higher CO_2 seems to be the main cause for the positive simulated yield response."

When model-based studies fully account for the growth-enhancing and water-conserving benefits of atmospheric CO_2 enrichment, they project significant gains for future agricultural production.

4.2 Biospheric Productivity: The Greening of the Earth

Since 1980, some parts of the world registered three of the warmest decades in the instrumental temperature record, intense and persistent El Niño events, large-scale deforestation, "unprecedented" forest fires, and the eruption of several volcanoes. Concurrently, the atmosphere's CO_2 content increased by 16% and the human population grew by 55%. How badly is the biosphere suffering in response to these much-feared events? Is it even suffering at all?

As reviewed in the subsections below, several research groups have explored those questions. This section begins with a discussion of what has been learned about the terrestrial biosphere as a whole, followed by a regional analysis exploring terrestrial productivity trends on continental and subcontinental scales.

4.2.1 Global Terrestrial

- The vigor of Earth's terrestrial biosphere has been increasing with time, revealing a great greening of the planet that extends across the globe. Satellite-based analyses of net terrestrial primary productivity (NPP) reveal an increase of 6–13% since the 1980s.There is no empirical evidence to support the model-based claim that future carbon uptake will diminish on a global scale due to rising temperatures.

Reichenau and Esser (2003) investigated the individual influences of the El Niño-Southern Oscillation (ENSO), volcanic eruptions, and the North Atlantic Oscillation (NAO) on the 1958–1994 time series of anomalous CO_2 fluxes using the High Resolution Biosphere Model of Esser *et al*. (1994) and real-world CO_2 measurements. Although the two researchers could conclude nothing about the NAO, other than to say "the influence of the NAO remain[s] unclear," they determined periods of anomalous rising atmospheric CO_2 concentrations coincided with El Niño periods, and times of anomalous declining atmospheric CO_2 concentrations coincided with periods of significant volcanism.

They write, "the globally averaged effect of [the El Niño] circulation pattern on the terrestrial biosphere is a net release of carbon," in agreement with the results of earlier investigations of the subject (Bacastow, 1976; Bacastow *et al*., 1980), which in turn "confirms earlier findings that the terrestrial biosphere is mainly responsible for atmospheric CO_2 variations on the ENSO timescale (Keeling *et al*., 1995; Lee *et al*., 1998; Feely *et al*., 1999; Gerard *et al*., 1999; Rayner and Law, 1999; Battle *et al*., 2000; Bousquet *et al*., 2000; Houghton, 2000; Knorr, 2000, LeQuere *et al*., 2000; Langenfelds *et al*., 2002)." At the other end of the spectrum, Reichenau and Esser report "volcanic eruptions with considerable aerosol production may create disturbances of the (biospheric) carbon cycle by increasing the photosynthetic carbon uptake due to the enhanced diffuse fraction of the incoming [solar] radiation." This accords with the findings of Roderick *et al*. (2001), Cohan *et al*. (2002), Law *et al*. (2002), and Gu *et al*. (2002, 2003).

The many published studies of anomalous CO_2 fluxes between Earth's surface and its atmosphere indicate warm El Niño conditions tend to reduce biospheric productivity, whereas cool volcanic conditions tend to enhance that productivity. At first glance, this appears to support claims of "cool is good" and "warm is bad" for the planet's plants. But there is much more to the story.

For one thing, the productivity-enhancing effect of volcanic eruptions arises not from their cooling influence, but from their increasing the amount of diffuse solar radiation received at Earth's surface, which allows for an enhanced penetration of solar radiation deeper into plant canopies, which reduces within-canopy shade and boosts rates of canopy net photosynthesis. As for the productivity-reducing effect of El Niños, it could be more a consequence of changes in global precipitation patterns than a direct effect of the temperature increases. Indermuhle *et al*. (1999), for example, demonstrated the pattern of biospheric productivity over the last 7,000 years of the Holocene was essentially that of a slow monotonic decline from the peak growth conditions of the interglacial's Climatic Optimum, and this productivity decline, they write, was "due to a change from the warmer and wetter mid-Holocene climate to colder and drier conditions."

Additional evidence of the benefits of long-term warming on plants comes from the study of Lin *et al*. (2010), who conducted a meta-analysis of data from 127 individual studies, reporting for the totality of terrestrial plants included in their analysis, "warming significantly increased biomass by 12.3%" and there

was a "significantly greater stimulation of woody (+26.7%) than herbaceous species (+5.2%)." They also state the warming effects on plant biomass production "did not change with mean annual precipitation or experimental duration," and "other treatments, including CO_2 enrichment, nitrogen addition, drought and water addition, did not alter warming responses of plant biomass." Thus the Chinese researchers conclude, "results in this and previous meta-analyses (Arft *et al.*, 1999; Rustad *et al.*, 2001; Dormann and Woodin, 2002; Walker *et al.*, 2006) have revealed that warming generally increases terrestrial plant biomass, indicating enhanced terrestrial carbon uptake via plant growth and net primary productivity."

These studies indicate long-term global warming tends to increase biospheric productivity. Deviations from this basic relationship evident in variations of CO_2 fluxes between Earth's surface and atmosphere are likely to be short-lived and anomalous.

Langenfelds *et al.* (1999) analyzed O_2/N_2 measurements of the contents of a suite of tanks filled with background air collected at Cape Grim, Tasmania between April 1978 and January 1997. The rates of carbon storage in the world's oceans and the terrestrial biosphere they derived from these data indicate the terrestrial biosphere was essentially in balance with respect to surface fluxes of carbon throughout this 19-year interval. However, other studies have established tropical deforestation produced a huge net loss of carbon during each of those years. Langenfelds *et al.* necessarily acknowledge the existence of a terrestrial carbon sink of like magnitude. They suggest this "compensating growth of the [terrestrial] biosphere" is due to "reforestation, higher rates of net production in response to climatic trends, fertilisation by elevated levels of atmospheric CO_2 or nitrogen deposition or a combination of these factors." Thus, the biosphere appears to be re-sequestering the carbon man takes out of it.

In a broad review of the scientific literature, Idso and Idso (2011) described a number of biological consequences of the "fertilization of elevated levels of atmospheric CO_2." The best-known of these impacts is probably CO_2's aerial fertilization effect, which works on plants that utilize all three of the major biochemical pathways of photosynthesis (C_3, C_4, and CAM). In the case of herbaceous plants, this phenomenon typically boosts their productivities by about a third in response to a 300-ppm increase in atmospheric CO_2 content, and it enhances the growth of woody plants by 50% or more, as demonstrated in

literally thousands of laboratory and field experiments (Idso and Singer, 2009) (see Chapter 1, this volume).

Plant water use efficiency, which may be defined as the amount of organic matter produced per unit of water transpired to the atmosphere, is directly enhanced by the aerial fertilization effect of atmospheric CO_2 enrichment and its anti-transpirant effect, which is produced by CO_2-induced decreases in the number density and degree of openness of leaf stomatal apertures that occur at higher atmospheric CO_2 concentrations (see Chapter 2). CO_2-induced percentage increases as large as, or even larger than, those exhibited by plant productivity are commonplace.

An important ramification of this CO_2-induced increase in plant water use efficiency is that it enables plants to grow and reproduce in areas previously too dry for them. The consequent increases in ground cover in these regions reduce the adverse effects of wind- and water-induced soil erosion. This creates a tendency to reverse desertification and make vast tracts of previously unproductive land able to support more abundant animal life, both above- and belowground.

In addition to helping vegetation overcome the stress of limited water supplies, elevated levels of atmospheric CO_2 help plants better cope with other environmental stresses, such as low soil fertility, low light intensity, high soil and water salinity, high air temperature, various oxidative stresses, and the stress of herbivory (see Chapter 3). When confronted with the specter of global warming, for example, many experiments have revealed concomitant enrichment of the air with CO_2 tends to increase the temperature at which plants function at their optimum, often making them even better suited to the warmer environment than they were to the cooler environment to which they were originally adapted. Under the most stressful of such conditions, extra CO_2 can be the deciding factor in determining whether a plant lives or dies.

These benefits of atmospheric CO_2 enrichment apply to both agricultural and natural ecosystems. As Wittwer (1995) has noted, "the rising level of atmospheric CO_2 could be the one global natural resource that is progressively increasing food production and total biological output in a world of otherwise diminishing natural resources of land, water, energy, minerals, and fertilizer." This phenomenon is thus a means, he says, "of inadvertently increasing the productivity of farming systems and other photosynthetically active ecosystems," and "the effects know no boundaries and both developing and developed countries are, and will

be, sharing equally."

In light of these observations and the rising CO_2 content of Earth's atmosphere, especially since 1950, one would expect to see some evidence of a greening of the Earth (Idso, 1986). As indicated in the papers described below, a growing number of researchers have joined Langenfelds *et al.* in acknowledging these stimulatory effects on Earth's biosphere.

Idso (1995) laid out the evidence for a worldwide increase in the growth rates of Earth's forests coeval with the progression of the Industrial Revolution and the rising CO_2 content of the atmosphere. The development of this concept begins with the study of LaMarche *et al.* (1984), who analyzed annual growth rings of two species of pine tree growing near the timberline in California, Colorado, Nevada, and New Mexico (USA), discovering large increases in growth rate between 1859 and 1983, rates that exceeded what might have been expected from climatic trends but were consistent with the global trend of atmospheric CO_2. A further development was provided by a study of ring-width measurements of Douglas fir trees in British Columbia, Canada, which also revealed a marked increase in growth in the trees' latter decades (Parker, 1987), leading the principal investigator of the project to state "environmental influences other than increased CO_2 have not been found that would explain this [phenomenon]." West (1988) reports much the same thing with respect to long-leaf pines in Georgia—their annual growth increments began to rise at an unusual rate about 1920, increasing by approximately 30% by the mid-1980s—and he too states "the increased growth cannot be explained by trends in precipitation, temperature, or Palmer Drought Severity Index," leaving the rising CO_2 content of the atmosphere as the likely cause of the increase in productivity.

Hari *et al.* (1984) and Hari and Arovaara (1988) reported stands of Scots pines in northern Finland were found to have experienced growth increases ranging from 15 to 43% between 1950 and 1983. The researchers state "CO_2 seems to be the only environ-mental factor that has been changing systematically during this century in the remote area under study."

Graybill and Idso (1993) found very long ring-width chronologies

(some stretching back nearly 1,800 years) of high-altitude long-lived bristlecone, foxtail, and limber pine trees in Arizona, California, Colo-rado, and Nevada (USA) showed an unprecedented upward growth trend in the 1850s that continued as far toward the present as the records extended. Comparisons of the chronologies with temperature and precipitation records ruled out the possibility either of these climatic variables played a significant role in enhancing the trees' growth rates, strongly implicating the historical rise in atmospheric CO_2 content as the factor responsible for their ever-increasing productivity over the prior century and a half.

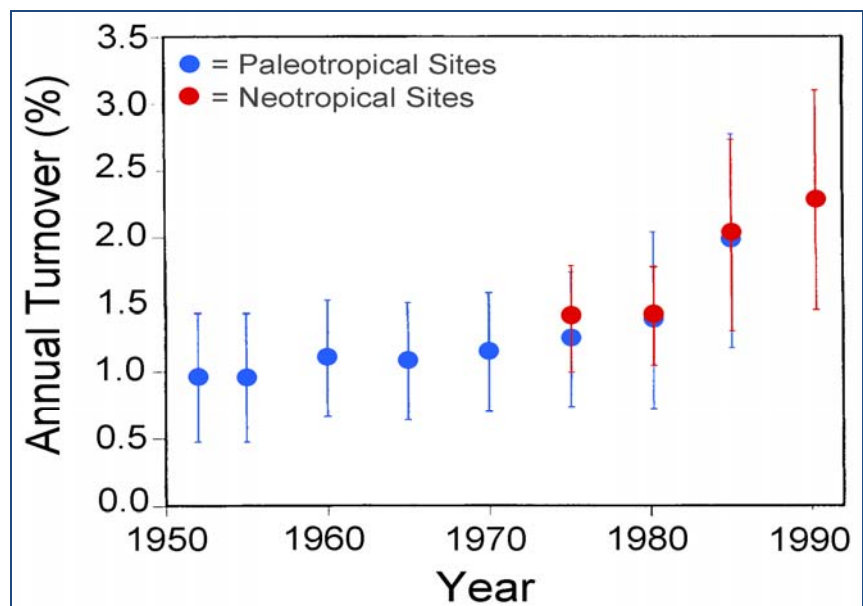
Phillips and Gentry (1994) provided perhaps the most striking evidence for the significant twentieth-century growth enhancement of Earth's forests by the historical increase in the air's CO_2 concentration. Noting turnover rates of mature tropical forests correlate well with measures of net productivity (Weaver and Murphy, 1990), the two scientists assessed the turnover rates of 40 tropical forests from around the world in order to test the hypothesis global forest productivity was increasing *in situ*. They found the turnover rates of these highly productive forests had indeed been continually rising since at least 1960, with an apparent pan-tropical acceleration since 1980 (see Figure 4.2.1.1). They note "the accelerating increase in turnover coincides with an accelerating buildup of CO_2," and as Pimm and Sugden (1994)


Figure 4.2.1.1. Average annual turnover rates (a surrogate for net productivity) for various tropical forests around the world since 1950. Adapted from Phillips and Gentry (1994).

note in a companion article, it was "the consistency and simultaneity of the changes on several continents that [led] Phillips and Gentry to their conclusion that enhanced productivity induced by increased CO_2 is the most plausible candidate for the cause of the increased turnover."

Four years later, a team of 11 researchers headed by Phillips (Phillips *et al*., 1998) reported another impressive finding. Working with data on tree basal area (a surrogate for tropical forest biomass) for the years 1958–1996, which they obtained from several hundred plots of mature tropical trees around the world, they report average forest biomass for the tropics as a whole increased substantially. They calculate the increase amounted to approximately 40% of the missing terrestrial carbon sink of the globe. Hence they suggest "intact forests may be helping to buffer the rate of increase in atmospheric CO_2, thereby reducing the impacts of global climate change," as Idso (1991a,b) had earlier suggested, and they identify the aerial fertilization effect of the ongoing rise in the atmospheric CO_2 content as one of the factors responsible for this phenomenon. Other contemporary studies support their findings (Grace *et al*., 1995; Malhi *et al*., 1998), verifying that neo-tropical forests were indeed accumulating ever-more carbon, and Phillips *et al*. (2002) state this phenom-enon was occurring "possibly in response to the increasing atmospheric concentrations of carbon dioxide (Prentice *et al*., 2001; Malhi and Grace, 2000)."

The conclusions of Phillips and company were repeatedly challenged (Sheil, 1995; Sheil and May, 1996; Condit, 1997; Clark, 2002; Clark *et al*., 2003). In response to those challenges, Phillips and 17 other researchers (Lewis *et al*., 2004c), including one who had earlier criticized his and his colleagues' conclusions, published a new analysis that vindicated Phillips *et al*.'s earlier thoughts on the subject.

One of the primary criticisms of Phillips *et al*.'s work was their meta-analyses included sites with a wide range of tree census intervals (two–38 years), which critics claimed could be confounding or "perhaps even driving conclusions from comparative studies," as Lewis *et al*. (2004c) write. In Lewis *et al*.'s detailed study of this potential problem, which they conclude was indeed real, they state a re-analysis of Phillips *et al*.'s published results "shows that the pan-tropical increase in stem turnover rates over the late 20th century cannot be attributed to combining data with differing census intervals." Or as they state in another place, "the conclusion that turnover rates have increased in tropical forests over the late 20th

century is robust to the charge that this is an artifact due to the combination of data that vary in census interval (cf. Sheil, 1995)."

Lewis *et al*. (2004c) additionally note "Sheil's (1995) original critique of the evidence for increasing turnover over the late twentieth century also suggests that the apparent increase could be explained by a single event, the 1982–83 El Niño Southern Oscillation (ENSO), as many of the recent data spanned this event." However, they continue, "recent analyses from Amazonia have shown that growth, recruitment and mortality rates have simultaneously increased within the same plots over the 1980s and 1990s, as has net above-ground biomass, both in areas largely unaffected, and in those strongly affected, by ENSO events (Baker *et al*., 2004; Lewis *et al*., 2004a; Phillips *et al*., 2004)."

In a review of these global forest studies and many others (which led to their citing 186 scientific journal articles), Boisvenue and Running (2006) examined reams of "documented evidence of the impacts of climate change trends on forest productivity since the middle of the 20th century." They write, "globally, based on both satellite and ground-based data, climatic changes seemed to have a generally positive impact on forest productivity when water was not limiting," which was most of the time, because they report "less than 7% of forests are in strongly water-limited systems." Thus there has been what Boisvenue and Running call a significant "greening of the biosphere" in recent years, the world's forests in particular.

In another review of the scientific literature on this issue of global biospheric productivity, Lewis *et al*. (2009a) evaluated tropical forest inventory data, plant physiology experiments, ecosystem flux observations, Earth observations, atmospheric measurements, and dynamic global vegetation models. The five researchers report both theory and experiments suggest that over the past several decades "plant photosynthesis should have increased in response to increasing CO_2 concentrations, causing increased plant growth and forest biomass." They find "long-term plot data collectively indicate an increase in carbon storage, as well as significant increases in tree growth, mortality, recruitment, and forest dynamism." They also say satellite measurements "indicate increases in productivity and forest dynamism," and five Dynamic Global Vegetation Models, incorporating plant physiology, competition, and dynamics, predict "increasing gross primary productivity, net primary productivity, and carbon storage when forced using late-twentieth century

climate and atmospheric CO_2 concentration data." They write, "the predicted increases in carbon storage via the differing methods are all of similar magnitude (0.2% to 0.5% per year)."

Another indication these CO_2- and temperature-induced biological benefits are indeed occurring in the real world of nature comes from the decline in the air's diurnal temperature range (DTR), evident in many parts of the world (Easterling *et al.*, 1997). Collatz *et al.* (2000) employed a simple land surface subroutine in a general circulation model of the atmosphere that included parameterizations of canopy physiological responses to various environmental changes, and by running the model with and without the vegetation subroutine, they were able to determine the degree of influence the planet's plant life may have on near-surface air temperature in a world of rising temperature and atmospheric CO_2 concentration.

They found realistic changes in the amount and physiological activity of Earth's plant life can produce changes in DTR of the order observed in the real world. The researchers state their results "suggest that reported increases in vegetation cover in the Northern Hemisphere during the 1980s [Myneni *et al.*, 1997] could have contributed to the lowered DTR." Thus, whereas some scientists have viewed the declining diurnal temperature range near the surface of Earth as a "fingerprint" of deleterious CO_2-induced global warming, evidence suggests the declining DTR may instead be an indication of beneficial CO_2-induced "global greening."

Alexandrov and Oikawa (2002) constructed a model of biospheric productivity based on empirical observations. Applied to the period 1980–1990, it suggests the total terrestrial carbon sink induced by the aerial fertilization effect of the contemporaneous increase in atmospheric CO_2 was approximately 1.3 Pg C yr^{-1}. This result compares well with estimates of up to 1.1 Pg C yr^{-1} derived from independent empirical observations of same-period anthropogenic CO_2 emissions, changes in land use, CO_2 uptake by the world's oceans, and increases in the air's CO_2 concentration.

Gurney and Eckles (2011) reported similar findings nearly a decade later. They state, "projections of atmospheric CO_2 concentrations and the resulting climate change rely to a significant degree on projections about future land and ocean uptake," citing Friedlingstein *et al.* (2006) and Sitch *et al.* (2008). To investigate how CO_2 uptake by Earth's terrestrial surfaces has varied over the past three decades, they examined the results of atmospheric CO_2 inversions—constrained by observed atmospheric CO_2 concentrations (Tans *et al.*, 1990) and simulated atmospheric transport—to estimate trends in air-to-land carbon fluxes, as per Enting (2002). They did so, they write, "at spatial scales down to the continents using the results of the TransCom 3 international atmospheric CO_2 inversion inter-comparison (Gurney *et al.*, 2002, 2008)," which involved 13 participating modeling groups. Their analyses indicate the global land carbon sink is intensifying (see Figure 4.2.1.2) at a rate of 0.057 PgC/year/year, resulting in 1.65 PgC of additional uptake over the period examined (1980–2008). This finding, they write, "is consistent with related findings in recent years," citing Cao *et al.* (2002), Cao *et al.* (2005), LeQuere *et al.* (2009), and Piao *et al.* (2009).
Figure 4.2.1.2. Global terrestrial biosphere net carbon exchange (positive from land to air, negative from air to land) during the years 1980–2008 (blue line), as calculated by Gurney and Eckles (2011). Also shown is the five-yr running mean (red line) and total 1σ flux uncertainty (light blue shading).

Other studies have produced additional evidence for a worldwide increase in vegetative productivity dating back to the inception of the Industrial Revolution. Joos and Bruno (1998), for example, used

ice core data and direct observations of atmospheric CO_2 and ^{13}C to reconstruct the histories of terrestrial and oceanic uptake of anthropogenic carbon over the past two centuries. They discovered the biosphere typically acted as a source of CO_2 during the nineteenth century and the first decades of the twentieth century, but it subsequently "turned into a sink." Lloyd (1999) calculated that from 1730 to the early 1980s the increase in temperate deciduous forest net primary productivity (NPP) due solely to the historical increase in the atmosphere's CO_2 concentration was approximately 7%, and the increase in NPP due to a modest proportional increase in nitrogen deposition over the same time period would have been about 25%. However, when CO_2 and nitrogen increased together in Lloyd's model, the NPP stimulation was 40%, more than the sum of the individual contributions of the extra CO_2 and nitrogen.

Tans (2009) employed measurements of atmospheric and oceanic carbon contents, along with reasonably constrained estimates of global anthropogenic CO_2 emissions, to calculate the residual fluxes of carbon (in the form of CO_2) from the terrestrial biosphere to the atmosphere (+) or from the atmosphere to the terrestrial biosphere (-), obtaining the results depicted in Figure 4.2.1.3.
Figure 4.2.1.3. Five-year smoothed rates of carbon transfer from land to air (+) or from air to land (-) vs. time. Adapted from Tans (2009).

As the figure illustrates, Earth's land surfaces were a net *source* of CO_2-carbon to the atmosphere until about 1940, primarily because of the felling of forests and the plowing of grasslands to make way for expanded agricultural activities. From 1940 onward, however, the terrestrial biosphere has become, in the mean, an increasingly greater *sink* for CO_2-carbon, and it has done so despite increasing temperatures, massive global deforestation, and rising atmospheric

CO_2, more than compensating for any negative effects these phenomena have on the global biosphere.

Such findings, which do "not depend on models" but "only on the observed atmospheric increase and estimates of fossil fuel emissions," led Tans to conclude "suggestions that the carbon cycle is becoming less effective in removing CO_2 from the atmosphere (e.g., LeQuere *et al.*, 2007; Canadell *et al.*, 2007) can perhaps be true locally, but they do not apply globally, not over the 50-year atmospheric record, and not in recent years." Tans continues, "to the contrary," and "despite global fossil fuel emissions increasing from 6.57 GtC in 1999 to 8.23 in 2006, the five-year smoothed global atmospheric growth rate has not increased during that time, which requires more effective uptake [of CO_2] either by the ocean or by the terrestrial biosphere, or both, to satisfy atmospheric observations." The results portrayed in Figure 4.2.1.3, adapted from Tans' paper, clearly indicate this "more effective uptake" of CO_2-carbon has occurred primarily over land.

Many researchers also have examined trends in biospheric productivity using satellite data. Nemani *et al.* (2003), for example, discovered the terrestrial biosphere is growing ever more robust (see Figure 4.2.1.4). Globally, the group of eight scientists found terrestrial net primary production (NPP) increased by 6.17%, or 3.42 PgC, over the 18 years between 1982 and 1999. In addition, they observed net positive responses over all latitude bands studied: 4.2% (47.5–22.5°S), 7.4% (22.5°S–22.5°N), 3.7% (22.5–47.5°N), and 6.6% (47.5–90.0°N).

Nemani *et al.* mention a number of likely contributing factors to these significant NPP increases: nitrogen deposition and forest regrowth in northern mid and high latitudes; wetter rainfall regimes in water-limited regions of Australia, Africa, and the Indian subcontinent;, increased solar radiation reception over radiation-limited parts of Western Europe and the equatorial tropics; warming in many parts of the world; and the aerial fertilization effect of rising atmospheric CO_2 concentrations.

Regarding the latter factor, Nemani *et al.* remark, "an increase in NPP of only 0.2% per 1-ppm increase in CO_2 could explain all of the estimated global NPP increase of 6.17% over 18 years and is within the range of experimental evidence." However, they report NPP increased by more than 1% per year in Amazonia alone, noting "this result cannot be explained solely by CO_2 fertilization."

Although Nemani *et al.*'s conclusion may be correct, the aerial fertilization effect of atmospheric CO_2 enrichment is most pronounced at higher tem-
Figure 4.2.1.4. Interannual variations in global Net Primary Productivity (NPP) in relation to atmospheric CO_2 growth rate during the years 1982 to 1999. Adapted from Nemani *et al*. (2003).

peratures, rising from next to nothing at a mean temperature of 10°C to a 0.33% NPP increase per 1-ppm increase in CO_2 at a mean temperature of 36°C for a mixture of plants comprised predominantly of herbaceous species (Idso and Idso, 1994). For woody plants, this number could likely be two (Idso, 1999) or even three (Saxe *et al*., 1998; Idso and Kimball, 2001; Leavitt *et al*., 2003) times larger, yielding a 0.7% to 1% NPP increase per 1-ppm increase in CO_2, which would indeed represent the lion's share of the growth stimulation Nemani *et al*. observed in tropical Amazonia.

Chen *et al*. (2004) utilized the monthly satellite-derived normalized difference vegetation index (NDVI) dataset of 1987–1997 obtained from the advanced very high resolution radiometer (AVHRR) to calculate an 11-year history of global (75°N to 55°S) terrestrial NPP, deriving three results based on the three "NPP coefficient sets" of Whittaker and Likens (1975), Atjay *et al*. (1979), and Olson *et al*. (1983). Calculating from the beginning and end points of the graphical presentations of Chen *et al*.'s results, global terrestrial NPP increased by approximately 6.6% between 1987 and 1997 when the Atjay *et al*. coefficients were used, 9.9% when the Olson *et al*. coefficients were used, and 13.8% when the Whittaker and Likens coefficients were used, for a mean NPP increase of about 10% over the 11-year period.

Cao *et al*. (2004) derived net primary production

(NPP) values at 8-km and 10-day resolutions for the years 1981–2000 using variables based almost entirely on satellite observations, as described in the Global Production Efficiency Model (GLO-PEM). The model consists, they write, "of linked components that describe the processes of canopy radiation absorption, utiliza-tion, autotrophic respiration, and the regulation of these processes by environmental factors (Prince and Goward, 1995; Goetz *et al*., 2000)." Over the last two decades of the twentieth century, "there was an increasing trend toward enhanced terrestrial NPP," which they say was "caused mainly by increases in atmospheric carbon dioxide and precipitation.

Cao *et al*. (2005) used the CEVSA (Carbon Exchanges in the Vegetation-Soil-Atmosphere sys-tem) model (Cao and Woodward, 1998; Cao *et al*., 2002), forced by observed variations in climate and atmospheric CO_2, to quantify changes in NPP, soil heterotrophic respiration (HR), and net ecosystem production (NEP) from 1981 to 1998. As an independent check on the NPP estimate of CEVSA, they also estimated 10-day NPP for 1981–2000 with the GLO-PEM model that uses data almost entirely from remote sensing, including both the normalized difference vegetation index and meteorological variables (Prince and Goward, 1995; Cao *et al*., 2004).

Cao *et al*. found "global terrestrial temperature increased by 0.21°C from the 1980s to the 1990s, and this alone increased HR more than NPP and hence reduced global annual NEP." They write, "combined changes in temperature and precipitation increased global NEP significantly," and "increases in atmospheric CO_2 produced further increases in NPP and NEP." They also note "the CO_2 fertilization effect [was] particularly strong in the tropics, compensating for the negative effect of warming on NPP."

They write, "the response of photosynthetic biochemical reactions to increases in atmospheric CO_2 is greater in warmer conditions, so the CO_2 fertilization effect will increase with warming in cool regions and be high in warm environments." They found global NEP increased "from 0.25 Pg C yr^{-1} in the 1980s to 1.36 Pg C yr^{-1} in the 1990s."

Commenting on their findings, Cao *et al*. note "the NEP that was induced by CO_2 fertilization and

climatic variation accounted for 30% of the total terrestrial carbon sink implied by the atmospheric carbon budget (Schimel *et al*., 2001), and the fraction changed from 13% in the 1980s to 49% in the 1990s," which indicates the growing importance of the CO_2 fertilization effect. Moreover, "the increase in the terrestrial carbon sink from the 1980s to the 1990s was a continuation of the trend since the middle of the twentieth century, rather than merely a consequence of short-term climate variability," suggesting as long as the atmosphere's CO_2 content continues to rise, so too will its stimulation of the terrestrial biosphere likely increase.

Using a newly developed satellite-based vegetation index (Version 3 Pathfinder NDVI) in conjunction with a gridded global climate dataset (global monthly mean temperature and precipitation at 0.5° resolution from New *et al*., 2000), Xiao and Moody (2005) analyzed trends in global vegetative activity from 1982 to 1998. The greening trends exhibited substantial latitudinal and longitudinal variability, with the most intense greening of the globe located in high northern latitudes, portions of the tropics, southeastern North America, and eastern China. Temperature correlated strongly with greening trends in Europe, eastern Eurasia, and tropical Africa. Precipitation, in contrast, was not a significant driver of increases in greenness, except for isolated and spatially fragmented regions. Some decreases in greenness also were observed, mainly in the Southern Hemisphere in southern Africa, southern South America, and central Australia, and these trends were associated with concomitant increases in temperature and decreases in precipitation. Large regions of the globe showed no trend in greenness over the 17-year period, and large areas underwent strong greening that showed no association with trends of either temperature or precipitation. These greening trends, the scientists conclude, must have resulted from other factors, such as "CO_2 fertilization, reforestation, forest regrowth, woody plant proliferation and trends in agricultural practices."

Young and Harris (2005) investigated, for the majority of Earth's land surface, a near 20-year time series (1982–1999) of NDVI data, based on measurements obtained from the advanced very high resolution radiometer (AVHRR) carried aboard U.S. National Oceanic and Atmospheric Administration satellites. They employed two datasets derived from the sensor: the Pathfinder AVHRR Land (PAL) dataset and the Global Inventory Modeling and Mapping Studies (GIMMS) dataset.

Based on their analysis of the PAL data, the two researchers report "globally more than 30% of land pixels increased in annual average NDVI greater than 4% and more than 16% persistently increased greater than 4%," while "during the same period less than 2% of land pixels declined in NDVI and less than 1% persistently declined." Regarding the GIMMS dataset, they report "even more areas were found to be persistently increasing (greater than 20%) and persistently decreasing (more than 3%)." All told, they report "between 1982 and 1999 the general trend of vegetation change throughout the world has been one of increasing photosynthesis."

As for what has been responsible for the worldwide increase in photosynthesis, the researchers mention global warming and "associated precipitation change and increases in atmospheric carbon dioxide," citing Myneni *et al*. (1997) and Ichii *et al*. (2002). In addition, they write, "many of the areas of decreasing NDVI are the result of human activity," primarily deforestation (Skole and Tucker, 1993; Steininger *et al*., 2001) and urbanization Seto *et al*. (2000).

Piao *et al*. (2006a) note "enhanced terrestrial vegetation growth in the middle and high latitudes of the Northern Hemisphere over the past two decades has been well documented (Zhou *et al*., 2001; Nemani *et al*., 2003)," but "the mechanisms for this phenomenon are still under debate." Using a leaf area index dataset for the years 1981–2000, created from satellite-derived observations of the normalized difference vegetation index parameter for land areas above 25°N latitude, the authors investigated "spatial patterns of mechanisms controlling current enhanced vegetation growth in the Northern Hemisphere," focusing on "how recent changes in precipitation, temperature [and] atmospheric CO_2 concentration have influenced vegetation growth."

Over the final two decades of the twentieth century, the researchers found, the mean rate of increase in growing-season leaf area index was 0.0041/year. They report 13% of that increase was provided by increases in precipitation, 31% by increases in temperature, and 49% by the increase in the atmosphere's CO_2 concentration.

Liu *et al*. (2010) looked for, and computed changes in, leaf area index (LAI) data derived from satellite observations for six latitude bands (50–90°N, 30–50°N, 10–30°N, 10°N–10°S, 10–30°S, and 30–63°S) that included all of Earth's continents but Antarctica. They report LAI "prominently increased" during the period July 1981 through December 2006 throughout Europe, Siberia, the Indian Peninsula, America and south Canada, the south region of the Sahara, the southwest corner of Australia, and the

Kgalagadi Basin, while it declined in southeast Asia, southeastern China, central Africa, central and southern South America, and arctic areas in North America. Despite the latter negative results, they found all six of the latitudinal bands they analyzed showed positive trends. Consequently, for the globe as a whole (the conglomerate of the six latitude bands they analyzed), they note, "LAI has increased at a rate of 0.0013 per year during July 1981–December 2006," while for the middle and high northern latitudes (north of 30°N), the linear LAI trend was 0.0032 per year.

Some researchers have expressed doubts the positive trends in global biospheric productivity are real or sustainable in a CO_2-induced globally warmed world of the future. Gloor *et al*. (2010) note the ratio of CO_2 accumulating in the atmosphere to the CO_2 flux into the atmosphere due to human activities—known as the airborne fraction (AF)—is central to predicting changes in Earth's surface temperature due to greenhouse gas-induced warming. This ratio has remained remarkably constant over the past five decades. However, they report Canadell *et al*. (2007) and Raupach *et al*. (2008) claim to have detected a long-term increasing trend in the airborne fraction, which they interpret as being indicative of "a decreasing trend in the efficiency of the ocean and land carbon sinks."

Gloor *et al*. report Knorr (2009) has challenged Canadell *et al*. and Raupach *et al*. regarding their detection of a positive AF trend, "arguing that given the noise in the data, the trend is not detectable." They then challenge the second claim of Canadell *et al*. and Raupach *et al*.—their contention a positive AF trend indicates a decreasing planetary carbon sink efficiency—by investigating "the question of what controls trends and decadal scale variations in CO_2 airborne fraction using simple linear models describing the evolution of an atmospheric perturbation in CO_2."

The three researchers first determined there is no one-to-one association between positive trends in CO_2 flux (due to fossil fuel emissions and changes in land use) to the atmosphere and negative trends in Earth's carbon sink efficiency. Second, they report in order to detect trends in sink efficiencies from the time of fossil fuel-derived CO_2 emissions and temporal changes in land use, "it is necessary to disentangle the spin-up time and fossil fuel growth rate variation signatures in the airborne fraction from signatures due to other causes." They make the pertinent

calculations for fossil-fuel and land-use changes and state they "do indeed find a positive trend in the residuals," but they argue this trend "is not statistically significant after correcting for known events such as the temporal distribution of the extrinsic forcings and likely omissions in the emissions (particularly from land-use change)." They note their analysis suggests "trends in airborne fraction are not a very good diagnostic to detect changes in carbon sink efficiency because variations in the signal are complex and the signal-to-noise ratio is small."

In describing another doubt about the recent greening of the Earth, Zhao and Running (2010) state "previous studies have shown that climate constraints were relaxing with increasing temperature and solar radiation, allowing an upward trend in NPP [net primary production] from 1982–1999," but over the past decade (2000–2009), satellite data "suggest a reduction in the global NPP." This finding caused some alarm in the scientific community. Zhao and Running demonstrate there is likely no cause for concern.

The graphical representation of this trend (Figure 4.2.1.5) illustrates that apart from the starting point of the initial year (2000) of their study, there is only one other year (2004) in which the global NPP was greater than it was at the end of the study (2009). Since global NPP was on the rise in 1982–1999, the more recent data would more accurately be described as a leveling off of that prior upward trend. Zhao and Running report the leveling off of global NPP over the past decade was induced by drought, and climate models have long predicted more frequent and more intense droughts would accompany global warming.

Figure 4.2.1.5. Interannual variations from the mean of global NPP over the past ten years. Adapted from Zhao and Running (2010).

The two researchers write, "NPP in the tropics explains 93% of variations in the global NPP," and "tropical rainforests explain 61% of global NPP variations." These findings are especially important because of the work of Coelho and Goddard (2009), who studied El Niño-induced tropical droughts as portrayed in climate models.

Coelho and Goddard write, "the majority of drought-related hazards and the attendant economic losses and mortality risks reside in the tropics," citing Dilley *et al*. (2005); They further note "changes in climate variability, including more frequent and damaging extreme events such as drought, is one of many anticipated impacts of climate change." More specifically (and germane to the subject at hand), they write, "El Niño brings widespread drought (i.e., precipitation deficit) to the tropics," and "stronger or more frequent El Niño events in the future" would "exacerbate drought risk in highly vulnerable tropical areas."

The two researchers evaluated "the patterns, magnitude, and spatial extent of El Niño-induced tropical droughts during a control period in the twentieth century in climate simulations, which have realistic evolution of greenhouse gases," after which they examined "the projected changes in the characteristics of El Niño and in the strength of the identified patterns of El Niño-induced tropical drought in the twenty-first century." That information allowed them to examine patterns of mean precipitation changes in order to "assess whether those changes exacerbate or ameliorate the risk of El Niño-induced drought conditions in the twenty-first century."

In the first instance, Coelho and Goddard say the models they studied "exhibit realistic patterns, magnitude, and spatial extent of El Niño-induced drought patterns in the twentieth century," and "the teleconnections are not projected to change in the twenty-first century." They add, "a possible slight reduction in the spatial extent of droughts is indicated over the tropics as a whole." They also report "all model groups investigated show similar changes in mean precipitation for the end of the twenty-first century, with increased precipitation projected between 10°S and 10°N."

De Jong *et al*. (2012) employed "detection of trend changes in normalized difference vegetation index (NDVI) satellite data between 1982 and 2008,"

based on "time series of 648 fortnightly images [that] were analyzed using a trend breaks analysis procedure," for 14 classes of land cover (biomes). The four researchers found short-term greening and browning trends in portions of the studied period for almost 15% of Earth's land surface, but for the entire time period, "net greening was detected in all biomes," and "the net global figure—considered over the full length of the time series—showed greening since the 1980s."

Ballantyne *et al*. (2012) used "global-scale atmospheric CO_2 measurements, CO_2 emission inventories and their full range of uncertainties to calculate changes in global CO_2 sources and sinks during the past fifty years." The five U.S. scientists say their mass balance analysis shows "net global carbon uptake has increased significantly by about 0.05 billion tonnes of carbon per year and that global carbon uptake doubled, from 2.4 ± 0.8 to 5.0 ± 0.9 billion tonnes per year, between 1960 and 2010" (see Figure 4.2.1.6).
Figure 4.2.1.6. Annual global net carbon (C) uptake by Earth's lands and oceans (solid blue line) for 1959–2010, adapted from Ballantyne *et al*. (2012). The linear trend (dashed red line) and 1σ (dark shaded bands) and 2σ (light shaded bands) uncertainties are also shown.

They conclude, "although present predictions indicate diminished C uptake by the land and oceans in the coming century, with potentially serious consequences for the global climate, as of 2010 there is no empirical evidence that C uptake has started to diminish on the global scale." Their results clearly indicate just the opposite appears to be the case, with global carbon uptake doubling over the past half-century. This most recent effort refutes the hypothesis of Canadell *et al*. (2007) and Raupach *et al*. (2008), who claimed to have detected a decreasing trend in

the efficiency of the planet's carbon sinks, and it vindicates the many studies described above revealing an increasing greening of planet Earth.

The above-described research demonstrates the terrestrial biomass of the globe has been rising, and it appears to be doing so at a remarkable rate. It is also clear recent increases in atmospheric CO_2 and temperature have positively affected those trends, likely responsible for the lion's share of the observed increase. This remarkable increase in biospheric productivity and observed greening of the Earth has occurred in spite of several real assaults on the globe's vegetation, such as deforestation and other land-use changes.

4.2.2 Continental Terrestrial

The following subsections analyze terrestrial productivity trends on continental and subcontinental scales, detailing what researchers have reported for Africa, Asia, Australia, Europe, North America, and South America.

4.2.2.1 Africa

- The ongoing rise in the air's CO_2 concentration and its anti-transpiration effect, which improves plant water-use efficiency, are enhancing and will continue to enhance the vegetative productivity of Africa.

According to a 2002 *New Scientist* article by Fred Pearce, "Africa's deserts are in 'spectacular' retreat," as vegetation is reclaiming great tracts of barren land across the entire southern edge of the Sahara. He notes, "the southern Saharan desert is in retreat, making farming viable again in what were some of the most arid parts of Africa." He writes, "Burkina Faso, one of the West African countries devastated by drought and advancing deserts 20 years ago, is growing so much greener that families who fled to wetter coastal regions are starting to go home."

"Vegetation," Pearce writes, "is ousting sand across a swathe of land stretching from Mauritania on the shores of the Atlantic to Eritrea 6000 kilometers away on the Red Sea coast." In addition to being widespread geographically, the greening was widespread in time, occurring since at least the mid-1980s.

Quoting Chris Reij of the Free University of Amsterdam, Pearce writes, "aerial photographs taken in June show 'quite spectacular regeneration of vegetation' in northern Burkina Faso." The data indicate the presence of more trees for firewood and more grassland for livestock. In addition, a survey Reij was collating showed, according to Pearce, "a 70 percent increase in yields of local cereals such as sorghum and millet in one province in recent years."

Kjeld Rasmussen of the University of Copenhagen studied the same area, reporting that since the 1980s there has been a "steady reduction in bare ground" with "vegetation cover, including bushes and trees, on the increase on the dunes."

Pearce also reports on the work of a team of geographers from Britain, Sweden, and Denmark who spent much of the summer of 2001 analyzing archived satellite images of the Sahel. Citing Andrew Warren of University College London as a source of information on this study, he says the results show "that 'vegetation seems to have increased significantly' in the past 15 years, with major regrowth in southern Mauritania, northern Burkina Faso, north-western Niger, central Chad, much of Sudan and parts of Eritrea."

In a study of a series of satellite images of the Central and Western Sahel taken from 1980 to 1995, Nicholson *et al*. (1998) found no evidence of any overall expansion of deserts and no drop in the rainfall use efficiency of native vegetation. Prince *et al*. (1998) further observed, in a satellite study of the Sahel from 1982 to 1990, a steady rise in rainfall use efficiency, suggesting plant productivity and coverage of the desert increased during this period.

Eklundh and Olsson (2003) provide further evidence. They analyzed normalized difference vegetation index (NDVI) data obtained from the U.S. National Oceanic and Atmospheric Administration's

satellite-borne advanced very high resolution radiometer (AVHRR) whenever it passed over the African Sahel for the years 1982–2000. They write, "strong positive change in NDVI occurred in about 22% of the area, and weak positive change in 60% of the area," and "weak negative change occurred in 17% of the area, and strong negative change in 0.6% of the area." In addition, "integrated NDVI has increased by about 80% in the areas with strong positive change," whereas in areas with weak negative change, "integrated NDVI has decreased on average by 13%." The primary story these data tell, therefore, is of strong positive trends in NDVI for large areas of the African Sahel over the last two decades of the twentieth century, and Eklundh and Olsson conclude the "increased vegetation, as suggested by the observed NDVI trend, could be part of the proposed tropical sink of carbon."

Many more scientists subsequently confirmed the recent stunning increase in African vegetation. In 2005, Africa was featured in a special issue of the *Journal of Arid Environments,* "The 'Greening' of the Sahel." In that issue, Anyamba and Tucker (2005) describe their development of an NDVI history of the region for the years 1981–2003. Comparing this history with the precipitation history of the Sahel developed by Nicholson (2005), they report, "the persistence and spatial coherence of drought conditions during the 1980s is well represented by the NDVI anomaly patterns and corresponds with the documented rainfall anomalies across the region during this time period." In addition, "the prevalence of greener than normal conditions during the 1990s to 2003 follows a similar increase in rainfall over the region during the last decade."

In another analysis of NDVI and rainfall data in the same issue of the *Journal of Arid Environments*, Olsson *et al*. (2005) report finding "a consistent trend of increasing vegetation greenness in much of the region," which they describe as "remarkable." They say increasing rainfall "is certainly one reason" for the greening phenomenon but "does not fully explain" the increase in greenness.

The three Swedish scientists note, "only eight out of 40 rainfall observations showed a statistically significant increase between 1982–1990 and 1991–1999." In addition, "further analysis of this relationship does not indicate an overall relationship between rainfall increase and vegetation trend." Olsson *et al*. suggest "another potential explanation could be improved land management, which has been shown to cause similar changes in vegetation response elsewhere (Runnstrom, 2003)." However, in more

detailed analyses of Burkina Faso and Mali, where production of millet rose by 55% and 35%, respectively, since 1980, they could find "no clear relationship" between agricultural productivity and NDVI, which argues against the land management explanation.

Olsson *et al*. then suggest the greening of the Sahel could be caused by increasing rural-to-urban migration. In this scenario, widespread increases in vegetation occur as a result of "reduced area under cultivation," due to a shortage of rural laborers, and/or "increasing inputs on cropland," such as seeds, machinery, and fertilizers made possible by an increase in money sent home to rural households by family members working in cities. Olsson *et al*. note, "more empirical research is needed to verify this [hypothesis]."

Ichii *et al*. (2005) "simulated and analyzed 1982–1999 Amazonian, African, and Asian carbon fluxes using the Biome-BGC prognostic carbon cycle model driven by National Centers for Environmental Prediction reanalysis daily climate data," after which they "calculated trends in gross primary productivity (GPP) and net primary productivity (NPP)." They found solar radiation variability to be the primary factor responsible for interannual variations in GPP, followed by temperature and precipitation variability. As to GPP trends, the authors report, "recent changes in atmospheric CO_2 and climate promoted terrestrial GPP increases with a significant linear trend in all three tropical regions." In the African region, the rate of GPP increase was about 0.3 PgC year^{-1} per decade. In identifying the major cause of the increased growth, Ichii *et al*. favored carbon dioxide, reporting "CO_2 fertilization effects strongly increased recent NPP trends in regional totals."

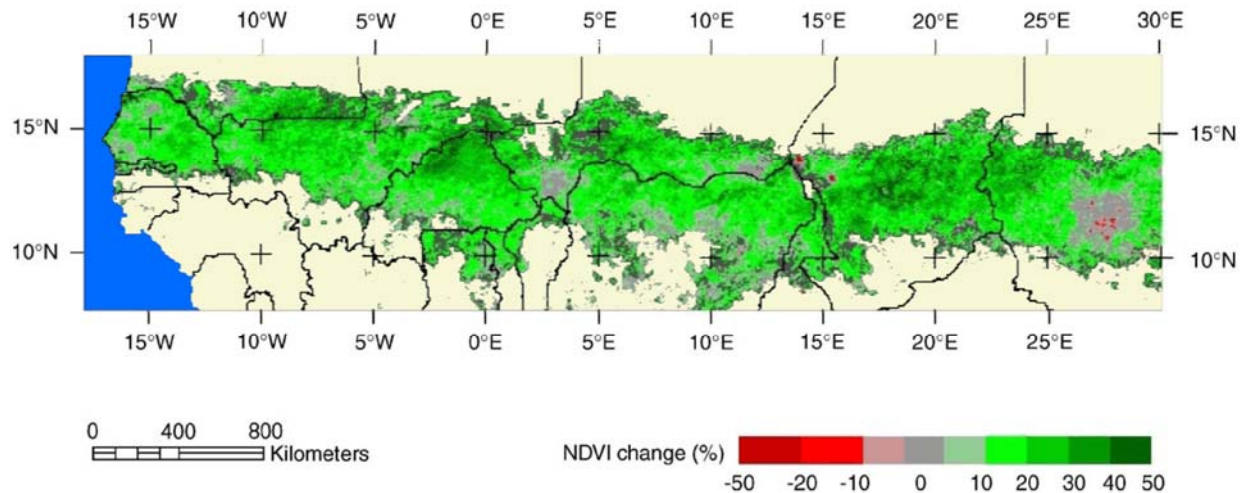
Herrmann *et al*. (2005) investigated the "temporal and spatial patterns of vegetation greenness and rainfall variability in the African Sahel and their interrelationships based on analyses of Normalized Difference Vegetation Index (NDVI) time series for the years 1982–2003 and gridded satellite rainfall estimates." The three researchers determined "the overall trend in monthly maximum NDVI [was] positive over a large portion of the Sahel region, reaching up to 50% increase in the average NDVI in parts of Mali, Mauritania and Chad" (see Figure 4.2.2.1.1). In addition, they report, "rainfall emerges as the dominant causative factor in the dynamics of vegetation greenness in the Sahel at an 8 km spatial resolution," but "the presence of spatially coherent and significant long-term trends in the residuals suggests that there might be another, weaker,


Figure 4.2.2.1.1. Percent change in vegetation greenness throughout the African Sahel during the years 1982–2003 based on monthly AVHRR NDVI time series data. Percentages indicate changes in average NDVI between 1982 and 2003. Adapted from Herrmann *et al*. (2005).

causative factor," as the "recovery of vegetation greenness [was] beyond what would be expected from the recovery of rainfall conditions alone."

Herrmann *et al*. state their study "confirms previous regional-scale findings for the years 1982–1999 by Eklundh and Olsson (2003) and Olsson *et al*. (2005), who observed widespread positive trends of both time-integrated NDVI and NDVI amplitudes, and Anyamba and Tucker (2005), who [observed] increases in growing season NDVI across most parts of the region." They conclude, "a greening of the Sahel expressed in positive trends in NDVI indicates a net increase in biomass production during the period 1982–2003, which challenges the notion of irreversible desertification in the Sahel."

Midgley and Seydack (2006) note "present and predicted future impacts of global environmental change on intact forests are both alarming and contentious," and "some local models have predicted the demise of South Africa's only significant extent of indigenous forest, the Knysna forest, by 2050," as reported by Midgley *et al*. (2001). To see how bad things had become by the end of the twentieth century, the authors measured and analyzed the growth of all trees greater than 10 cm in diameter at breast height in 108 0.04-ha plots distributed throughout an unharvested nature reserve in the Knysna forest for the years 1991–2001.

Following a protocol that provided what they say is "probably an under-estimate," the two researchers state, "net basal area and aboveground biomass increased over the 10-year study period by 2% and

there was a 1.2% increase in stem numbers, distributed almost equally amongst all size-classes." Because of the nature of the Knysna forest, Midgley and Seydack say "over relatively short periods such as our decade, the aboveground biomass of this forest is more sensitive to negative/stressful conditions that would increase mortality, than to factors which may increase growth." Nevertheless, they found "biomass increased." And because "precipitation over the period 1991–2001 was some 5% less than the long-term average," they conclude the observed increase in growth rate "may have been the effect of the increase in global atmospheric carbon dioxide."

Seaquist *et al*. (2006) provided important new details about the "greening up" of the African Sahel. Using a satellite data-driven light-use efficiency model to assess changes in absolute amounts of net primary production (NPP), expressed as carbon content, and its interannual variability in the African Sahel for the years 1982–1999, Seaquist *et al*. report they found an extensive, albeit discontinuous, east-west band of NPP increase (>10 g C m^{-2} year^{-1}). The band extends up to about 17°N and includes several hotspots (>20 g C m^{-2} year^{-1}) in central Senegal, south-western Mali, southern Chad, southern Sudan, and the Ivory Coast and southern Benin. For the Sahel in its entirety, the researchers calculate the mean rate of change per pixel was 8.4 g C m^{-2} year^{-1}, yielding a total mean rate of change of 51.0 Mt C year^{-1} and an absolute net gain in NPP over the 18-year period of 918.0 Mt C. In addition, they report, "this increase is associated with a decrease in the inter-annual

variability of NPP for the 1990s compared to the 1980s," such that "overall, the increase in NPP through time appears to be associated with an increase in the stability of this ecosystem," with the changes in carbon capture and increase in stability being driven primarily by rainfall "followed by atmospheric CO_2."

Lewis *et al*. (2009a) documented changes in aboveground carbon storage in "79 permanent sample plots spanning 40 years (1968–2007), located in closed-canopy moist forest, spanning West, Central and Eastern Africa," based on data on more than 70,000 individual trees in 10 countries. They found "aboveground carbon storage in live trees increased by 0.63 Mg C ha^{-1} year^{-1} between 1968 and 2007," and "extrapolation to unmeasured forest components (live roots, small trees, necromass) and scaling to the continent implies a total increase in carbon storage in African tropical forest trees of 0.34 Pg C year^{-1}."

The 33 researchers say the observed changes in carbon storage "are similar to those reported for Amazonian forests per unit area, providing evidence that increasing carbon storage in old-growth forests is a pan-tropical phenomenon," and "combining all standardized inventory data from this study and from tropical America and Asia together yields a comparable figure of 0.49 Mg C ha^{-1} year^{-1}," which equates to "a carbon sink of 1.3 Pg C year^{-1} across all tropical forests during recent decades." That can account for roughly half of the so-called missing carbon sink.

Lewis *et al*. conclude, "taxon-specific analyses of African inventory and other data suggest that widespread changes in resource availability, such as increasing atmospheric carbon dioxide concentrations, may be the cause of the increase in carbon stocks, as some theory (Lloyd and Farquhar, 1996) and models (Friedlingstein *et al*., 2006; Stephens *et al*., 2007; Ciais *et al*., 2008) predict."

Ciais *et al*. (2009) modeled the terrestrial carbon balance of Africa over the past century (1901–2002) using a spatially resolved process-based vegetation model (ORCHIDEE), which is forced by changing climate, human-induced changes in land use, and a parameterization of natural fires. They found the African net terrestrial carbon (C) balance increased "from a net CO_2 source to the atmosphere of 0.14 Pg C per year in the 1980s to a net sink of 0.15 Pg C per year in the 1990s." In addition, the land use flux due to deforestation was "a source of 0.13 Pg C per year," and "this implies that climatic trends (mainly increasing precipitation) and CO_2 increase (the fertilization effect), are causing a sink of 0.28 Pg C per year which

offsets the land-use source."

The five researchers write, "the trend of gross primary production is closely matching the trend in satellite observed NDVI." They state their simulated trend in gross primary production "is also consistent with an increased vegetation activity over [the] Sahel reported by Eklundh and Olsson (2003) and Olsson *et al*. (2005)." At the continental scale, they say the gross primary production trend can be largely (70%) explained by the CO_2 fertilization effect.

Doherty *et al*. (2010) modeled future changes in land biogeochemistry and biogeography in the region bounded by 12.5°N, 12.5°S, 25°E, and 42.5°E, representing most of East Africa (Kenya, Tanzania, Uganda, Rwanda, Burundi, Ethiopia, and Somalia) and portions of Central Africa (the Democratic Republic of Congo and Southern Sudan). They used 18 future climate projections derived from nine general circulation models that figured prominently in IPCC's *Fourth Assessment Report*, employing the projections as input to the Lund-Potsdam-Jena dynamic global vegetation model that simulates changes in vegetation and ecosystem carbon cycling under future climate conditions, based on what they describe as "a coupled photosynthesis-hydrological scheme [that] computes gross primary productivity, plant respiration, and evapotranspiration on a daily time step based on the current climate, atmospheric CO_2 concentration, vegetation structure and phenological state, and soil water content."

Doherty *et al*. report "all simulations showed future increases in tropical woody vegetation over the region at the expense of grasslands," noting "regional increases in net primary productivity (18–36%) and total carbon storage (3–13%) by 2080–2099 compared with the present-day were common to all simulations," and "seven out of nine simulations continued to show an annual net land carbon sink in the final decades of the 21st century because vegetation biomass continued to increase." They write, "overall, our model results suggest that East Africa, a populous and economically poor region, is likely to experience some ecosystem service benefits through increased precipitation, river runoff and fresh water availability," and "resulting enhancements in net primary productivity may lead to improved crop yields in some areas." They note their results "stand in partial contradiction of other studies that suggest possible negative consequences for agriculture, biodiversity and other ecosystem services caused by temperature increases."

Scheiter and Higgins (2009) write, "recent IPCC projections suggest that Africa will be subject to

particularly severe changes in atmospheric conditions" in the future, and these changes could have equally severe repercussions for its flora and fauna. How the continent's "grassland-savanna-forest complex will respond to these changes has rarely been investigated," they note, and "most studies on global carbon cycles use vegetation models that do not adequately account for the complexity of the interactions that shape the distribution of tropical grasslands, savannas and forests."

The two scientists developed a new vegetation model—the adaptive dynamic global vegetation model (aDGVM)—that employs established submodels for photosynthesis, respiration, canopy scaling, competition for water, competition for light, reproduction, and mortality. Their model also contains novel elements: dynamic carbon allocation and phenology functions, as well as a fire model that estimates fire intensity as a function of fuel biomass, fuel moisture, and wind speed, and which simulates topkill (stem mortality) as a function of individual tree size and fire intensity. All of these phenomena are related to the individual plant's physiological state and the environmental conditions surrounding it.

Simulations to the year 2100 with this model suggest "grasslands will spread into the Sahara and into the horn of Africa, such that the total area covered by deserts or bare soil decreases by 5.7%." In addition, "it is predicted that 34.6% of today's grasslands are transformed into savannas," and "45.3% of today's savannas are transformed into deciduous woodlands." As a result, "the total biomass stored in each of the biomes increases, with high relative changes in grasslands and savannas (by 256% and 241%, respectively)," with a 102% increase in tree biomass.

Heubes *et al*. (2011) modeled the future spatial distribution of desert, grassland, savanna, and deciduous and evergreen forests in West Africa using six bioclimatic models. None of the models accounted for the photosynthetic-enhancing and transpiration-reducing effects of projected increases in atmospheric CO_2 concentration, as they were based solely on the climatic projections of 17 general circulation models of the atmosphere for emissions scenario A2a, as described in the *Fourth Assessment Report* of IPCC (2007). These projections were downscaled to 0.1 degree of latitude and longitude as described by Ramirez and Jarvis (2008).

Heubes *et al*. report finding "a climate-driven greening trend," with "northward spread of grassland into the Sahara and the replacement of savannas by deciduous forest." These results, they write, "are

concordant with results from Cramer *et al*. (2001), Scholze *et al*. (2006) and Scheiter and Higgins (2009)," although they add the latter investigators "attributed the greening to increased CO_2 levels." They say the models they used "indicate climatic change alone can yield this pattern," where "the expected 'greening' of the Sahara is primarily driven by increasing precipitation," as they note Hickler *et al*. (2005) also suggested.

Using satellite images that reflect the region's current vegetation state, Heubes *et al*. additionally modeled "real" as opposed to "potential" vegetation, which enabled them to "clearly show," as they describe it, "effects of human activity negatively affecting tree cover, as also demonstrated by other case studies, e.g. in Senegal (Vincke *et al*., 2010) and Mali (Ruelland *et al*., 2010)." They report, in West Africa, "agricultural expansion, sometimes facilitated by other human activities such as wood extraction, has been identified as major drivers of forest loss and degradation," citing Norris *et al*. (2010).

"Considering climate change alone," Heubes *et al*. write, "the model results of potential vegetation (biomes) show a 'greening' trend by 2050," although "the modeled effects of human impact suggest future forest degradation."

The research presented here indicates the ongoing rise in the air's CO_2 concentration and its anti-transpiration effect, which improves plant water-use efficiency, are enhancing and will continue to enhance the vegetative productivity of Africa.

4.2.2.2 Asia

- The rise of the air's CO_2 concentration and temperature to their highest values of the past century enhanced the terrestrial vegetative productivity of all parts of Asia, including deserts, forests, grasslands, and the Tibetan Plateau.

Many scientists have examined terrestrial productivity trends in Asia, with a vast majority of those studies focusing on locations in China. The material below is arranged into two sub-headings: *China* and *All Other Asian Countries*. In addition, given the sheer number of studies conducted in China, that subsection is further divided into five sub-regions: *Country-wide*, *Deserts*, *Forests*, *Grasslands*, and the *Tibetan Plateau*.

4.2.2.2.1 China

4.2.2.2.1.1 Country-wide

Liu *et al*. (2004) derived detailed estimates of the economic impact of predicted climate change on agriculture in China. They used county-level agricultural, climate, social, economic, and edaphic data for 1,275 agriculture-dominated counties for the years 1985–1991, together with the outputs of three general circulation models of the atmosphere based on five scenarios of anthropogenic CO_2-induced climate change that yielded a mean countrywide temperature increase of 3.0°C and a mean precipitation increase of 3.9% for the 50-year period ending in AD 2050. They determined "all of China would benefit from climate change in most scenarios." They also note, "the effects of CO_2 fertilization should be included, for some studies indicate that this may produce a significant increase in yield."

Fang *et al*. (2003) also looked at the whole of China, finding its terrestrial NPP increased by 18.7%

between 1982 and 1999. Referring to this result as "an unexpected aspect of biosphere dynamics," they say this increase "is much greater than would be expected to result from the fertilization effect of elevated CO_2, and also greater than expected from climate, based on broad geographic patterns." They may be wrong in that assessment. From 1982 to 1999 the atmosphere's CO_2 concentration rose by approximately 27.4 ppm, which could be expected to have increased the NPP of the forest types found in China by about 7.3% (see http://www.co2science.org/ articles/V5/N38/EDIT.php for an explanation of this calculation).

And this increase is only part of the total NPP increase one could expect, for Fang *et al*. note "much of the trend in NPP appeared to reflect a change towards an earlier growing season," which was driven by the 1.1°C increase in temperature they found in their region of study between 1982 and 1999. White *et al*. (1999) analyzed 88 years of data (1900–1987) from 12 locations in the eastern U.S. deciduous forest that stretches from Charleston, South Carolina to Burlington, Vermont, finding a 1°C increase in mean annual air temperature increases the length of the forest's growing season by approximately five days. They further report a one-day extension in growing season increased the mean forest NPP of the 12 sites they studied by an average of 1.6%.

Applying White *et al.*'s results to Fang *et al*.'s findings suggests there could easily be an additional increase in the NPP of China's forests due to the warming-induced growing season expansion experienced there from 1982 to 1999: 1.6%/day x 5 days = 8.0%, bringing the total CO_2-induced plus warming-induced increase in NPP for China to 15.3%.

Moreover, as noted previously in this chapter, there is a well-documented positive synergy between increasing air temperature and CO_2 concentration (Idso and Idso, 1994), so the 1°C increase in temperature experienced in China between 1982 and 1999 could easily boost the initial CO_2-induced 7.3% NPP enhancement to 10.7% . That, when combined with the 8.0% enhancement caused by the warming-induced increase in growing season length, would produce the 18.7% increase in NPP Fang *et al*. detected in the satellite data.

Piao *et al*. (2005a) found "terrestrial NPP in China increased at a rate of 0.015 Pg C yr^{-1} over the period 1982–1999, corresponding to a total increase of 18.5%, or 1.03% annually." They also report, "during the past 2 decades the amplitude of the seasonal curve of NPP has increased and the annual

peak NPP has advanced," which "may indirectly explain the enhanced amplitude and advanced timing of the seasonal cycle of atmospheric CO_2 concentration (Keeling *et al*., 1996)." They further suggest the enhanced amplitude of the seasonal CO_2 cycle "was probably due to the rise in atmospheric CO_2 concentration, elevated temperature, and increased atmospheric N and P deposition," and they attribute the advanced timing of the seasonal cycle to "advanced spring onset and extended autumn growth owing to climate warming."

Citing 20 scientific papers, Piao *et al*. conclude "results from observed atmospheric CO_2 and O_2 concentrations, inventory data, remote sensing data, and carbon process models have all suggested that terrestrial vegetation NPP of the Northern Hemisphere has increased over the past 2 decades and, as a result, the northern terrestrial ecosystems have become important sinks for atmospheric CO_2."

Zhu *et al*. (2007a) analyzed 18 years (1982–1999) of climatic data and satellite observations of normalized difference vegetation index (NDVI) throughout China, calculating terrestrial vegetative net primary productivity (NPP) using the revised light-use efficiency model of Zhu *et al*. (2006) and Zhu *et al*. (2007b). They find "climatic changes in China have eased some critical climatic constraints on plant growth." They note, for example, "water availability most strongly limits vegetation growth over 28% of the whole country surface, whereas temperature limits growth over 43% and radiation over 29%," but "from 1982 to 1999, modeled NPP increased by 1.42% per year in water-limited regions of Northwest China, 1.46% per year in temperature-limited regions of Northeast China and Tibet Plateau, and 0.99% per year in radiation-limited regions of South China and East China." Summed over the 18-year period, total Chinese terrestrial vegetation NPP increased by 24.2%. They report "interannual variations of NPP in Chinese terrestrial vegetation are positively correlated with global increases in atmospheric CO_2 growth rate, indicating that NPP in Chinese terrestrial vegetation will increase with the global increases in atmospheric CO_2 growth rate."

Peng *et al*. (2011) report, "using satellite-derived normalized difference vegetation index (NDVI) datasets, previous studies have found that vegetation growth significantly increased in most areas of China during the period 1982–99 and that the increased vegetation growth was significantly correlated with increased temperature (e.g., Zhou *et al*., 2001; Piao *et al*., 2003)." In addition, "the increased temperature boosted vegetation growth through an increase in growing season length and enhanced photosynthesis (e.g., Zhou *et al*., 2001; Slayback *et al*., 2003; Piao *et al*., 2006b)."

Peng *et al*. used NOAA/AVHRR NDVI composites at a spatial resolution of 0.083° and 15-day intervals produced by the Global Inventory Modeling and Mapping Studies (GIMMS) program, Tucker *et al*. (2005), to explore vegetation activity over China for the years 1982–2010. They note "the GIMMS NDVI datasets have been corrected to minimize the effects of volcanic eruptions, solar angle and sensor errors and shifts," as described by Zhou *et al*. (2001) and Slayback *et al*. (2003), and state these datasets also have proved to be "one of the best products to depict the temporal change of vegetation growth," as Beck *et al*. (2011) demonstrated.

At the national scale and for the average growing season (April–October) a linear regression model predicts a significant increasing NDVI trend of 0.0007/year from 1982 to 2010, with an R^2 value of 0.40 and P < 0.001 (see Figure 4.2.2.2.1.1.1). They also found increasing trends for all three subsets of the growing season: April–May, June–August, and September–October.

Figure 4.2.2.2.1.1.1. Interannual variations in growing season (April-October) NDVI for China during the years 1982–2010. The linear trend in the data, as mentioned in the text, is also shown. Adapted from Peng *et al*. (2011).

Mao *et al*. (2009) used a modified version of the Sheffield Dynamic Global Vegetation Model described by Woodward and Lomas (2004) to study changes in the structure, composition, and carbon storage of vegetation and soils throughout China in response to changes in climate and atmospheric CO_2 concentration between 1901 and 2000. They report their modeling exercise indicates "during the past

100 years a combination of increasing CO_2 with historical temperature and precipitation variability in continental China have caused the total vegetation carbon storage to increase by 2.04 Pg C, with 2.07 Pg C gained in the vegetation biomass but 0.03 Pg C lost from the organic soil carbon matter." They also found "the increasing CO_2 concentration in the 20th century is primarily responsible for the increase of the total potential vegetation carbon."

Mu *et al*. (2008) used "a well-documented daily ecosystem process model Biome-BGC (Running and Hunt, 1993; White *et al*., 2000; Thornton *et al*., 2002) to differentiate the effects of changing climate and increasing CO_2 on the carbon cycle for terrestrial China for two time periods, 1961–2000 (present conditions), and future (2071–2110) conditions with projected climate change under doubled CO_2." The five researchers write, "during 1961–2000 at the national scale, changes in climate reduced carbon storage in China's ecosystems, but increasing CO_2 compensated for these adverse effects of climate change, resulting in an overall increase in the carbon storage of China's ecosystems." They continue, "under the future scenario (2071–2110), with a doubling [of] CO_2, China will experience higher precipitation and temperature," but "the concomitant doubling of CO_2 will continue to counteract the negative effects of climate change on carbon uptake in the future, leading to an increase in carbon storage relative to current levels."

4.2.2.2.1.2 Deserts

Brogaard *et al*. (2005) examined the dry northern and northwestern regions of China, including the Inner Mongolia Autonomous Region (IMAR), which had been thought to have experienced declining vegetative productivity over the past few decades due to "increasing livestock numbers, expansion of cultivated land on erosive soils and the gathering of fuel wood and herb digging." These practices were believed to have been driven by rising living standards that, in combination with a growing population, increased the pressure on these marginal lands. Brogaard *et al*. note the total number of livestock in the IMAR increased from approximately 46 million head in 1980 to about 71 million in 1997.

To better assess the seriousness of this "ongoing land degradation process," as they describe it, the researchers adapted a satellite-driven parametric model, originally developed for Sahelian conditions, to the central Asian steppe region of the IMAR by

including "additional stress factors and growth efficiency computations." The applied model, they write, "uses satellite sensor-acquired reflectance in combination with climate data to generate monthly estimates of gross primary production." They found, "despite a rapid increase in grazing animals on the steppes of the IMAR for the 1982–1999 period," their model estimates did "not indicate declining biological production."

Clearly, some strong positive influence compensated for the increased human and animal pressures on the lands of the IMAR over the period of Brogaard *et al*.'s study. They mention the possibility of increasing productivity on the agricultural lands of the IMAR, but crops are grown on "only a small proportion of the total land area." They also mention "an increase in precipitation, as well as afforestation projects." Two things they do not mention are the aerial fertilization and transpiration-reducing effects of the increase in the air's CO_2 concentration over the study period. Applied together, these positive influences, and possibly others that remain unknown, are demonstrably sufficient to keep plant productivity from declining in the face of greatly increasing animal and human pressures.

Yang *et al*. (2011) studied *Caragana microphylla* plantations established five to 40 years ago in the semi-arid Loess Plateau of northwestern Shanxi, China in efforts to combat desertification, which in the 1960s had claimed 48.5% of the region's surface area. These perennial leguminous and sand-binding shrubs have well-developed stems with many clustered branches and large root systems capable of adapting to poor nutrient conditions, and they were positioned in groups to act as sand barriers and windbreaks.

The establishment and development of the *C. microphylla* shrubs, in the words of the five Chinese scientists, "improved soil texture, enhanced soil organic matter (SOM), total nitrogen (TN), and cation exchange capacity (CEC)." In addition, "SOM, TN, and CEC were significantly higher at the center than at the outside of the shrub canopies and were higher at the 0–5 cm depth than at the 5–10 cm depth." They report "the differences in SOM, TN, and CEC from the center to the outside of shrub canopies were greater under 30- and 40-year-old shrubs than under 10- and 5-year-old shrubs." They found the spatiotemporal heterogeneity of the soil properties "facilitated the development of herbaceous species diversity and the restoration of the [region's] natural ecosystem," which had been lost to desertification.

Peng *et al*. (2010) used snow-depth measure-

ments collected at 279 meteorological stations across China, plus co-located satellite-derived normalized difference vegetation index (NDVI) data, to investigate spatio-temporal changes in snow depth for the years 1980–2006 and the effects of those changes on vegetative growth the following spring and summer. The five researchers report, "over the past three decades, winter snow depth overall increased in northern China, particularly in the most arid and semiarid regions of western China where desert and grassland are mainly distributed." In those areas they found positive correlations between mean winter snow depth and spring NDVI data. They also note Piao *et al*. (2005b) determined the net primary productivity of the same desert and grasslands during 1982–1999 "increased by 1.6% per year and 1.1% per year, respectively," and "desertification has been reversed in some areas of western China since the 1980s," citing Runnstrom (2000), Wu (2001), Zhang *et al*. (2003), and Piao *et al*. (2005b).

Peng *et al*. state the "increase in vegetation coverage in arid and semiarid regions of China, possibly driven by winter snow, will likely restore soil and enhance its anti-wind-erosion ability, reducing the possibility of released dust and mitigating sand-dust storms," noting the frequency of sand-dust storms has indeed "declined in China since the early 1980s (Qian *et al*., 2002; Zhao *et al*., 2004)."

Piao *et al*. (2005b) used a time series of NDVI data from 1982 to 1999, together with precipitation and temperature data, to investigate variations of desert area in China by "identifying the climatic boundaries of arid area and semiarid area, and changes in NDVI in these areas." They discovered "average rainy season NDVI in arid and semiarid regions both increased significantly during the period 1982–1999." They report the NDVI increased for 72.3% of total arid regions and for 88.2% of total semiarid regions, such that the area of arid regions decreased by 6.9% and the area of semiarid regions decreased by 7.9% (see Figure 4.2.2.2.1.2.1). They also report, by analyzing Thematic Mapper satellite images, "Zhang *et al*. (2003) documented that the process of desertification in the Yulin area, Shannxi Province showed a decreased trend between 1987 and 1999," and "according to the national monitoring data on desertification in western China (Shi, 2003), the annual desertification rate decreased from 1.2% in the 1950s to -0.2% at present."

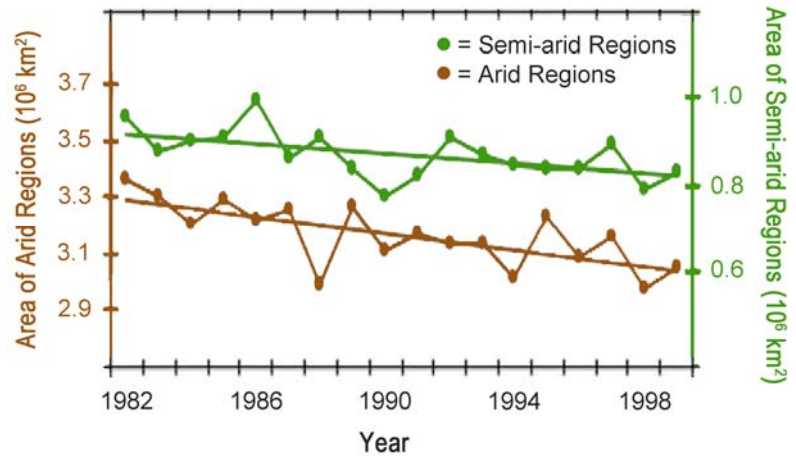
Further noting "variations in the vegetation coverage of these regions partly affect the frequency of sand-dust storm occurrence (Zou and Zhai, 2004)," Piao *et al*. conclude "increased vegetation coverage in these areas will likely fix soil, enhance its anti-wind-erosion ability, reduce the possibility of released dust, and consequently cause a mitigation of sand-dust storms." They report, "recent studies have suggested


Figure 4.2.2.2.1.2.1. Interannual variation in area of arid (brown line) and semiarid region (green line) in China during the years 1982 to 1999. Adapted from Piao *et al*. (2005b).

that the frequencies of strong and extremely strong sand-dust storms in northern China have significantly declined from the early 1980s to the end of the 1990s (Qian *et al*., 2002; Zhao *et al*., 2004)."

Zhao *et al*. (2011) note "many studies based on analyses of satellite images have detected a greening trend at global (Myneni *et al*., 1997; Nemani *et al*., 2003; Potter *et al*., 2007; Zhou *et al*., 2001) and regional scales (Donohue *et al*., 2009; Fang *et al*., 2004; Herrmann *et al*., 2005)," and they point out "the response of vegetation to climatic changes widely differed by biome (Fang *et al*., 2005; Piao *et al*., 2006c) and bioregion (Verbyla, 2008)." Focusing on the grassland-oasis-desert complex of northwest China, the four Chinese researchers "investigated spatio-temporal changes in vegetation growth and their responses to a changing climate by biome and bioregion, using satellite-sensed Normalized Difference Vegetation Index (NDVI) data from 1982 to 2003, along with corresponding climate data."

Over the 22 years of their study, during which annual mean temperature increased by 0.06°C/year, "about 30% of the total vegetated area showed an annual increase of 0.7% in growing season NDVI," they write. This trend "occurred in all biomes and all

bioregions except Sawuer, a sub-region of the study area with no significant climate change." They report the NDVI increase was remarkable during 1982–1988, then tended to be slight, and finally declined a bit from 1998 to 2003. This pattern largely resembles the concomitant pattern of global air temperature change, which could have been responsible for the shifts in regional precipitation that appeared to be driving the observed shifts in NDVI. Zhao *et al*. note "previous analyses of satellite-measured vegetation growth suggested a greening trend of vegetation in the central United States (Wang *et al*., 2001, 2003) and the Sahel (Anyamba and Tucker, 2005; Herrmann *et al*., 2005) due to the effects of increasing precipitation at seasonal or annual scales."

The findings presented above indicate the vegetation in China's deserts has fared well in response to what has been called the most dramatic global warming and CO_2 rise of the past two millennia.

4.2.2.2.1.3 Forests

Ren *et al*. (2011) note, "in recent decades, there has been increased concern that elevated tropospheric ozone (O_3) and climate change have [negatively] influenced the ability of China's ecosystems to provide people with essential goods and services." They investigated "the potential effects of elevated O_3 along with climate change/variability on NPP [net primary production] and NCE [net carbon exchange] in China's forest ecosystems for the period 1961–2005 using a process-based dynamic land ecosystem model (DLEM, Tian *et al*., 2005, 2010a,b)," while also considering "other environmental factors such as land-cover/land-use change (LCLUC), increasing [atmospheric] CO_2 and nitrogen deposition."

Ren *et al*. report O_3 pollution had consistent negative effects on forest production, reducing total NPP by 0.2 to 1.6% from the 1960s to 2000–2005; without O_3 pollution, carbon uptake rates would have increased by 3.5% in the 1960s and 12.6% in the six years of 2000–2005. Climate change had both negative and positive effects on NPP and NCE, and it was thus the major factor controlling the interannual variability of these two productivity parameters.

LCLUC also had negative impacts on NPP and NCE, but Ren *et al*. note "nitrogen deposition alone could compensate for the combined negative effects of O_3 and LCLUC in China." They also report an increase in NPP occurred in the CO_2-N combination simulation, which they write, "was consistent with previous studies (e.g., Ollinger *et al*., 2002; Felzer *et al*., 2004; Hanson *et al*., 2005)." They suggest CO_2 and nitrogen deposition working together "could offset the combined negative effects of O_3 pollution, climate change and LCLUC on annual NCE." It would appear the combination of atmospheric CO_2 enrichment and nitrogen deposition provide powerful antidotes for the negative effects of ozone pollution, land-cover/land-use change, and various deleterious climatic phenomena on NPP and NCE in China and, by inference, other parts of the world as well.

Su and Sang (2004) used an ecosystem process model to explore the sensitivity of the net primary productivity (NPP) of an oak forest near Beijing to the global climate changes projected to result from a doubling of the atmosphere's CO_2 concentration from 355 to 710 ppm. They found the aerial fertilization effect of the increase in the atmospheric CO_2 content would raise the forest's NPP by 14.0%; a concomitant temperature increase of 2°C would boost the NPP increase to 15.7%; and adding a 20% increase in precipitation would push the NPP increase to 25.7%. They also calculate a 20% increase in precipitation and a 4°C increase in temperature would boost the forest's NPP by 25.7%.

Su *et al*. (2007) used a process-based model (BIOME-BGC) "to investigate the response of *Picea schrenkiana* forest to future climate changes and atmospheric carbon dioxide concentration increases in the Tianshan Mountains of northwestern China," which they "validated by comparing simulated net primary productivity (NPP) under current climatic conditions with independent field-measured data." They modeled a double-CO_2-induced temperature increase of 2.6°C and a precipitation increase of 25%.

When they considered the predicted precipitation increase by itself, Su *et al*. found the NPP of the *P. schrenkiana* forest increased by 14.5%. The predicted temperature increase by itself increased forest NPP by 6.4%, and the CO_2 increase by itself boosted NPP by only 2.7%. When the predicted increases in precipitation and temperature occurred together, forest NPP increased by 18.6%, just slightly less than the sum of the two individual effects. When the CO_2 concentration increase was added to the mix and all three factors increased together, the Chinese researchers report forest NPP "increased dramatically, with an average increase of about 30.4%."

Su *et al*. conclude the results derived from the various scenarios of their study indicate "the effects of precipitation and temperature change were simply

additive, but that the synergy between the effects of climate change and doubled CO_2 was important," as it made the whole response much larger than the sum of its separate responses, because "feedback loops associated with the water and nitrogen cycles [which may be influenced significantly by atmospheric CO_2 enrichment] ultimately influence the carbon assimilation response."

4.2.2.2.1.4 Grasslands

Noting the climate of China's temperate grasslands "experienced dramatic change in the past several decades," Piao *et al*. (2006) investigated the impact of that climate change on the productivity of the country's grasslands. They analyzed normalized difference vegetation index (NDVI) data from the U.S. National Oceanic and Atmospheric Administration's very high-resolution radiometer at a spatial resolution of 8 x 8 km and at 15-day intervals from January 1982 to December 1999, comparing those results with temperature, precipitation, and Thornthwaite (1948) moisture index data generated from 680 well-distributed climate stations across China.

Piao *et al*. found little or no increase in precipitation and moisture index over the period of their study. For temperature, they found a least-squares linear warming of 0.89°C between 1982 and 1999 with $R = 0.59$ and $P = 0.009$, which they describe as "dramatic." Even more dramatic, "mean growing season NDVI increased significantly ($R = 0.73$, $P = 0.001$) from 0.25 in 1982 to 0.28 in 1999," or by approximately 12%.

At first glance it would appear the dramatic increase in temperature is what drove the dramatic increase in grassland productivity. But more detailed analyses revealed "the positive effect of temperature on the growth of grassland decreased as temperature rose." Piao *et al*. suggest the "atmospheric CO_2 fertilization effect, increased nutrient deposition, and human activity such as grazing management [and] land abandonment due to migration into urban areas" may have compensated for the decreasing strength of the growth enhancement provided by the region's warming.

One year later, using national grassland resource inventory data, a normalized difference vegetation index (NDVI) time series dataset, and a satellite-based statistical model, Piao *et al*. (2007) identified changes in the size and distribution of the aboveground biomass carbon (C) stocks of China's

grasslands between 1982 and 1999. The authors report "aboveground biomass C stocks ... significantly increased from 136.3 Tg C in the early 1980s to 154.0 Tg C in the late 1990s," for a total increase of 13% (Figure 4.2.2.2.1.4.1). They note "growing season average temperature for the study area increased by 0.052°C per year and growing season precipitation also tended to increase," which led them to conclude "increased temperature may be associated with increasing C stocks and interannual changes in precipitation may be a factor in the fluctuations of C stocks." In addition, the "atmospheric CO_2 fertilization effect and human activity such as land management may also partly account for the observed increase in biomass C stocks of China's grassland."
Figure 4.2.2.2.1.4.1. Interannual variations in aboveground biomass for China's grassland during the years 1982–1999. Adapted from Piao *et al*. (2007).

Peng *et al*. (2010) used snow-depth measurements collected at 279 meteorological stations across China, plus collocated satellite-derived normalized difference vegetation index (NDVI) data, to investigate spatio-temporal changes in snow depth during the years 1980–2006 and the effects of those changes on vegetative growth the following spring and summer. The five researchers report, "over the past three decades, winter snow depth overall increased in northern China, particularly in the most arid and semiarid regions of western China where desert and grassland are mainly distributed," and in those areas there were positive correlations between mean winter snow depth and spring NDVI data. They note Piao *et al*. (2005) determined the net primary productivity of the same desert and grasslands during 1982–1999 "increased by 1.6% per year and 1.1% per year, respectively," and "desertification has been

reversed in some areas of western China since the 1980s," citing Runnstrom (2000), Wu (2001), Zhang *et al*. (2003), and Piao *et al*. (2005).

Peng *et al*. write, the "increase in vegetation coverage in arid and semiarid regions of China, possibly driven by winter snow, will likely restore soil and enhance its antiwind-erosion ability, reducing the possibility of released dust and mitigating sand-dust storms," noting the frequency of sand-dust storms has indeed "declined in China since the early 1980s (Qian *et al*., 2002; Zhao *et al*., 2004)."

As the world warmed over the past three decades, a climatic change across China above 40°N latitude (an increase in winter snow depth) has prompted a biological change (increased vegetative growth in desert areas and grasslands) that has prompted yet another climatic change (a reduction in sand-dust storms). All of these changes are positive developments.

4.2.2.2.1.5 Tibetan Plateau

Taking a long temporal view of how vegetative productivity has fared in this region of China, Herzschuh *et al*. (2011) "critically review possible driving forces for early- to mid-Holocene vegetation shifts on the upper Tibetan Plateau (including precipitation, growing season length, radiation, human impact) with particular emphasis on changing CO_2 concentrations to better predict future environmental change and impacts on the Tibetan Plateau in a rapidly changing world."

The four researchers report, "numerous pollen records from across the upper Tibetan Plateau indicate that *Kobresia*-dominated high-alpine meadow invaded alpine steppes during the mid- to late-Holocene." Their investigation, which employed a pollen-moisture transfer function, indicates "this marked vegetation change cannot be satisfactorily explained by climate change." In addition, they note "a literature review did not reveal convincing evidence for any widespread human impact on mid-Holocene vegetation." They propose the reconstructed vegetation changes likely were "a response to Holocene CO_2 concentration changes," with values rising from approximately 260 ppm in the early Holocene to near-present-day values on the order of 375 ppm.

Their conclusion is based on four lines of evidence: (1) "high-elevation vegetation is particularly sensitive to CO_2 changes due to lowered CO_2 partial pressure"; (2) "water conservation of steppe vegetation in response to experimental CO_2 enrichment was of the same order of magnitude as inferred from mid- to late-Holocene Tibetan pollen records"; (3) "modern remote sensing-aided vegetation monitoring of the Central Tibetan Plateau yielded an increase in biomass, most probably as a response to modern CO_2 increase," even in spite of "increasing land-use by herding"; and (4) "experimental CO_2 fertilization of

dry grassland and desert vegetation performed in several regions world-wide has stimulated plant growth directly through enhanced photosynthesis and indirectly through enhanced water-use efficiency (Morgan *et al*., 2004)."

Zhuang *et al* . (2010) used a process-based biogeochemistry model—the Terrestrial Ecosystem Model or TEM, which also employed a soil thermal model—to examine permafrost dynamics and their effects on the carbon dynamics of the Tibetan Plateau. They accomplished this by "parameterizing and verifying" the TEM using real-world data for soil temperature, permafrost distribution, and carbon and nitrogen distributions throughout the region, and then extrapolating the model and its parameters to the whole of the plateau.

The six scientists report, "during the 20th century, the Tibetan Plateau changed from a small carbon source or neutral in the early part of the century to a sink later" (Figure 4.2.2.2.1.5.1), noting "net primary production and soil respiration increased by 0.52 and 0.22 Tg C/year, respectively, resulting in a regional carbon sink increase of 0.3 Tg C/year," so "by the end of the century, the regional carbon sink reached 36 Tg C/year and carbon storage in vegetation and soils is 32 and 16 Pg C, respectively."

Figure 4.2.2.2.1.5.1. Five year running average of Net Ecosystem Production (NEP) on the Tibetan Plateau during the years 1901–2002. Negative values reveal the region to be a carbon source, positive values indicate it is a carbon sink. Adapted from Zhuang *et al*. (2010).

Zhuang *et al*. say the "increasing soil temperature and deepening active layer depth enhanced soil respiration, increasing the net nitrogen mineralization rate," and "together with the [positive] effects of warming air temperature and rising CO_2 concentrations on photosynthesis, the stronger plant nitrogen

uptake due to the enhanced available nitrogen stimulate[d] plant carbon uptake, thereby strengthening the regional carbon sink as the rate of increase in net primary production was faster than that of soil respiration." They say their study implies "future warming will increase thawing of the permafrost, increase soil temperature and dry up soil moisture," and "these physical dynamics may enhance [the] future strength of the regional carbon sink, since the rate of increase of net primary production is higher than that of soil respiration on the Tibetan Plateau."

Satellite-based measurements taken over the past three decades provide further evidence the productivity of the Tibetan Plateau's vegetation has recently increased. Piao *et al*. (2006), for example, investigated net primary production (NPP) derived from a carbon model (Carnegie-Ames-Stanford approach, CASA) and its interannual change in the Qinghai-Xizang (Tibetan) Plateau using 1982–1999 NDVI data and paired ground-based information on vegetation, climate, soil, and solar radiation. Over the study period, NPP rose at a mean annual rate of 0.7%. Piao *et al*. report, "the NPP trends in the plateau over the two decades were divided into two distinguished periods: without any clear trend from 1982 to 1990 and significant increase from 1991 to 1999."

The three researchers say their findings indicate "vegetation growth on the plateau in the 1990s has been much enhanced compared to that in [the] 1980s, consistent with the trend in the northern latitudes indicated by Schimel *et al*. (2001)." They write, "previous observational and NPP modeling studies have documented substantial evidence that terrestrial photosynthetic activity has increased over the past two to three decades in the middle and high latitudes in the Northern Hemisphere," and "satellite-based NDVI data sets for the period of 1982–1999 also indicate consistent trends of NDVI increase," citing multiple references. Piao *et al*.'s findings add to the growing body of evidence that reveals a significant greening of the Earth in response to the ongoing recovery of the planet from the growth-inhibiting chill of the Little Ice Age, which was likely the coldest period of the current interglacial; the aerial fertilization effect of the historical and still-ongoing rise in the atmosphere's CO_2 concentration; and the growth-promoting effect of anthropogenic nitrogen deposition.

Zhou *et al*. (2007) investigated interannual variations of Tibetan Plateau vegetative productivity using a 21-year (1982–2002) normalized difference vegetation index (NDVI) dataset to quantify the consequences of changes in temperature and precipitation for the regional ecosystem. They report, "the maximum, minimum and mean temperature fluctuations all present an increasing trend over the 21 years." They note "the NDVI is comparatively large during the warm years, such as 1988, 1994, 1998, and 1999," and "relatively small NDVI values are well coupled with the cold extreme and mean temperature in 1982, 1983 and 1997." This relationship, they continue, "suggests a positive correlation between vegetation activity and surface air temperature on the plateau." They report, "the correlation coefficient between the NDVI and the maximum, minimum and mean temperature reaches 0.674 (significant at the 99% level), 0.53 (significant at the 95% level) and 0.55 (significant at the 99% level), respectively." In contrast, "the precipitation fluctuation does not show a detectable trend, and therefore its correlation with DNVI is not obvious."

Zhou *et al*. conclude, "vegetation variability on the Tibetan Plateau might be mostly driven by thermal impacts (i.e., surface air temperature), whereas precipitation impact is less clear." Overall, "vegetation activity demonstrates a gradual enhancement in an oscillatory manner during 1982–2002," suggesting a significant positive impact of what IPCC calls "unprecedented" global warming on the Tibetan Plateau, which Zhou *et al*. describe as "one of the most prominent features on Earth."

4.2.2.2.2 All Other Asian Countries

This section examines how vegetative productivity has fared in Asian countries other than China over the past few decades.

Grunzweig *et al*. (2003) studied the Yatir forest, a 2,800-hectare stand of Aleppo and other pine trees, planted some 35 years earlier at the edge of the Negev Desert in Israel. They characterize the forest as growing in poor soil of only 0.2 to 1.0 meter's depth above chalk and limestone. Although it is located in an arid part of Asia that receives less annual precipitation than all of the other stations in the FluxNet global network of micrometeorological tower sites (Baldocchi *et al*., 2001), the forest's annual net ecosystem CO_2 exchange was just as high as that of many high-latitude boreal forests and actually higher than those of most temperate forests.

Grunzweig *et al*. note the increase in atmospheric CO_2 concentration that has occurred since pre-industrial times should have improved water use efficiency (WUE) in most plants by increasing the ratio of CO_2 fixed to water lost via evapo-transpiration. That this hypothesis is correct has been demonstrated by Leavitt *et al*. (2003) in the context of the long-term atmospheric CO_2 enrichment experiment of Idso and Kimball (2001) on sour orange trees. It also has been confirmed in nature by Feng (1999), who obtained results identical to the study of Leavitt *et al*. for 23 groups of naturally occurring trees across western North America for the years 1800–1985; a response,

Feng concludes, that "would have caused natural trees in arid environments to grow more rapidly, acting as a carbon sink for anthropogenic CO_2," which is what Grunzweig *et al*. found in the Yatir forest on the edge of the Negev Desert. Grunzweig *et al*. also report, "reducing water loss in arid regions improves soil moisture conditions, decreases water stress and extends water availability," which "can indirectly increase carbon sequestration by influencing plant distribution, survival and expansion into water-limited environments."

Singh *et al*. (2011) used U.S. National Oceanic and Atmospheric Administration (NOAA) satellite-derived advanced very high resolution radiometer (AVHRR) data, together with the Global Production Efficiency Model (GloPEM) developed by Prince and Goward (1995), to calculate annual NPP over India for the years 1981–2000 (Figure 4.2.2.2.2.1). According to the five researchers, regression analysis of the 20-year NPP database showed a significant increase in the temporal trend of NPP over India ($r=0.7$, $p<0.001$), with the mean rate of increase being 10.43 $gC/m^2/year$, which yields a mean rate-of-increase in carbon fixation of 34.3 TgC/year for the country, including its arid and semi-arid regions, its forests, and its dry-land and irrigated agricultural regions.

Figure 4.2.2.2.2.1. Average annual NPP estimated for India during the years 1981–2000 using NOAA-AVHRR data, as per Singh *et al*. (2011).

In Russia, in an area extending from 72°02'N to 72°40'N and from 101°15'E to 102°06' E—a total of approximately 36,000 ha that includes the Ary-Mas forest (the northernmost forest on the planet) plus

larch forests on southeastern slopes descending to the Khatanga River—Kharuk *et al.* (2006) analyzed remote-sensing images made by Landsat satellites in 1973 and 2000. They found "the most significant changes were observed in the class of normal larch stands (canopy density > 0.3): their area increased by 66%," and "the areas of open and sparse forests (0.1 < canopy density < 0.3, and canopy density < 0.1) increased by 16 and 8%, respectively, whereas the background area became 19% smaller." They report the rates of expansion of larch onto tundra "for sparse, open, and normal stands were estimated at 3, 9, and 11 m per year, respectively." They remark, "since sparse stands are at the forefront of advancement to the tundra, the rate for this class (approximately 3 m per year) should be regarded as the rate of larch expansion in general," and "the above rates reflect not only the expansion of trees into the tundra, but also an increase in the density of sparse and open stands."

Kharuk *et al.* suggest the changes they reported were "induced by climatic trends" and the continuation of this process "will result in the expansion of larch to the Arctic coast," which they describe as a "phenomenon that took place in the Holocene." Thus the Ary Mas forest evidently is reclaiming what previously had been lost due to the progressive cooling of the planet after the Holocene Climatic Optimum, as this cooling culminated in the record interglacial cold of the Little Ice Age from which Earth and its biosphere are now recovering.

Lapenis *et al.* (2005) analyzed trends in forest biomass in all 28 ecoregions of the Russian territory, based on data collected from 1953 to 2002 in 3,196 sample plots comprising about 50,000 entries. This database, they write, "contains all available archived and published data." Over the period 1961–1998, they write, "aboveground wood, roots, and green parts increased by 4%, 21%, and 33%, respectively," such that "the total carbon density of the living biomass stock of the Russian forests increased by ~9%." They also report a concomitant increase of ~11% in the land area of Russian forests. In addition, the U.S., Austrian, and Russian scientists note, "within the range of 50–65° of latitude [the range of 90% of Russian forests], the relationship between biomass density and the area-averaged NDVI is very close to a linear function, with a slope of ~1," citing Myneni *et al.* (2001). They continue, "changes in the carbon density of live biomass in Russian forests occur at about the same rate as the increase in the satellite-based estimate in the seasonally accumulated NDVI."

Acknowledging remote sensing data suggest tundra vegetation in North America may be responding to recent warming via enhanced photosynthetic activity (Goetz *et al.*, 2005; Verbyla , 2008), Forbes *et al.* (2010) write, "at a circumpolar scale, the highest photosynthetic activity and strongest growth trends are reported in locations characterized by erect shrub tundra (Reynolds *et al.*, 2006)," noting "live leaf phytomass from deciduous shrubs, shown to have increased in northern Alaska during the second half of the last century (Sturm *et al.*, 2001; Tape *et al.*, 2006), is believed to be a key driver of the observed trends (Jia *et al.*, 2003; Goetz *et al.*, 2005; Verbyla, 2008)." Forbes *et al.* analyzed annual ring growth for 168 stem slices of 2- to 3-cm thickness they collected from 40 *Salix lanata* L. (*sensu latu*)—an abundant deciduous dioecious willow with nearly circumpolar geographic distribution from the northern boreal forest of Russia to the northern limits of the Low Arctic. Their samples were taken from 15 sites in an area of approximately 3 x 2.3 km located at about 68°40'N, 58°30'E.

The three researchers found "a clear relationship with photosynthetic activity for upland vegetation at a regional scale for the years 1981–2005, confirming a parallel 'greening' trend reported for similarly warming North American portions of the tundra biome," and they write, "the standardized growth curve suggests a significant increase in shrub willow growth over the last six decades." Noting "the quality of the chronology as a climate proxy is exceptional," Forbes *et al.* state their findings "are in line with field and remote sensing studies that have assigned a strong shrub component to the reported greening signal since the early 1980s," adding the growth trend agrees with the qualitative observations of nomadic reindeer herders, which suggest there have been "recent increases in willow size in the region." Forbes *et al.* say their analysis "provides the best proxy assessment to date that deciduous shrub phytomass has increased significantly in response to an ongoing summer warming trend."

Lioubimtseva *et al.* (2005) describe a number of findings generally not available to the international scientific community because of their publication in Russian. According to the four-member team of Russian and American scientists, "there has been a general warming trend in Central Asian republics on the order of 1–2°C since the beginning of the 20th century." They note the trend is expressed most strongly in winter and "the amplitude of this trend seems to be comparable with Holocene climate variability," suggesting it is nothing unusual nor does it require an anthropogenic explanation. Citing IPCC

(2001), they report precipitation has remained basically unchanged throughout the twentieth century, stating "there were no discernible trends in annual precipitation during 1900–95 for the region as a whole, nor in most parts of this region."

In the face of unchanging precipitation and significant warming, it might be expected the aridity of Central Asia would have increased significantly in recent years, especially throughout the 1990s, when IPCC purports the world had its most oppressive heat of both the twentieth century and the past two millennia. However, Lioubimtseva *et al*. report, "analyses of the NOAA AVHRR temporal series since the 1980s showed a decrease in aridity from 1991–2000 compared to 1982–1990 in the northern part of the region and a southward shift of the northern boundary of the desert zone in Central Asia," citing Zolotokrylin (2002). Lioubimtseva *et al*. suggest the cause of this unexpected development may have been the historical rise in the atmospheric CO_2 content.

The scientists note "an increased atmospheric CO_2 concentration has direct and relatively immediate effects on two important physiological processes in plants: it increases the photosynthetic rate, but decreases stomatal opening and therefore the rate at which plants lose water," so "the combination of these two factors, increased photosynthesis and decreased water loss, implies a significant increase of water [use] efficiency (the ratio of carbon gain per unit water loss) and ... a reduction in the sensitivity to drought stress in desert vegetation as a result of elevated atmospheric CO_2," citing Smith *et al*. (2000). They note these effects could "increase productivity and biomass of natural desert vegetation," which would make the land less arid.

Buttressing this reasoning with experimental evidence from the region, Lioubimtseva *et al*. report, "CO_2-enrichment experiments (both chamber and free-air) conducted in the Kara Kum (Voznesensky, 1997) and Kyzyl Kum (Voznesensky, 1997; Zelensky, 1977) deserts showed a 2–4 times increase in the photosynthetic rate under the saturating CO_2 concentrations," and "three Kara Kum species (*Eminium lehmanii*, *Rhemum turkestanuikum* and *Ephedra stobilacea*) responded with a six-fold increase in photosynthetic rate (Nechaeva, 1984)." They report, "the CO_2 fertilization effects included not only higher vegetation but also microphytic communities including mosses, lichens, fungi, algae, and cyanobacteria"; these communities, they write, "form biogenic crusts on the soil surface varying from a few millimeters to several centimeters in thickness

and play a significant role in the desert ecosystems controlling such processes as water retention and carbon and nitrogen fixation in soils."

Zhou *et al*. (2001) analyzed satellite-derived normalized difference vegetation index (NDVI) data from July 1981 to December 1999, between 40 and 70° N latitude. They found a persistent increase in growing season vegetative productivity in excess of 12% over this broad contiguous swath of Asia stretching from Europe through Siberia to the Aldan plateau, where almost 58% of the land is forested. In a companion study, Bogaert *et al*. (2002) determined this productivity increase occurred at a time when this vast Asian region showed an overall warming trend "with negligible occurrence of cooling."

Ichii *et al*. (2005) simulated and analyzed carbon fluxes during the years 1982–1999 "using the Biome-BGC prognostic carbon cycle model driven by National Centers for Environmental Prediction re-analysis daily climate data," after which they "calculated trends in gross primary productivity (GPP) and net primary productivity (NPP)." They found solar radiation variability to be the primary factor responsible for inter-annual variations in GPP, followed by temperature and precipitation variability. In terms of GPP trends, the authors report, "recent changes in atmospheric CO_2 and climate promoted terrestrial GPP increases with a significant linear trend in all three tropical regions." The rate of GPP increase for Asia was about 0.3 PgC year^{-1} per decade. Ichii *et al*. favor carbon dioxide as the likely cause, reporting "CO_2 fertilization effects strongly increased recent NPP trends in regional totals."

In a study examining a large portion of the Northern Hemisphere (East Asia, including China, Japan, Korea, and Mongolia), Piao *et al*. (2011) used three process-based ecosystem models—the Lund-Potsdam-Jena Dynamic Global Vegetation Model (LPJ-DGVM) described by Sitch *et al*. (2003), the ORganizing Carbon and Hydrology In Dynamic Ecosystems (ORCHIDEE) model described by Krinner *et al*. (2005), and the Sheffield model (SDGVM) described by Woodward and Lomas (2004)—to investigate East Asia's net primary productivity (NPP) response to the climatic change and rising atmospheric CO_2 concentration of the past century. They ran each of the three models for the years 1901 to 2002, using observed values of monthly climatology and annual global atmospheric CO_2 concentrations (Figure 4.2.2.2.2.2).

Between 1901 and 2002, modeled NPP "significantly increased by 5.5–8.5 Tg C per year (15–20% growth)," the authors write, and this
Figure 4.2.2.2.2.2. Terrestrial Net Primary Productivity anomalies for East Asia for the years 1901–2002 as determined from the three process-based ecosystem models described in the text (LPJ, ORCIDEE, and SDGVM). Adapted from Piao *et al.* (2011).

increase in NPP "caused an increased cumulated terrestrial carbon storage of about 5–11 Pg C," about 50–70% of which "is located in vegetation biomass." In addition, "40–60% of the accumulated carbon uptake of the 20th century is credited to the period of 1980–2002," the warmest two-decade interval of that century-long period, according to IPCC.

Thus Piao *et al.* demonstrate the rise of the air's CO_2 concentration and temperature to their highest values of the past century enhanced the terrestrial vegetative productivity of East Asia. This and the many other observations described above indicate plant productivity in Asia is increasing as atmospheric CO_2 concentrations and temperatures rise.

4.2.2.3 Australia

- Evergreen vegetation, woody plants, and other plant life have increased across Australia over the past 200 years as a result of CO_2 enrichment.

Banfai and Bowman (2006) note "a number of processes are thought to be threatening the ecological integrity of monsoon rainforests in Northern Australia," testing this retracting-rainforest claim with a comprehensive repeat aerial photography study of the Northern Territory's Kakadu National Park, where monsoon rainforest exists as an archipelago of hundreds of small patches within a larger eucalypt savanna matrix. The two Australian researchers from Charles Darwin University's School for Environmental Research assessed changes to the boundaries of 50 monsoon rainforest patches using temporal sequences of digitized aerial photography taken in 1964, 1984, 1991, and 2004, to ascertain the relative importance of factors driving any change.

They found "rainforest patches increased in size between 1964 and 2004 by an average of 28.8%" (see Figure 4.2.2.3.1). After lengthy analyses of several phenomena that might have been responsible for the range increases, the two researchers conclude "the expansion is likely to have been primarily driven by increases in variables such as rainfall and atmospheric CO_2." They note, "the average [area] change for dry rainforests from 1964 to 2004 was an increase of 42.1%, whereas for wet rainforests [the increase] was one-third of this at 13.1%." With respect to dry rainforests, they found "an almost linear increase in rainforest area over the study period."

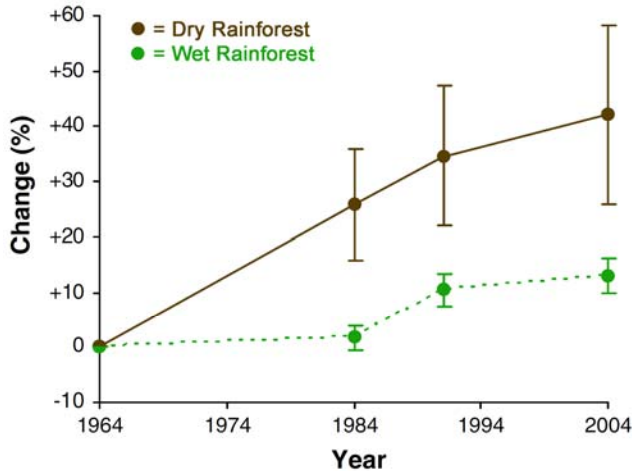
In further support of the validity of their findings, and "contrary to the view that monsoon rainforests are contracting," the two researchers note other repeat aerial photography studies conducted in Northern Australia also have revealed rainforest "expansion at the expense of more open vegetation." These studies include those of monsoon rainforests in Litchfield


Figure 4.2.2.3.1. Average percentage change in rainforest area in Kakadu National Park, Northern Territory of Australia, relative to 1964 for dry rainforest (brown line) and wet rainforest (green dashed line). Standard errors are indicated. Adapted from Banfai and Bowman (2006).

National Park near Darwin (Bowman *et al.*, 2001)—where forest patches nearly doubled in size between 1941 and 1994—and in the Gulf of Carpentaria (Bowman *et al.*, 2006). Banfai and Bowman write, "these changes parallel the observed expansion of tropical rainforest on the east coast of Australia (Harrington and Sanderson, 1994; Russell-Smith *et al.*, 2004)."

Macinnis-Ng *et al.* (2011) note, "woody thickening" is typically defined as "the increase in woody standing biomass in a landscape already containing woody biomass." Both it and woody plant invasion, they continue, "are global phenomena commonly observed in arid and semi-arid regions, including Australia (Bowman *et al.*, 2001; Burrows *et al.*, 2002; Asner *et al.*, 2003; Fensham *et al.*, 2005; Scott *et al.*, 2006; Witt *et al.*, 2009)," the "tropical rainforests of Central and South America (Phillips *et al.*, 1998), and temperate forests globally (Birdsey *et al.*, 1993)." Although "the cause of woody thickening remains debated," they write, "there is an increasing awareness of potential roles for climate and changes in atmospheric CO_2 concentration in causing woody thickening (and woody invasion)," citing Fensham *et al.* (2005), Berry and Roderick (2006), Davis *et al.* (2007), and Sankaran *et al.* (2008).

The four researchers examined the responses of gross primary production (GPP) and water use of a typical Australian woodland using the soil-plant atmosphere (SPA) model of Williams *et al.* (1996), which they applied to the functioning of a temperate

open woodland in Australia (Zeppel *et al.*, 2008) that provided a methodology for testing the conceptual model of Eamus and Palmer (2007), which posits increasing atmospheric CO_2 concentration and declining evaporative demand "may explain the global phenomenon of woody thickening."

Macinnis-Ng *et al.* demonstrate that as the atmosphere's CO_2 content rises, plant stomatal conductance decreases, such that water use per tree decreases and, therefore, soil water content increases, leading to increases in leaf area index that allow more light to be intercepted, enabling existing trees to grow bigger, even in the case of photosynthetic acclimation. This set of phenomena constitutes the complex process of woody thickening. Noting their results "provide a valid mechanism for the conclusion of Berry and Roderick (2002) that evergreen vegetation has increased across Australia over the past 200 years as a result of CO_2 enrichment," they conclude "woody thickening in Australia and probably globally can be explained by the changes in landscape GPP and soil moisture balance arising principally from the increased atmospheric CO_2 concentration."

4.2.2.4 Europe

- Over the last two decades of the twentieth century, Europe became greener and much of it is seeing an increase in its woodlands due to the recent rise in atmospheric CO_2, which has tended to offset the detrimental effects of climate change in the region.

- Opposite the forecasts promulgated by the models used by IPCC, land-based plants of the Arctic and near-Arctic regions of North America are thriving, thanks in large part to the ongoing rise in the atmosphere's CO_2 concentration and global warming.

Using an empirically based mechanistic model of Mediterranean shrub vegetation, Osborne *et al.* (2000) set out to address two important questions: Has recent climate change, especially increased drought, negatively impacted Mediterranean shrublands? And has the historical increase in the air's CO_2 concentration modified this impact?

The data-based model they employed suggests the warming and reduced precipitation experienced in the Mediterranean area over the past century should have had negative impacts on net primary production and leaf area index. When the measured increase in atmospheric CO_2 concentration experienced over the period was factored into the calculation, however, these negative influences were overpowered: net primary productivity increased by 25% and leaf area index by 7%. These results, they write, "indicate that the recent rise in atmospheric CO_2 may already have had significant impacts on productivity, structure and water relations of sclerophyllous shrub vegetation, which tended to offset the detrimental effects of climate change in the region."

Model-predicted changes in Earth's precipitation regime indicate a doubling of the atmosphere's CO_2 content will lead to a modest intensification of the planet's hydrologic cycle. In the Mediterranean region over the past century, however, there has been a recent tendency toward drier conditions. Hence the specific case Osborne *et al.* investigated represents a much-worse scenario than what is predicted by

current climate models for Earth as a whole, yet the area's vegetation has grown even better than it did before the climatic change, thanks to the over-powering beneficial biological effects of the concurrent rise in atmospheric CO_2.

Cheddadi *et al*. (2001) employed a standard biogeochemical model (BIOME3)—which uses monthly temperature and precipitation data, certain soil characteristics, cloudiness, and atmospheric CO_2 concentration as inputs—to simulate the responses of various biomes in the region surrounding the Mediterranean Sea to changes in both climate (temperature and precipitation) and atmospheric CO_2 content. They first validated the model for two test periods, the present and 6,000 years before present (BP). They used recent instrumental records for atmospheric CO_2, temperature, and precipitation data for the present period; for 6,000 years BP, they used pollen data to reconstruct monthly temperature and precipitation values and ice core records to determine the atmospheric CO_2 concentration. They determined winter temperatures 6,000 years ago were about 2°C cooler than temperatures today, annual rainfall was approximately 200 mm less than today, and the air's CO_2 concentration averaged 280 ppm, considerably less than the 345 ppm the researchers used to represent the present—the midpoint of the period used for calculating 30-year climate normals at the time they wrote their paper. Applying the model to these two sets of conditions, they demonstrated "BIOME3 can be used to simulate ... the vegetation distribution under ... different climate and CO_2 conditions than today."

Cheddadi *et al*. used their validated model to explore the vegetative consequences of an increase in anthropogenic CO_2 emissions that pushes the air's CO_2 concentration to a value of 500 ppm and its mean annual temperature to a value 2°C higher than today's mean value. The basic response of the vegetation to this change in environmental conditions was "a substantial southward shift of Mediterranean vegetation and a spread of evergreen and conifer forests in the northern Mediterranean."

They write, "when precipitation is maintained at its present-day level, an evergreen forest spreads in the eastern Mediterranean and a conifer forest in Turkey." Current xerophytic woodlands in this scenario become "restricted to southern Spain and southern Italy and they no longer occur in southern France." In northwest Africa, "Mediterranean xerophytic vegetation occupies a more extensive territory than today and the arid steppe/desert boundary shifts southward," as each vegetation zone becomes signifi-

cantly more verdant than it is today.

In identifying the cause of these positive developments, Cheddadi *et al*. write, "the replacement of xerophytic woodlands by evergreen and conifer forests could be explained by the enhancement of photosynthesis due to the increase of CO_2." They also note, "under a high CO_2 stomata will be much less open which will lead to a reduced evapotranspiration and lower water loss, both for C_3 and C_4 plants," adding "such mechanisms may help plants to resist long-lasting drought periods that characterize the Mediterranean climate."

Contrary to what IPCC predicts for much of the world's moisture-challenged lands, the authors report, "an increase of CO_2, jointly with an increase of *ca*. 2°C in annual temperature would not lead to desertification on any part of the Mediterranean unless annual precipitation decreased drastically," defining a drastic decrease as a decline of 30% or more. Equally important in this context, Hennessy *et al*. (1997) found a doubling of atmospheric CO_2 content would lead to a 5 to 10% increase in annual precipitation at Mediterranean latitudes, which is also what is predicted for most of the rest of the world. Thus the results of Cheddadi *et al*.'s study, where precipitation was held constant, may be considered a worst-case scenario, with the true vegetative response being even better than they projected.

Bellassen *et al*. (2011) write, "several parties to the United Nations Framework Convention on Climate Change (UNFCCC) are calling for 'forward-looking baselines'" to develop country-specific scenarios based on forest age structure that can be used "to credit only the part of the forest sink going beyond business-as-usual practices." They derived such a baseline for Europe.

Using ORCHIDEE-FM—a process-based vege-tation model that differs from earlier versions of ORCHIDEE by "its explicit representation of stand growth and idealized forest management"—Bellassen *et al*. applied the model on a grid across Europe to "simulate changes in the net ecosystem productivity (NEP) of forests with and without changes in climate, CO_2 and age structure." The six scientists report the model they used "simulates carbon stocks and volume increments comparable … with inventory-derived estimates at country level for 20 European countries," providing "an upwards trend of forest NEP of 1 ± 0.5 g C/m^2/year between 1950 and 2000 across the EU 25," ending with "a mean European forest NEP of 175 ± 52 g C/m^2/year in the 1990s" (see Figure 4.2.2.4.1). They write, "61% of the change in NEP [over the last half of the 20th century] was attributed
Figure 4.2.2.4.1. Simulated reconstruction of Net Ecosystem Productivity (NEP) in European forests for the years 1951–2000. Adapted from Bellassen *et al.* (2011).

to changes in CO_2, 26% to changes in climate, and 13% to changes in forest age structure."

As intriguing as these model-based studies are, it is important to examine the issue through the lens of real-world data to see how plant productivity has actually responded to modern warming, which IPCC claims is unprecedented over the past one to two thousand years. A number of scientists have done just that.

Allen *et al.* (1999) analyzed sediment cores from a lake in southern Italy and from the Mediterranean Sea, developing high-resolution climate and vegetation datasets for this region over the past 102,000 years. They found rapid changes in vegetation were well-correlated with rapid changes in climate, such that complete shifts in natural ecosystems would sometimes occur over periods of less than 200 years. Over the warmest portion of the record (the Holocene), the total organic carbon content of the vegetation reached its highest level, more than doubling values experienced over the rest of the record. Other proxy indicators reveal the increased vegetative cover also led to less soil erosion during the more-productive woody-plant period of the Holocene. This study thus demonstrates the biosphere can respond successfully to rapid changes in climate. As the 15 researchers write, "the biosphere was a full participant in these rapid fluctuations, contrary to widely held views that vegetation is unable to change with such rapidity." Their work also reveals warmer was always better in terms of plant growth, suggesting future warming in this region may return it to a level of biological productivity higher than it currently achieves.

Bert *et al.* (1997) calculated a 120-year (1860–

1980) history of intrinsic water-use efficiency (defined as the ratio of CO_2 assimilation rate to stomatal conductance for water vapor) for silver fir (*Abies alba* Mill.) trees, based on $\delta^{13}C$ data obtained from cores extracted from individual trees that grew within 208 pure stands in the Jura Mountains near the border that separates France and Switzerland. They found little net change in silver fir water-use efficiency from 1860 to 1930, but over the next half-century (1930 to 1980), when the atmosphere's CO_2 concentration rose at a rate more than three times faster than its rate of rise over the earlier period, this important tree physiological property rose by approximately 30% (see Figure 4.2.2.4.2). The three researchers state their results—which were "obtained at the level of mature trees"—are "consistent with the physiological effects of increasing CO_2 concentrations as observed in controlled experiments on young seedlings" and are also "consistent with the strong increases in radial growth observed for *Abies alba* in western Europe over the past decades."

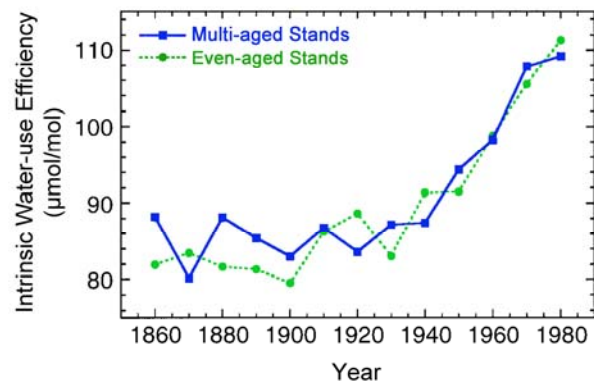

Figure 4.2.2.4.2. Intrinsic water-use efficiency (the ratio of CO_2 assimilation rate to stomatal conductance for water vapor) calculated from tree rings sampled in multi-aged and even-aged forest stands from the Jura Mountains in Eastern France for the years 1860–1980. Adapted from Bert *et al.* (1997).

Jandl *et al.* (2007) evaluated the growth rates of two Norway spruce (*Picea abies*) stands in the Bohemian Massif of Northern Austria over the prior four decades by analyzing the stem characteristics (height and diameter) of several trees they felled at two sites, and by comparing their results with data obtained from control plots of other experiments conducted there over an even longer period of time. The three researchers found "forest productivity is currently about two yield classes higher than it is in

the regionally valid yield tables," which were derived from data collected at the end of the nineteenth century, and "the height and diameter of dominant stems exceed expectations." Jandl *et al.* conclude, "the sites are in a steady process of aggradation and that site productivity is rising."

The Austrian researchers contend climate was unlikely to be the main driver of the elevated growth rates of the forest stands they studied, because neither air temperature nor precipitation were strong predictors of the increment rates at their experimental sites. In addition, they state the "ongoing improvement" was "not the mere consequence of a nitrogen-enriching effect." Hence, they considered "the enriching effect of increasing CO_2 concentrations" and possibly changes in management practices (such as the abandonment of forest litter raking) to be the only viable alternative explanations for the steady historical increase in Norway spruce productivity at the sites they studied.

Leal *et al.* (2008) discovered "a very clear change in the sensitivity of the growth rate of [black pine (*Pinus nigra*)] tree stems to water availability in the late 20th century" in the Vienna basin of Austria in the European Eastern Alps, noting "trees previously sensitive to spring-summer drought show a lack of response to this climatic parameter in recent decades." They explain "tree-ring indices were larger in the second half of the 20th century than predicted given prevailing spring-summer drought conditions and the previous sensitivity of growth to these conditions." They also found "a decrease in correspondence between the occurrence of extreme events in precipitation and rate of change of growth," such that "in the second half of the century this correspondence was not significant" and "recent extreme droughts did not result in the formation of very narrow rings, which means the droughts were not as limiting to tree growth as they had been in the past."

The five researchers conclude by suggesting the greater atmospheric CO_2 concentrations of the latter decades of the twentieth century "induced improved water-use efficiency enabling *P. nigra* growing in the Vienna basin to avoid the impact of recurrent dry conditions." This phenomenon also has been observed in many other parts of the world in a number of different tree species, another indication of the propensity of the ongoing rise in the atmospheric CO_2 content to promote a greening of the Earth.

Martinez-Vilalta *et al.* (2008) used tree-ring data from the Catalan Ecological and Forest Inventory "to study the temporal variability of Scots pine stem radial growth (period 1901–1997) across a relatively large region (Catalonia, NE Spain) situated close to the southern limit of the distribution of the species." This inventory "included a total of 10,664 plots randomly distributed throughout the forested area of Catalonia." Scots pine was present in 30.2% of the plots and was the dominant tree species in 18.4%.

The researchers found "an overall increase of 84% in Scots pine BAI [basal area increment] during the 20th century (see Figure 4.2.2.4.3), consistent with most previous studies for temperate forests." They state "this trend was associated with increased atmospheric CO_2 concentration," which they characterize as "a fertilization effect." The five scientists note over the same time period there was "a marked increase in temperature across the study region (0.19°C per decade on average)," and "this warming had a negative impact on radial growth, particularly at the drier sites." However, they found "its magnitude was not enough to counteract the fertilization effect."

Figure 4.2.2.4.3. Basal area increment (BAI) for Scots pine trees growing in NE Spain during the years 1901–1997. Adapted from Martinez-Vilalta *et al.* (2008).

Noting "protected areas provide excellent opportunities for [determining] baseline descriptions and trends that ... can be used to evaluate the impact of global environmental change on terrestrial ecosystem functioning," Alcaraz-Segura *et al.* (2008) employed satellite-derived normalized difference vegetation index (NDVI) data—which provide a measure of net primary production, "the most integrative indicator of ecosystem functioning"—to "evaluate the impact of global environmental change on terrestrial ecosystem functioning of [Spain's] national parks." This information provides a sound basis for determining what could have been expected

to have occurred throughout the rest of the country and much of Europe (Julien *et al*., 2006) independent of confounding effects not related to global environmental change.

The four researchers from Argentina, Spain, and the United States report, "most parks showed areas with positive NDVI trends that tended to have higher proportions of Mediterranean coniferous and mixed forests, oro-Mediterranean scrublands, heathlands, maquis and garrigues," whereas "negative trends were scarce." Alcaraz-Segura *et al*. conclude "protected areas are changing in the short term and, at least in terms of vegetation greenness, they are changing in a directional way," such that "a large part of the Spanish National Parks is intercepting more photosynthetically active radiation than in the past."

Hallinger *et al*. (2010) studied male plants of the medium-sized *Juniperus nana* shrub at a site just three kilometers from the Abisko Scientific Research Station (68°21'N, 18°49'E) in the Northern Swedish Scandes. They collected the main stems of five to eight shrubs every hundred meters of elevation until the shrub zone ended. Ring-width measurements on these stems were then performed, they write, "to measure radial and vertical growth, to track growth changes over time, to age the shrub individuals and to correlate annual shrub growth with climate," the characteristics of which were derived from records of the nearby Abisko Station.

The three researchers say their analysis "documented a distinct increase in radial and vertical growth rates of *J. nana* shrubs during recent decades in the subalpine zone of North Sweden" (see Figure 4.2.2.4.4), and "the age structure of shrubs along the elevational gradient provides evidence that an upslope advance of the altitudinal shrubline is underway." They "observed significant, strong and stable correlations between annual ring width and summer temperatures (June, July, August)," and "the acceleration of radial and vertical growth since 1970 also coincides with the recent three decades of rising arctic air temperatures and the warming trend of 0.2°C per decade for the average temperature since 1956 at Abisko." These findings, they write, add to the "mounting evidence that shrubs are expanding into alpine and arctic areas because of climate warming," and "this expansion occurs in both evergreen and deciduous shrub types," citing Forbes *et al*. (2009).

Kullman (2010a) presents "an integrative review of results from long-term monitoring of subalpine/ alpine vegetation" in the Swedish Scandes, from which he derives "tentative projections of landscape transformations in a potentially warmer future," based

Figure 4.2.2.4.4. Indexed radial growth of juniper trees in the northern Swedish Scandes during the years 1850–2006, smoothed with a 10-year filter. Adapted from Hallinger *et al*. (2010).

on "actual observations and paleoecological data (Kullman and Kjallgren, 2006; Kullman 2006)." The professor of physical geography at Sweden's Umea University writes post-Little Ice Age warming has broken "a multi-millennial trend of plant cover retrogression" and "floristic and faunal impoverishment, all imposed by progressive and deterministic neoglacial climate cooling." He reports the "upper range margin rise of trees and low-altitude (boreal) plant species, expansion of alpine grasslands and dwarf-shrub heaths are the modal biotic adjustments during the past few decades, after a century of substantial climate warming." Currently, "alpine plant life is proliferating, biodiversity is on the rise and the mountain world appears more productive and inviting than ever." Kullman notes "in contrast to model predictions, no single alpine plant species has become extinct, neither in Scandinavia nor in any other part of the world in response to climate warming over the past century," citing, in addition to his own studies, Pauli *et al*. (2001, 2007), Theurillat and Guisan (2001), and Birks (2008).

In a contemporaneous study published in the *Nordic Journal of Botany*, Kullman describes how extensive the recent proliferation of plant life has been (Kullman, 2010c). He reports the findings of species inventories he conducted on the uppermost 20 meters of four high-mountain summits in the Swedish Scandes (Kullman 2007a,b), the results of which he compared with the findings of "historical species inventories from the early 1950s, executed by a highly competent and experienced botanist (Kilander,

1955)," which "can be seen as an evaluation of a full-scale 'natural experiment' (cf. Grabherr *et al*., 2001)."

Kullman (2010c) writes the species pools at the tops of the studied mountains have "increased by 60–170% since the 1950s," "some of the invading species are new to the alpine tundra, with more silvine and thermophilic properties than the extant alpine flora," and "not a single species of the original flora has disappeared from any of the summits." Kullman concludes, "the alpine flora appears to be more adaptive and responsive to climate change than generally believed," and "overall, a richer, greener and more productive alpine world has emerged in the wake of the recent climate warming episode (Kullman, 2010a, 2010b)."

Rundqvist *et al*. (2011) documented "rapid and substantial increases in the abundance of prominent tree and shrub species near [the] tree-line and forest-line in sub-Arctic Sweden," on an east-facing slope of the Slattatjakka/Njulla mountains (68°21'N, 18°49'W) in the Abisko Valley about 200 km north of the Arctic Circle in Sweden. They "recorded an invasion by a thermophilic tree species not present in the plots 34 years ago."

The seven Swedish scientists say their observations mesh well with those of many other researchers, noting "there is an indication that the shrub layer near the tree-line has expanded, since the 1930s, in the Abisko area (Enquist *et al*., 1933; Sandberg, 1963)," and "data from Canada, Fennoscandia, Alaska and Russia reveal that there is a Pan-Arctic expansion of shrubs and trees in progress (e.g. Kullman, 2002; Tommervik *et al*., 2004; ACIA, 2005; Tape *et al*., 2006; Karlsson *et al*., 2007; Olofsson *et al*., 2009; Hallinger *et al*., 2010; Hendenas *et al*., 2011)." They state the change in shrubs and small trees they observed is "consistent with anticipated changes due to climate change and reduced herbivory," and this change "could be interpreted as an ongoing natural re-establishment of plants at higher altitudes due to a natural increase in the temperature since the 'Little Ice Age' (Kammer *et al*., 2007)."

Hedenas *et al*. (2011) state, "during the last 15 years, there has been an increasing focus on how climate change has and will affect

the distribution and extent of ecosystems around the globe including alpine and Arctic areas (e.g., Callaghan *et al*., 2005)." They report, "field studies and remote sensing have revealed a recent increase in altitude of the tree line (e.g., Kullman, 2002)," as well as "an extension and increased cover of mountain birch forest (Tommervik *et al*., 2009; Rundqvist *et al*., 2011)." They say Tommervik *et al*. determined "tree biomass has doubled over a 43-year period, within an area of Finnmarksvidda, and Rundqvist *et al*. have observed an increased density and cover of mountain birch in the treeline over the last three decades, within an area near Abisko village."

Hedenas *et al*. in 2010 re-surveyed shrub, tree, and vegetation data at 549 plots grouped into 61 clusters originally surveyed in 1997 in two areas close to the Abisko village approximately 200 km north of the Arctic Circle at 68°20'N, 18°50'E. They found "tree basal area and biomass increased by 19% between 1997 and 2010 with the main increase occurring in established birch forest" (see Figure 4.2.2.4.5), and this result "concurs with the results of other studies which suggest that there has been a general increase in cover and biomass of trees and shrubs in sub-Arctic and Arctic areas," citing Sturm *et al*. (2001), Tape *et al*. (2006), Danby and Hik (2007), Forbes *et al*. (2010), Hallinger *et al*. (2010), and Van Bogaert *et al*. (2011). They found the 19% net

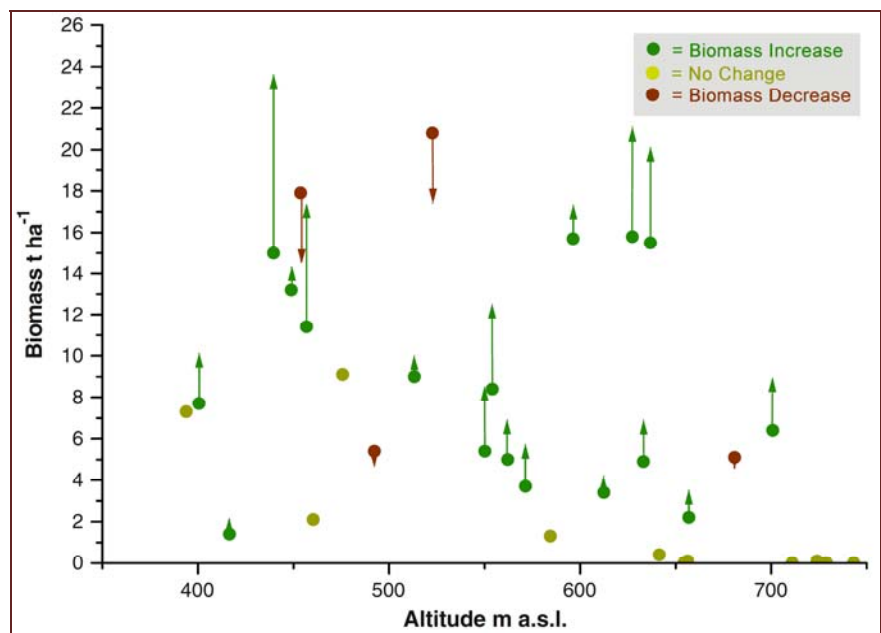

Figure 4.2.2.4.5. Change in mean tree biomass by altitude during the years 1997–2010 from various locations throughout the Swedish sub-Arctic. Colors reveal the direction of the change (green = biomass increase, yellow = no change, and red = biomass decrease), and arrows indicate the magnitude of the change over the 13-year period. Adapted from Hedenas *et al*. (2010).

increase in biomass occurred in spite of the increased browsing pressure provided by a growing reindeer population over the period of their study, as well as periodic outbursts of geometrid moths, which severely defoliated the birch trees in their study area in 2004 (Babst *et al.*, 2010). They write, "it has been suggested that increased nutrient availability associated with higher soil temperatures, and a longer growing season could underpin increased tree and shrub abundance and biomass in the Arctic (e.g., Chapin, 1983; Weih and Karlsson, 1997; Hartley *et al.*, 1999)," as a result of "a delayed re-expansion of shrubs and trees following the 'Little Ice Age,'" as suggested by Grubb (2008).

Noting forests are exposed to a changing environment and "responses to recent climate change start to become visible if observation periods become long enough," Pilegaard *et al.* (2011) present the results of continuous CO_2 flux measurements they made above a mature Danish beech stand in the Lille Bogeskov forest located near Soro on the island of Zealand (55°29'13"N, 11°38'45"E) during the years 1996–2009, describing the long-term changes they observed and relating them to possible causes.

They report observing "significant linear trends of increasing gross ecosystem exchange (GEE: 29 g $C/m^2/year$) and increasing net ecosystem exchange (NEE: 23 g $C/m^2/year$), while the positive trend for ecosystem respiration (RE: 5 g $C/m^2/year$) was not significant." They also state, "the length of the carbon uptake period increased by 1.9 day/year, whereas there was a non-significant increase of 0.3 day/year in the leafed period," which means, they write, "the leaves stay active longer." They say "the increase in the carbon uptake period explained only part of the increasing NEE (9 $gC/m^2/year$)." And noting "the maximum rate of photosynthetic assimilation increased by 15% during the 14-year period," they speculate the increase in canopy carbon uptake capacity "could be due to a combination of [the] increase in atmospheric CO_2, higher summer precipitation, and increased availability of nitrogen."

Lopatin *et al.* (2006) collected discs and cores from 151 Siberian spruce trees and 110 Scots pines in the Komi Republic in the northeast European sector of Russia, from which they developed ring-width chronologies that revealed yearly changes in forest productivity. They developed satellite-based time series of NDVI for the months of June, July, and August of the years 1982–2001, correlated their site-specific ring-width-derived productivity histories with same-site NDVI time series, and used the resulting relationship to establish six regional forest pro-

ductivity histories for the years 1982–2001. They compared the six regional productivity trends over this period with corresponding-region temperature and precipitation trends. For all six vegetation zones of the Komi Republic, this work indicates the 1982–2001 trends of integrated NDVI values from June to August were positive, and the "increase in productivity reflected in [the] NDVI data [was] maximal on the sites with increased temperature and decreased precipitation."

The three scientists write, "several studies (Riebsame *et al.*, 1994; Myneni *et al.*, 1998; Vicente-Serrano *et al.*, 2004) have shown a recent increase in vegetation cover in different world ecosystems." What is special about their study, as they describe it, is "in Europe, most forests are managed, except for those in north-western Russia [the location of their work], where old-growth natural forests are dominant (Aksenov *et al.*, 2002)." They conclude "productivity during recent decades also increased in relatively untouched forests," where non-management-related "climate change with lengthening growing season, increasing CO_2 and nitrogen deposition" are the primary determinants of changes in forest productivity.

Julien *et al.* (2006) "used land surface temperature (LST) algorithms and NDVI [normalized difference vegetation index] values to estimate changes in vegetation on the European continent between 1982 and 1999 from the Pathfinder AVHRR [advanced very high resolution radiometer] Land (PAL) dataset." This analysis revealed arid and semi-arid areas (Northern Africa, Southern Spain, and the Middle East) have seen their mean LST increase and NDVI decrease, and temperate areas (Western and Central Europe) have suffered a slight decrease in LST but a more substantial increase in NDVI, especially in Germany, the Czech Republic, Poland, and Belarus. In addition, parts of continental and Northern Europe experienced either slight increases or decreases in NDVI while LST values have decreased. The Dutch and Spanish researchers conclude, over the last two decades of the twentieth century, "Europe as a whole has a tendency to greening," and much of it is "seeing an increase in its wood land proportion."

4.2.2.5 North America

As in Asia, a significant amount of terrestrial productivity research has been conducted for locations in North America. We group that research into these subsections: *Entire Continent*, *High Latitude Regions*, *Eastern USA*, *Central USA,* and *Western USA*.

4.2.2.5.1 Entire Continent

Zhou *et al*. (2001) determined the satellite-derived normalized difference vegetation index (NDVI) rose by 8.44% over the North American continent between 1981 and 1999. Noting the NDVI "can be used to proxy the vegetation's responses to climate changes because it is well correlated with the fraction of photosynthetically active radiation absorbed by plant canopies and thus leaf area, leaf biomass, and potential photosynthesis," Zhou *et al*. suggest the increases in plant growth and vitality implied by their NDVI data were driven primarily by increases in near-surface air temperature. Ahlbeck (2002) suggests the observed upward trend in NDVI was primarily driven by the rise in atmospheric CO_2 content over the period, since warming was rather muted in North America and in the United States in particular, where temperatures may have declined throughout the eastern part of the country over the period of the study. It is likely both parameters played a role in the observed productivity increase, although the CO_2 increase was more likely the predominant one given the lack of temperature increase over the period of time under study.

Hicke *et al*. (2002) computed net primary productivity (NPP) over North America for the years 1982–1998 using the Carnegie-Ames-Stanford Approach (CASA) carbon cycle model driven by a satellite NDVI record at 8 km spatial resolution. They found NPP increases of 30% or more occurred across the continent from 1982 to 1998. During this period,

the air's CO_2 concentration rose by 25.74 ppm, as calculated from the Mauna Loa data of Keeling and Whorf (1998), which is 8.58% of the 300 ppm increase often used as a reference for expressing plant growth responses to atmospheric CO_2 enrichment. Consequently, for herbaceous plants that display NPP increases of 30–40% in response to a 300 ppm increase in atmospheric CO_2 concentration, the CO_2-induced NPP increase experienced between 1982 and 1998 would have been 2.6–3.4%. Similarly, for woody plants that display NPP increases of 60–80% in response to a 300 ppm increase in atmospheric CO_2 (Saxe *et al*., 1998; Idso and Kimball, 2001), the expected increase in productivity between 1982 and 1998 would have been 5.1–6.9%. As both of these NPP increases are considerably less than the 30% or more observed by Hicke *et al*., additional factors must have helped to stimulate NPP over this period. Those factors may have included concomitant increases in precipitation and air temperature, the tendency for warming to lengthen growing seasons and enhance the aerial fertilization effect of rising CO_2 con-centrations, increasingly intensive crop and forest management, increasing use of genetically improved plants, the regrowth of forests on abandoned cropland, and improvements in agricultural practices such as irrigation and fertilization.

Lim *et al*. (2004) correlated the monthly rate of relative change in NDVI, derived from advanced very high resolution radiometer (AVHRR) data, with the rate of change in atmospheric CO_2 concentration during the natural vegetation growing season in three eco-region zones of North America (Arctic and sub-Arctic zone, humid temperate zone, and dry and desert zone, which they further subdivided into 17 regions) during the years 1982–1992. They explored the temporal progression of annual minimum NDVI during the years 1982–2001 throughout the eastern humid temperate zone of North America. In all of the regions but one, according to the researchers, "δCO_2 was positively correlated with the rate of change in vegetation greenness in the following month, and most correlations were high," which they say is "consistent with a CO_2 fertilization effect" of the type observed in "experimental manipulations of atmospheric CO_2 that report a stimulation of photosynthesis and above-ground productivity at high CO_2." They determined the yearly "minimum vegetation greenness increased over the period 1982–2001 for all the regions of the eastern humid temperate zone in North America."

Lim *et al*. say rising CO_2 could "increase minimum greenness by stimulating photosynthesis at

the beginning of the growing season," citing Idso *et al*. (2000), who discovered that although new spring branch growth of sour orange trees began on exactly the same day of the year in both ambient (400 ppm) and CO_2-enriched (700 ppm) open-top chambers, the rate of new-branch growth was initially vastly greater in the CO_2-enriched trees. Three weeks after branch growth began in the spring, for example, new branches on the CO_2-enriched trees were typically more than four times more massive than their counterparts on the ambient-treatment trees, and on a per-tree basis, more than six times more new-branch biomass was produced on the CO_2-enriched trees, before declining to an approximate 80% stimulation typical of the bulk of the growing season.

By looking for a manifestation of the CO_2 fertilization effect at the time of year it is apt to be most strongly expressed, Lim *et al*. may have found it. Between 1982 and 2001, the air's CO_2 concentration rose by approximately 30 ppm. From Idso *et al*.'s findings of more than a 300% initial increase in the biomass of new sour orange tree branches for a 300 ppm increase in the air's CO_2 concentration and more than a 500% initial increase in per-tree new-branch biomass, it can be calculated yearly minimum greenness should have increased by an amount between just over 30% and just over 50%, if other woody plants respond to atmospheric CO_2 enrichment as sour orange trees do. When the mean 19-year increase in NDVI for the seven regions for which Lim *et al*. present data is calculated, the result is an increase of just over 40%, indicating Lim *et al*.'s data are not only qualitatively consistent with their hypothesis but on the mark quantitatively as well.

Xiao and Moody (2004) examined the responses of the normalized difference vegetation index integrated over the growing season (gNDVI) to annual and seasonal precipitation, maximum temperature (T_{max}), and minimum temperature (T_{min}) over an 11-year period (1990–2000) for six biomes in the conterminous United States (evergreen needleleaf forest, deciduous broadleaf forest, mixed forest, open shrubland, woody savanna, and grassland), focusing on within- and across-biome variance in long-term average gNDVI and emphasizing the degree to which this variance is explained by spatial gradients in long-term average seasonal climate. They found the greatest positive climate-change impacts on biome productivity were caused by increases in spring, winter, and fall precipitation and increases in fall and spring temperature, especially T_{min}, which historically has increased at roughly twice the rate of T_{max} in the United States. They write, "if historical climatic

trends and the biotic responses suggested in this analysis continue to hold true, we can anticipate further increases in productivity for both forested and non-forested ecoregions in the conterminous US, with associated implications for carbon budgets and woody proliferation."

4.2.2.5.2 High Latitude Regions

- Opposite the forecasts promulgated by the models used by IPCC, land-based plants of the Arctic and near-Arctic regions of North America are thriving, thanks in large part to the ongoing rise in the atmosphere's CO_2 concentration and global warming.

For many years, some researchers argued rising temperatures would change the Arctic from a carbon sink to a carbon source, further exacerbating the cause of ecosystem change—regional warming—by adding to the atmosphere's burden of greenhouse gases and hastening that portion of the biosphere's inevitable degradation (Oechel *et al.*, 1993, 1995).

In the early to mid-1970s, for example, when the first carbon balance studies of Alaskan Arctic ecosystems were conducted, wet-sedge communities and moist-tussock tundra were observed to be net sinks of carbon. By the mid-1980s and early 1990s, however, following significant increases in air temperature and surface water deficit, both ecosystems had become net sources of carbon. Then, between 1992 and 1996, in response to further warming and drying that resulted, Oechel *et al.* (2000a) write, in "the highest average summer temperature and surface water deficit observed for the entire 39-year period," both ecosystems' net summer releases of CO_2 to the atmosphere declined, and they became CO_2 sinks.

How did it happen? Oechel *et al.* say their observations indicated "a previously undemonstrated capacity for ecosystems to metabolically adjust to long-term (decadal or longer) changes in climate."

But how did *that* happen? Was there help along the way from the concomitant rise in atmospheric CO_2 content and its aerial fertilization and anti-transpirant effects? Although these well-documented consequences of atmospheric CO_2 enrichment are known to enable plants to better respond to the environmental challenges of warming and drying, Oechel *et al.* downplayed these effects, instead noting other plausible possibilities.

First, there is the likelihood that during the initial stages of warming and soil drying, younger and more labile carbon would be rapidly decomposed, shifting the net summer carbon balance of the ecosystems from carbon sequestration to carbon evolution. After this initial perturbation, Oechel *et al.* suggest "enhanced rates of net nitrogen-mineralization should eventually stimulate rates of gross primary production and atmospheric CO_2 sequestration."

Another possibility is a gradual shift in plant species towards more productive types that would further reduce the large initial carbon losses over time. The researchers state, "there is evidence that the relative abundance of deciduous shrubs has increased in response to climate change over the past 1–2 decades in Alaskan moist-tussock tundra eco-systems," which is also expected to occur as a consequence of the ongoing rise in atmospheric CO_2 content. Capers and Stone (2011), for example, report, in response to rising air temperatures, "trees have established where they did not previously occur, both in alpine areas (Wardle and Coleman, 1992; Peterson, 1994; Kullman, 2001, 2002), and in arctic tundra (Lescop-Sinclair and Payette, 1995; Danby and Hik, 2007)," while "increasing shrub abundance also has been reported in alpine (Klanderud and Birks, 2003) and arctic locations (Sturm *et al.*, 2001; Tape *et al.*, 2006; Wilson and Nilsson, 2009)."

Noting "canopy-forming shrubs are reported to be increasing at sites around the circumpolar Arctic," Myers-Smith *et al.* (2011) examined historic photographs, repeated vegetation surveys, and conducted monitoring of long-term plots on Canada's Herschel Island (69.57°N, 138.91°W) to see what had occurred over the past century on this 100-km^2 parcel of land just off the western Arctic coast of Canada's Yukon Territory. They "found evidence of increases of each of the dominant canopy-forming willow species (*Salix richardsonii*, *Salix glauca* and *Salix pulchra*), during the twentieth century," along with evidence "the majority of willow patches for each of these species became established between 1910 and 1960," "with stem ages and maximum growth rates indicating that some patches could have established as late as the 1980s."

The seven scientists note their observations are an example of the twentieth-century greening of the Circumpolar Arctic, noting "recent evidence indicates an expansion of canopy-forming shrubs at sites on the North Slope of Alaska (Sturm *et al.*, 2001; Tape *et al.*, 2006), on the coast of the Northwest Territories (Lantz *et al.*, 2009), in Northern Quebec (B. Tremblay *et al.*, personal communication), and in northern Russia (Forbes *et al.*, 2010a)." They write, "in Arctic Alaska, canopy cover of alder shrubs has increased by 14–20% on average within the last 40 years, with increases of up to 80% in some areas (Tape *et al.*, 2006)." Also, they note, "studies of population structures of shrub and tree species indicate advancing of shrubs up slopes in alpine tundra ecosystems in subarctic Sweden (Hallinger *et al.*, 2010)," as well as in sites in Norway (Hofgaard *et*

al., 2009), further noting "local indigenous Nenets people in the western Russian Arctic report increasing willow shrubs (Forbes *et al*., 2010b)" and "similar observations of vegetation change by Inuit have been reported in Arctic Canada (Thorpe *et al*., 2002)."

The team of Canadian researchers also states "pollen records indicate willows were widespread in Arctic ecosystems during warmer periods after the last glacial maximum (Brubaker *et al*., 1983; Bigelow *et al*. (2003)." These observations seem to suggest the entire Circumpolar Arctic is in the process of returning to conditions of an earlier period when that part of the planet was a good deal greener—and a good deal livelier—than it has been for a long, long time.

Goetz *et al*. (2005) also documented increased plant growth in the high latitudes of North America. They transformed satellite-derived NDVI data obtained across boreal North America (Canada and Alaska) for the years 1982–2003 into photosynthetically active radiation absorbed by green vegetation and treated the result as a proxy for relative June–August gross photosynthesis (Pg), stratifying the results by vegetation type and comparing them with spatially matched concomitant trends in surface air temperature data. They found area-wide tundra experienced a significant increase in Pg in response to a similar increase in air temperature, and "this observation is supported by a wide and increasing range of local field measurements characterizing elevated net CO_2 uptake (Oechel *et al*., 2000b), greater depths of seasonal thaw (Goulden *et al*., 1998), changes in the composition and density of herbaceous vegetation (Chapin *et al*., 2000; Epstein *et al*., 2004), and increased woody encroachment in the tundra areas of North America (Sturm *et al*., 2001)." For interior forest, they found no significant increase in air temperature and essentially no change in Pg, with the last data point of the series being essentially indistinguishable from the first. This seemingly aberrant observation is in harmony with the fact that at low temperatures the growth-promoting effects of increasing atmospheric CO_2 levels are often very small or even nonexistent (Idso and Idso, 1994), which is what appears to have been the case with North American boreal forests over that time period. As a result, the tundra ecosystems of Canada and Alaska exhibited increasing productivity over the past couple of decades, but their boreal forests did not.

Ropars and Boudreau (2012) state, "Myneni *et al*. (1997, 1998) were the first to report evidence of the pan-Arctic increase in vegetation cover," noting, "by analyzing worldwide NDVI [normalized difference vegetation index] trends between 1981 and 1991, they showed that the greatest increase in photosynthetic activity occurred in regions above 50°N," and "since then, this phenomenon has been observed for different regions," including Alaska (Silapaswan *et al*., 2001; Jia *et al*., 2003; Verbyla, 2008), Russia (Forbes *et al*., 2010a), and Western Canada (Olthof and Pouliot, 2010), over a longer time span (Jia *et al*., 2003; Goetz *et al*., 2005; Verbyla, 2008; Forbes *et al*., 2010a; Olthof and Pouliot, 2010), and at a better resolution (Jia *et al*., 2003; Olthof and Pouliot, 2010). Focusing on an area near the Boniface River research station 35 km east of Hudson Bay and 10 km south of the treeline in subarctic Quebec (Canada), Ropars and Boudreau (2012) evaluated changes in shrub cover over a half-century, comparing two aerial photographs taken in July 1957 and a satellite image of the same area obtained in July 2008.

They found "both hilltops and terraces recorded an increase in shrub cover" (Figure 4.2.2.5.2.1), and "the increase was significantly greater on terraces than on hilltops (21.6% versus 11.6%)," further noting "this finding corroborates other studies using a similar method conducted in different regions of the Arctic," including Alaska (Sturm *et al*., 2001; Tape *et al*., 2006), northern Quebec (Tremblay, 2010), and Russia (Forbes *et al*., 2010), and studies that revealed a major increase of the NDVI over the past few decades (Jia *et al*., 2003; Verbyla, 2008). Ropars and Boudreau conclude, "according to ground truthing, the shrub cover densification is associated mainly with an increase of *Betula glandulosa* Michx"—more commonly known as dwarf birch—and "the

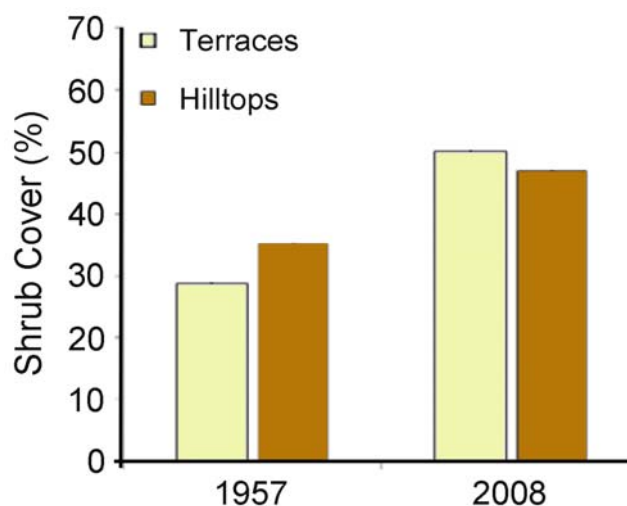

Figure 4.2.2.5.2.1. Percent shrub cover on terraces and hilltops in subarctic Quebec, Canada in 1957 and 2008. Adapted from Ropars and Boudreau (2012).

numerous seedlings observed during the ground truthing suggest that shrub densification should continue in the future."

Hudson and Henry (2009) note the Arctic has warmed by about 1.6°C over the past four decades, citing McBean *et al.* (2005), and this temperature increase has "led the Arctic Climate Impact Assessment (ACIA) and Intergovernmental Panel on Climate Change (IPCC) to predict tundra ecosystems will be particularly threatened by climate change [i.e., warming] over the next century." To provide real-world data with which to judge those predictions, Hudson and Henry measured biomass and com-position changes in a heath community dominated by several vascular plants and bryophytes at an 8-km^2 coastal lowland adjacent to Alexandra Fiord on the east-central coast of Ellesmere Island, Nunavut, Canada. They did so over a period of 13 years (1995–2007), using a point-intercept method in permanent plots, and over a period of 27 years (1981–2008) using a biomass harvest comparison.

"Results from both methods," the Canadian scientists write, "indicate the community became more productive over time," that "bryophyte and evergreen shrub abundances increased," and "deciduous shrub, forb, graminoid, and lichen cover did not change," so "species diversity also remained unchanged." Hudson and Henry further report, "satellite-based remote sensing models, such as green trends derived from the normalized difference vegetation index (NDVI; e.g., Myneni *et al.*, 1997; Zhou *et al.*, 2001; Stow *et al.*, 2004; Verbyla, 2008), and global vegetation and ecosystem process simulations of the terrestrial carbon cycle (e.g., Kimball *et al.*, 2006; Zhang *et al.*, 2008), indicate increasing trends in vegetation photosynthetic activity and net primary production in the Arctic over the past several decades." They write, "it is likely that warming directly increased plant growth and reproduction and indirectly increased resource supply," noting "increased temperatures also lengthened the growing season, increased soil tem-perature, deepened the active [soil] layer, and consequently may have influenced nutrient uptake in the plant community."

Hudson and Henry (2010) used open-top chambers to passively warm an evergreen-shrub heath by 1.0–1.3°C over a period of 15 years, during which time there was also a significant background warming, at the same location at Alexandra Fiord, Nunavut, Canada (79°N), an effort they describe as "the longest-running passive warming experiment in the Canadian Arctic." They report, "experimental

warming did not strongly affect vascular plant cover, canopy height or species diversity, but it did increase bryophyte cover by 6.3% and decrease lichen cover by 3.5%," although "temporal changes in plant cover were more frequent and of greater magnitude than changes due to experimental warming," as pointed out in their study published the year prior and highlighted above.

Madsen *et al.* (2011) compared the aboveground biomass of the graminoid marsh vegetation observed on Jameson Land, low Arctic, East Greenland in surveys conducted in 1982–1984 with similar surveys conducted in 2008, to see what had happened over the intervening period of significant global—and local—warming. The five researchers say the data they obtained in 2008 yielded a standing crop biomass of 98.2 g/m^2, which was 2.34 times greater than what had been measured in the same location in 1984. They note, "on Bylot Island, northeast Canada, graminoid above-ground production in wetlands has increased by 84% between 1990 and 2007, most likely as a consequence of climate warming," citing Cadieux *et al.* (2008), adding "on Svalbard, it is known that early snow melt has a dramatic positive effect on the density of nesting geese and their fecundity," citing Madsen *et al.* (2007) and noting "the climate in East Greenland has been warming during the last 30 years."

Villarreal *et al.* (2012) write, "climate warming is pronounced at high northern latitudes (ACIA, 2005; Serreze, 2010)," and "time series analysis of satellite remote sensing between 1982 and 2008 suggests that there has been a greening of arctic landscapes," citing Bhatt *et al.* (2010). They note "remotely detected changes in the normalized difference vegetation index (NDVI) of the arctic coastal plain near Barrow, Alaska, appear to be among the most dramatic recorded for much of the Arctic," again citing Bhatt *et al.* (2010).

Noting "there is a general scarcity of ground-based studies that examine vegetation change in the Arctic over decade time scales," Villarreal *et al.* in 1999, 2008, and 2010 resampled for species cover and presence 330 marked plots at 33 sites established in 1972, as part of the International Biological Program, in an area near Barrow at the northernmost point of the Alaskan Coastal Plain (71°18'N, 156°40'W).

Over the 38-year study period, they found, ecosystem diversity "increased for most plant communities, and wetter communities changed more than dry and moist plant communities." These findings, they say, support other observational

studies, such as Wilson and Nilsson (2009). Of the 19 species that made up more than 80% of the overall relative cover, they say five had higher relative cover in 2010 than in 1972. Their results for changes in shrub cover "are somewhat consistent with other long-term observations and experimental studies that report increased shrub abundance (Myers-Smith *et al.*, 2011; Tape *et al.*, 2006; Walker *et al.*, 2006; Sturm *et al.*, 2001)," as well as warming-induced "treeline advancement (Lloyd, 2005; Danby and Hik, 2007)."

Tape *et al.* (2006) analyzed repeat photography data from a photo study of the Colville River, Alaska conducted between 1945 and 1953, plus 202 new photos of the same sites obtained between 1999 and 2002, to determine the nature of shrub expansion in that region over the past half-century. They found "large shrubs have increased in size and abundance over the past 50 years, colonizing areas where previously there were no large shrubs." They say their review of plot and remote sensing studies confirms "shrubs in Alaska have expanded their range and grown in size" and "a population of smaller, inter-tussock shrubs not generally sampled by the repeat photography, is also expanding and growing." They conclude, "these three lines of evidence allow us to infer a general increase in tundra shrubs across northern Alaska."

Tape *et al.* are inclined to attribute their findings to large-scale pan-Arctic warming, and from analyses of logistic growth curves, they estimate the expansion began about 1900, "well before the current warming in Alaska (which started about 1970)." Hence, they conclude "the expansion predates the most recent warming trend and is perhaps associated with the general warming since the Little Ice Age." These inferences appear reasonable, although the 80 ppm increase in the atmosphere's CO_2 concentration since 1900 likely played a role in the shrub expansion as well.

Elmendorf *et al.* (2012) note, "remote-sensing data indicate contemporary climate warming has already resulted in increased productivity over much of the Arctic," and "normalized difference vegetation index (NDVI) values have increased over the tundra biome in recent years, indicating a greening of the tundra ecosystem coincident with climate warming trends," citing Pouliot *et al.* (2009) and Bhatt *et al.* (2010). Because "plot-based evidence for vegetation transformation is not widespread," they analyzed "change in tundra vegetation surveyed between 1980 and 2010 in 158 plant communities spread across 46 locations throughout the Arctic," the majority of which were in North America.

The 47 researchers from 12 countries found "biome-wide trends of increased height of the plant canopy and maximum observed plant height for most vascular growth forms; increased abundance of litter; increased abundance of evergreen, low-growing and tall shrubs, and decreased abundance of bare ground." These data confirm the findings of prior satellite assessments of the vegetative transformation of Earth's northernmost collection of landscapes over the past three decades, attributable not only to global warming but also to the aerial-fertilization and water-use-efficiency-enhancing effects of atmospheric CO_2 enrichment.

Wang *et al.* (2006) examined ring-width development in cohorts of young and old white spruce trees in a mixed grass-prairie ecosystem in southwestern Manitoba, Canada, where a 1997 wildfire killed most of the older trees growing in high-density spruce islands but younger trees slightly removed from the islands survived. "Within each of a total of 24 burned islands," the three researchers write, "the largest dominant tree (dead) was cut down and a disc was then sampled from the stump height," while "adjacent to each sampled island, a smaller, younger tree (live) was also cut down, and a disc was sampled from the stump height."

After removing size-, age-, and climate-related trends in radial growth from the ring-width histories of the trees, Wang *et al.* plotted the residuals as functions of time for the 30-year periods for which the old and young trees would have been approximately the same age: 1900–1929 for the old trees and 1970–1999 for the young trees. During the first of these periods, the atmosphere's CO_2 concentration averaged 299 ppm, and during the second it averaged 346 ppm. The mean rate of rise of the atmosphere's CO_2 concentration was 0.37 ppm/year for the first period and 1.43 ppm/year for the second.

The researchers found the slope of the linear regression describing the rate of growth of the ring-width residuals for the later period (when the air's CO_2 concentration was 15% greater and its rate-of-rise 285% greater) was more than twice that of the earlier period. The researchers say these results show, "at the same developmental stage, a greater growth response occurred in the late period when atmospheric CO_2 concentration and the rate of atmospheric CO_2 increase were both relatively high." They note, "these results are consistent with expectations for CO_2-fertilization effects," saying "the response of the studied young trees can be taken as strong

545

circumstantial evidence for the atmospheric CO_2-fertilization effect."

Wang *et al*. also learned the "postdrought growth response was much stronger for young trees (1970–1999) compared with old trees at the same development stage (1900–1929)," and the "higher atmospheric CO_2 concentration in the period from 1970–1999 may have helped white spruce recover from severe drought." They report young trees showed a weaker relationship to precipitation than did old trees, noting "more CO_2 would lead to greater water-use efficiency, which may be dampening the precipitation signal in young trees."

The results presented here for the high latitude region of North America paint a picture of the planet's terrestrial vegetation opposite of that promulgated by the models used by IPCC. Instead of a world heading toward environmental degradation and extinction, land-based plants of the Arctic and near-Arctic regions of North America are thriving, thanks in large part to the ongoing rise in the atmosphere's CO_2 concentration and global warming.

4.2.2.5.3 Eastern USA

- Late twentieth-century increases in air temperature and atmospheric CO_2 concentration did not negatively affect plant communities in the eastern United States. Rather, the temperature and CO_2 increases significantly enhanced local and regional productivity, and there is little reason to think such enhancements will not continue throughout the foreseeable future.

Pan *et al*. (2009) examined "how changes in atmospheric composition (CO_2, O_3 and N deposition), climate and land-use affected carbon dynamics and sequestration in Mid-Atlantic temperate forests during the 20th century," modifying and applying "a well-established process-based ecosystem model with a strong foundation of ecosystem knowledge from experimental studies." They validated the model "using the U.S. Forest Inventory and Analysis (FIA) data."

For previously harvested and currently regrowing forests, the calibrated model produced changes in net ecosystem productivity (NEP) due to observed changes in N deposition (+32%), CO_2 (+90%), O_3

(-40%), CO_2 + O_3 (+60%), CO_2 + N deposition (+184%), and CO_2 + N deposition + O_3 (+138%). Corresponding changes in NEP for undisturbed forests were +18%, +180%, -75%, +78%, +290%, and +208%. They report "the 'fertilization' effect of N deposition mainly stimulates carbon allocation to short-lived tissues such as foliage and fine roots," but "the 'fertilization' effect by elevated CO_2 likely enhances more sustainable carbon storage such as woody biomass (including coarse roots)."

The four USDA Forest Service scientists say their findings indicate "the change in atmospheric composition, particularly elevated CO_2, will gradually account for more of the carbon sink of temperate forests in the Mid-Atlantic region," and "such a significant 'fertilization effect' on the forest carbon sequestration could eventually result in a 'greener world' after a long period of chronic change in atmospheric composition and cumulative impact."

Westfall and Amateis (2003) used mean height measurements made at three-year intervals over a period of 15 years from dominant stands of loblolly pine plantations growing at 94 locations across the southeastern United States to calculate a site index related to the mean growth rate for each of the five three-year periods. They expected the index would increase monotonically if growth rates were being enhanced above normal by some monotonically increasing factor that promotes growth. The researchers found, the "mean site index over the 94 plots consistently increased at each re-measurement period," suggesting "loblolly pine plantations are realizing greater than expected growth rates." They found the growth rate increases grew larger with each succeeding three-year period.

Westfall and Amateis considered attributing their findings to increases in temperature and precipitation in addition to rising atmospheric CO_2 concentrations, but they report a review of annual precipitation amounts and mean ground surface temperatures showed no trends in these factors over the period of their study. They also say if increased nitrogen deposition were the cause, "such a factor would have to be acting on a regional scale to produce growth increases over the range of study plots." Hence, they favor the aerial fertilization effect of atmospheric CO_2 enrichment as being responsible for the accelerating pine tree growth rates.

McMahon *et al*. (2010) state, "there are indications that forest biomass accumulation may be accelerating where nutrients and water are not limiting," citing Myneni *et al*. (1997), Lewis *et al*. (2004), Lewis *et al*. (2009), Boisvenue and Running (2006), Delpierre *et al*. (2009), Salzer *et al*. (2009), and Chave *et al*. (2008). They further investigated the subject because of the great significance such growth portends for the planet's carbon balance and the future course of potential CO_2-induced global warming.

Using unique datasets of tree biomass collected from 55 temperate forest plots with known land-use histories and stand ages ranging from five to 250 years (which were derived from knowledge of when the stands had begun to regrow following major disturbances such as significant logging, various natural disasters that had decimated large patches of trees, or the clearing of trees to make room for agriculture that was ultimately abandoned), McMahon *et al*. "estimated biomass change, while controlling for stand regeneration" (see Figure 4.2.2.5.3.1) in parts of a temperate deciduous forest in the vicinity of the Smithsonian Environmental Research Center, Edgewater, Maryland (USA). They compared recent (the prior 22 years or less) rates of biomass accumulation of the various stands with rates predicted for those age intervals by the overall growth function derived from the combined data of all of the stands. They compared their findings with "over 100 years of local weather measurements and 17 years of on-site atmospheric CO_2 measurements."

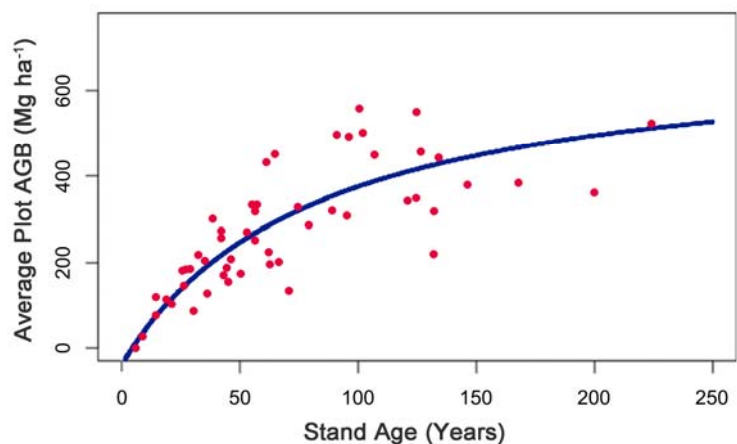

Figure 4.2.2.5.3.1. Graphic showing the relationship between above-ground biomass (AGB) and stand age of multiple-censused forest plots in a temperate deciduous forest in and near the Smithsonian Environmental Research Center in Edgewater, MD. The plot indicates younger trees are growing faster than older ones. Adapted from McMahon *et al*. (2010).

The authors report the results of their analysis reveal "recent biomass accumulation greatly exceeded the expected growth caused by natural recovery," and they note in stands younger than 50 years the observed rate increase was generally at least one-third of total growth, and in older stands it typically was "the majority of growth," even though past experience and the ensemble relationship of growth vs. age derived from their data suggest "old forests should grow very little as they approach equilibrium."

The Smithsonian scientists write, "increases in temperature, growing season [which is largely driven by temperature], and atmospheric CO_2 have documented influences on tree physiology, metabolism, and growth," and they state these factors may have been "critical to changing the rate of stand growth observed across stands."

Capers and Stone (2011) "studied a community in western Maine, comparing the frequency and abundance of alpine plants in 2009 with frequency and abundance recorded in 1976," noting "the 2009 survey was designed to provide a fair comparison with that of 1976," which was conducted and described by Stone (1980). The two researchers found the 2009 survey "provided evidence of the increasing importance of woody plants—both trees and shrubs—in the alpine community" (Figure 4.2.2.5.3.2), commenting, "the most widespread tree species increased dramatically." They "recorded an increase in total species richness of the community with the addition of four lower montane species that had not been recorded previously" and "found no evidence that species with high-arctic distributions had declined more than other species."

Capers and Stone write the changes they recorded "are consistent with those reported in tundra communities around the world." And although there is some concern the observed increase in species richness could turn out to be temporary if alpine species were to disappear because of competition from new species, they state, "species losses resulting from competition have not typically been found with rising richness in high alpine areas, possibly because newly arriving species occupy different micro-habitats," citing Walther et al. (2005).

Ziska et al. (2004) characterized the gradual changes that occur in a number of environmental variables as one moves from a rural location (a farm approximately 50 km from the center of the city of

Figure 4.2.2.5.3.2. The relative frequency of five functional plant groups from surveys taken in 1976 and 2009 in a Northeast United States alpine plant community. The relative frequency of trees increased by a significant 14%, whereas the changes in forbs and graminoids were only marginally significant. Adapted from Capers and Stone (2011).

Baltimore, Maryland (USA)) to a suburban location (a park approximately 10 km from the city center) to an urban location (the Baltimore Science Center approximately 0.5 km from the city center). At each of these locations, four 2 x 2 m plots were excavated to a depth of about 1.1 m and filled with identical soils, the top layers of which contained seeds of naturally occurring plants of the general area. These seeds sprouted in the spring, and the plants they produced were allowed to grow until they senesced in the fall, after which all were cut at ground level, removed, dried, and weighed.

Along the rural to suburban to urban transect, the only consistent differences in the environmental variables Ziska et al. measured were a rural to urban increase of 21% in average daytime atmospheric CO_2 concentration and increases of 1.6 and 3.3°C in maximum (daytime) and minimum (nighttime) daily temperatures, respectively. These changes, they write, "were consistent with most short-term (~50 year) global change scenarios regarding CO_2 concentration and air temperature." They write, "productivity, determined as final above-ground biomass, and maximum plant height were positively affected by daytime and soil temperatures as well as enhanced CO_2, increasing 60 and 115% for the suburban and urban sites, respectively, relative to the rural site."

The three researchers say their results suggest "urban environments may act as a reasonable surrogate for investigating future climatic change in vegetative communities," and those results

demonstrate rising air temperatures and CO_2 concentrations tend to produce dramatic increases in the productivity of the natural ecosystems typical of the greater Baltimore area and, by inference, probably those of many other areas as well.

The studies discussed above find late twentieth-century increases in air temperature and atmospheric CO_2 concentration did not negatively affect plant communities in the eastern United States. Rather, the temperature and CO_2 increases significantly enhanced local and regional productivity, and there is little reason to think such enhancements will not continue throughout the foreseeable future.

4.2.2.5.4 Central USA

- The late twentieth-century rise in temperature and CO_2 has improved the productivity of plant communities in the central region of the United States, notwithstanding model-based concerns to the contrary.

Voelker *et al*. (2006) studied two species of oak (*Quercus velutina* Lam. and *Quercus coccinea* Muench.) and one of pine (*Pinus echinata* Mill.) in the Ozark Mountains of Missouri (USA). They report since 1850 the stem growth of the three species has risen "coincidently with increases in atmospheric CO_2," such that the overall trend in ring-width in recent years is "nearly two times that" experienced prior to 1850 (Figure 4.2.2.5.4.1). They note "long-term increases in radial growth appear unrelated to historical disturbance levels for the region, to long-term changes in relevant climatic variables, or to productivity of sites sampled." The four Department of Forestry researchers from the University of Missouri suggest a continual rise in the atmosphere's CO_2 concentration, aided by continued nitrogen deposition, likely will "stimulate further increases in the rates of stand development and carbon storage."

Figure 4.2.2.5.4.1. Mean ring width responses by pith date calculated across 11 equally spaced cambial ages from 1 to 50, for randomly sampled oak and pine trees in the Ozark Mountains of Missouri, USA. The means for P. echinata (Stambaugh and Guyette 2004) were calculated from three cambial ages but were shifted to the pith date for accurate intercomparisons among datasets (see Voelker *et al*., 2006). The smoothed grand mean was calculated across each of the closest 14 ring widths. Adapted from Voelker *et al*. (2006).

Cole *et al*. (2010) note quaking aspen (*Populus tremuloides* Michx.) is a dominant forest type in north-temperate, montane, and boreal regions of North America, "the most widely distributed tree species on the continent," and aspen and related poplars are "quintessential foundation species (Ellison *et al*., 2005), shaping the structure and function of the communities and ecosystems in which they occur

(Whitham *et al*., 2006; Schweitzer *et al*., 2008; Madritch *et al*., 2009)." They sought to determine how this keystone species may have responded to the increase in atmospheric CO_2 concentration that has occurred over the past several decades, especially in light of the climatic changes that occurred concurrently.

The four researchers collected branches from 919 trees after their leaves had dropped in the fall, obtaining samples that represented 189 genets or clones (five trees per clone) at 11 sites distributed throughout three regions of Wisconsin (USA). The sampled trees ranged from five to 76 years of age and came from second-growth unmanaged forests south of the areas defoliated by forest tent caterpillars in 1980–1982, 1989–1990, and 2001–2002. In addition, the scientists recorded trunk diameter at breast height for each sampled tree, a parameter, they write, "is very highly correlated with total biomass in aspen," citing Bond-Lamberty *et al*. (2002).

The Minnesota and Wisconsin scientists report, "age-specific ring width increased over time" and "the greatest increase occurred for relatively young trees, so young trees grew faster in recent years than did young trees several decades ago." During the past half-century, for example, they found the growth of trees 11–20 years old rose by 60% (Figure 4.2.2.5.4.2). They write, "rising CO_2 causes ring width to increase at all moisture levels, apparently resulting from improved water use efficiency," so "the overall increase results from historical increases in both CO_2 and water availability." When they separated out the impacts of the two factors, they found "the effect of rising CO_2 had been to increase ring width by about 53%" as a result of "a 19.2% increase in ambient CO_2 levels during the growing season, from 315.8 ppm in 1958 (when CO_2 records began) to 376.4 ppm in 2003."

Cole *et al*. comment "the magnitude of the growth increase uncovered by this analysis raises the question of how much other major forest species have responded to the joint effects of long-term changes in CO_2 and precipitation."

Woody plants in the U.S. Northern Great Plains

Figure 4.2.2.5.4.2. Mean ring width of quaking aspen trees sampled in Wisconsin, USA. Adapted from Cole *et al*. (2010).

also have responded positively to the twentieth-century increase in atmospheric CO_2 by expanding their ranges, and that expansion has led to greater benefits beneath the soil as well. Springsteen *et al*. (2012) note, "changes in soil attributes under woody vegetation have been documented in the arid grasslands of the southern Great Plains, including increases in soil carbon and nitrogen," citing Reynolds *et al*. (1999), Hibbard *et al*. (2001, 2003), McCulley *et al*. (2004), Schade and Hobbie (2005), and Liao *et al*. (2006). In their own investigation, Springsteen *et al*. examined near-surface (upper 15 cm) soil biogeochemistry along a 42-year (1963–2005) chronosequence, which encompassed grassland, woodland, and grassland-woodland transition zones in a northern Great Plains grassland at the USDA-ARS Northern Great Plains Research Laboratory near Mandan, North Dakota (USA), to determine the influence of woody plant expansion on soil carbon and nitrogen contents.

The four researchers report total soil carbon content rose by 26% across the chronosequence from grassland to woodland within the 0–15 cm soil depth, and total soil nitrogen content rose by 31%. The rate of woody shrub expansion from 1963 to 1988 (25 years) was ~1,800 m^2 per year at their study site, and from 1988 to 2005 (17 years) it was ~3,800 m^2 per year, just a little more than doubled. Soil carbon sequestration driven by woody-plant invasions of grasslands, which are driven to a significant degree by the ongoing rise in the atmospheric CO_2 content, as well as the increases in soil nitrogen content required to sustain them, are growing with the passage of time.

In a vastly different type of study based on a 48-year record derived from an average of 17 measurements per year, Raymond and Cole (2003) demon-

strated the export of alkalinity, in the form of bicarbonate ions, from the USA's Mississippi River to the Gulf of Mexico had increased by approximately 60% since 1953. "This increased export," they write, was "in part the result of increased flow resulting from higher rainfall in the Mississippi basin," which had led to a 40% increase in annual Mississippi River discharge to the Gulf of Mexico over the period. The remainder of the increased export of alkalinity had to have been due to increased rates of chemical weathering of soil minerals.

The two researchers note the mechanisms potentially responsible for this phenomenon include "an increase in atmospheric CO_2, an increase [in] rainwater throughput, or an increase in plant and microbial production of CO_2 and organic acids in soils due to biological responses to increased rainfall and temperature." They don't mention as a mechanism, but should have, the increase in terrestrial plant productivity produced by the increase in the aerial fertilization effect of the atmosphere's rising CO_2 content, which also leads to an increase in plant and microbial production of CO_2 and organic acids in soils.

The findings presented above indicate the late twentieth-century rise in temperature and CO_2 has improved the productivity of plant communities in the central region of the United States, notwithstanding model-based concerns to the contrary.

4.2.2.5.5 Western USA

- The late twentieth-century rise in temperature and CO_2 has improved the productivity of plant communities in the western region of the United States, notwithstanding model-based projections of unprecedented ecological disaster due to rising temperatures and drought.

Baron *et al*. (2000) used an empirically based hydro-ecological simulation model to evaluate the consequences of a doubling of atmospheric CO_2 content and 2 to 4°C increases in air temperature on ecosystem performance in a high-elevation Rocky Mountain watershed. They found "both photosynthesis and transpiration were highly responsive to doubled CO_2." They also determined the positive effects of the 4°C temperature increase "were additive, so a warmer and carbon-rich environment increased plant growth by 30%." The authors conclude, "forests will expand at the expense of tundra in a warmer, wetter, and enriched CO_2 world," and observed increases in tree height and density in recent decades illustrate "the rapidity with which vegetation can respond to climate change."

Because urban environments are affected by urban heat islands, carbon dioxide domes, and high-level nitrogen deposition, Shen *et al*. (2008) write, "to some extent they portend the future of the global ecosystem," and they "provide a unique 'natural laboratory' to study potential ecosystem responses to anthropogenic environmental changes." The team of four authors used a version of the Patch Arid Land Simulator-Functional Types (PALS-FT) process-based ecosystem model—originally developed for the Chihuahuan Desert but modified to represent the *Larrea tridentata*-dominated ecosystem characteristic of the Sonoran Desert in which Phoenix, Arizona (USA) is located—to investigate the impacts of previously documented city-to-desert gradients of atmospheric CO_2 concentration, air temperature (TA), and nitrogen deposition (N_{dep}) on aboveground net primary productivity (ANPP) and soil organic matter (SOM).

In response to the mean maximum rural-to-urban increases in CO_2 (160 ppm), N_{dep} (24 kg per ha/year) and TA (4.0°C) characteristic of Phoenix, mean ANPP changes of +52.5, +42.7 and -7.8 g dry matter (DM) per m^2/year were obtained, respectively, from the 76.3 g DM per m^2/year characteristic of desert conditions, when each of the three factors was increased individually. When all three parameters were increased together, the researchers found the net increase in ANPP was even greater than the sum of the three individual results: 108 vs. 87.4 g DM per m^2/year, translating to respective percentage increases

of 142% vs. 115%. In the case of SOM, increases of 18.5, 12.3, and 1.2 g C per m^2/year were obtained for mean maximum individual increases in CO_2, N_{dep}, and TA, respectively, and the combined increase was 30.9 g C per m^2/year. These findings indicate that even in a desert region as hot as Phoenix, the types of CO_2, temperature, and nitrogen deposition increases predicted for the years ahead portend huge increases in indigenous ecosystem productivity and soil organic matter buildup.

Zavaleta and Kettley (2006) examined patterns of production, standing biomass, carbon (C) and nitrogen (N) storage, community composition, and soil moisture along a 25-year chronosequence of sites in an annual, exotic-dominated grassland at Stanford University's Jasper Ridge Biological Preserve in the interior foothills of the central coast range south of San Francisco, California (USA), various parts of which had been invaded at a number of different times over the past quarter-century by *Baccharis pilularis* shrubs.

The two researchers report increasing above- and below-ground biomass along the chronosequence "drove increases in ecosystem N sequestration of ~700% and in C storage of over 125%," including a 32% increase in total soil C over the 25-year period. They write, "increases in carbon storage also did not appear to be saturating at 25 years after shrub establishment in any pool, suggesting the potential for additional carbon gains beyond 25 years." *Baccharis* shrubs began to decline in prominence after about 20 years, as native oaks "with life spans of centuries" and the potential to drive even larger ecosystem changes began to grow in the shrub-dominated areas.

Zavaleta and Kettley note they "initially hypothesized *Baccharis*-invaded sites would experience increasing N limitation as N was immobilized in biomass and litter." However, they found "total soil N increased rapidly with shrub age" and "the magnitude of increase in total soil nitrogen was much larger than the increase in nitrogen immobilization in biomass and litter over time." They say their findings "illustrate the potential for important vegetation-mediated ecosystem responses and feedbacks to atmospheric CO_2 and climate change." In particular, they highlight the great potential for a CO_2-induced range expansion of trees, and they pretty much lay to rest the claim (Hungate *et al.*, 2003) that the availability of nitrogen, in forms usable by plants, will probably be too low for large future increases in carbon storage driven by CO_2-induced increases in plant growth and development.

Peterson and Neofotis (2004) grew velvet mesquite (*Prosopis velutina* Woot.) seedlings for six weeks from their time of planting (as seeds) in small pots in environmentally controlled growth chambers maintained in a laboratory setting at atmospheric CO_2 concentrations of 380 and 760 ppm and two levels of water availability (high and low). Although they did not see a significant CO_2-induced increase in plant growth, by the end of their six-week study they observed a significant reduction of approximately 41% in the volume of water transpired by *P. velutina* in response to the experimental doubling of the atmospheric CO_2 content. "This large reduction in whole-plant water use," they write, "occurred because the reduction in transpiration per unit leaf area at elevated CO_2 was not offset by a proportional increase in total leaf area."

The pair of scientists from the Biosphere 2 Center near Oracle, Arizona (USA) say their findings suggest "under a future [high-CO_2] scenario, seedlings may deplete soil moisture at a slower rate than they do currently," and "this could facilitate seedling survival between intermittent rain events." They note their work "corroborates the conclusions of Polley *et al.* (1994, 1999, 2003) that increasing levels of atmospheric CO_2 may facilitate the establishment of mesquite seedlings through a reduction in soil water depletion." They note "mesquites and other woody species in the semiarid southwestern United States have shown substantial increases in population density and geographic range since Anglo-American settlement of the region approximately 120 years ago," citing Van Auken and Bush (1990), Gibbens *et al.* (1992), Bahre and Shelton (1993), Archer (1995), Boutton *et al.* (1999), Van Auken (2000), Ansley *et al.* (2001), Wilson *et al.* (2001), and Biggs *et al.* (2002).

Among such studies could also be listed the work of Feng (1999), who derived variations in plant intrinsic water-use efficiency over the preceding two centuries from 23 carbon isotope tree-ring chronologies. Their results were nearly identical to the historical trend in the atmospheric CO_2 content, with plant intrinsic water-use efficiency rising by 10 to 25% from 1750 to 1970, during which time the air's CO_2 concentration rose by approximately 16%. Feng concludes, "in arid environments where moisture limits the tree growth, biomass may have increased with increasing transpiration efficiency," noting the enhanced growth of trees in arid environments may "have operated as a carbon sink for the anthropogenic CO_2" emitted during that period.

Soule and Knapp (2006) studied ponderosa pine trees at eight sites in the Pacific Northwest of the

United States to see how they may have responded to the increase in the atmosphere's CO_2 concentration that occurred after 1950. The two geographers say the sites they chose "fit several criteria designed to limit potential confounding influences associated with anthropogenic disturbance." They selected locations with "a variety of climatic and topo-edaphic conditions, ranging from extremely water-limiting environments ... to areas where soil moisture should be a limiting factor for growth only during extreme drought years." They also note all sites were located in areas "where ozone concentrations and nitrogen deposition are typically low."

At all eight of the sites, Soule and Knapp obtained core samples from about 40 mature trees that included "the potentially oldest trees on each site," so their results would indicate, as they put it, "the response of mature, naturally occurring ponderosa pine trees that germinated before anthropogenically elevated CO_2 levels, but where growth, particularly post-1950, has occurred under increasing and substantially higher atmospheric CO_2 concentrations." Utilizing meteorological evaluations of the Palmer Drought Severity Index, they compared ponderosa pine radial growth rates during matched wet and dry years pre- and post-1950.

Overall, the two researchers discovered a post-1950 radial growth enhancement "more pronounced during drought years compared with wet years, and the greatest response occurred at the most stressed site" (see Figure 4.2.2.5.5.1). As for the magnitude of the response, they write, "the relative change in growth [was] upward at seven of our [eight] sites, ranging from 11 to 133%."

Soule and Knapp say their results show "radial growth has increased in the post-1950s period ... while climatic conditions have generally been unchanged," which suggests "nonclimatic driving forces are operative." They say the "radial growth responses are generally consistent with what has been shown in long-term open-top chamber (Idso and Kimball, 2001) and FACE studies (Ainsworth and Long, 2005)." They conclude their findings "suggest that elevated levels of atmospheric CO_2 are acting as a driving force for increased radial growth of ponderosa pine, but the overall influence of this effect may be enhanced, reduced or obviated by site-specific conditions."

Soule and Knapp note they "hypothesized that ponderosa pine ... would respond to gradual increases in atmospheric CO_2 over the past 50 years, and that these effects would be most apparent during drought stress and on environmentally harsh sites," and they report their results "support these hypotheses." They conclude, "an atmospheric CO_2-driven growth-enhancement effect exists for ponderosa pine growing under specific natural conditions within the interior Pacific Northwest."

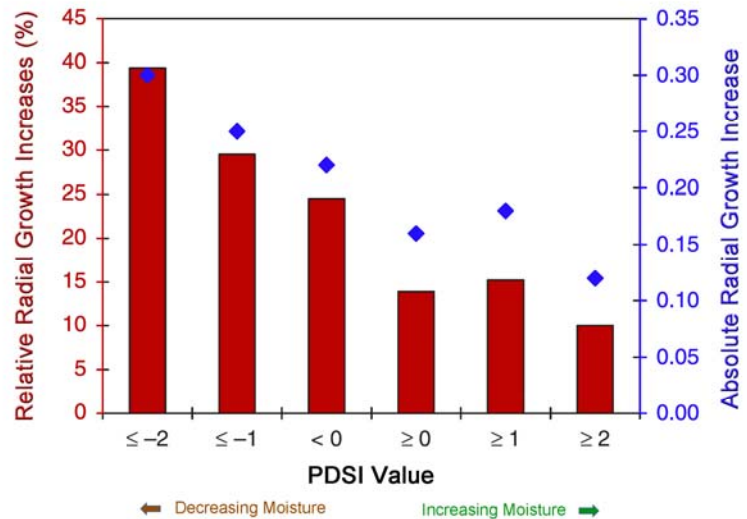

Figure 4.2.2.5.5.1. Relative and absolute radial growth increases of Ponderosa pine (Pinus ponderosa) in the Pacific Northwest, USA, post-1950 compared with pre-1950 during years falling into various Palmer Drought Severity Index (PDSI) categories of drought (moist) severity. Adapted from Soule and Knapp (2006).

The studies in this section document the late twentieth-century rise in temperature and CO_2 has improved the productivity of plant communities in the western region of the United States, notwithstanding model-based projections of unprecedented ecological disaster due to rising temperatures and drought.

4.2.2.6 South America

- Warmer temperatures and higher CO_2 concentrations are resulting in net primary productivity increasing across tropical South America, overcoming the effects of deforestation, forest fires, and incursions by human civilization into natural areas.

Beerling and Mayle (2006) investigated the Amazonian ecosystem's response to the large-scale environmental changes experienced during glacial-interglacial cycles via a series of 21,000-year simulations. They used a dynamic process-based ecosystem model for three scenarios: real-world glacial-to-interglacial changes in CO_2 concentration and climate, the real-world change in CO_2 with a constant preindustrial climate, and the real-world change in climate with a constant preindustrial CO_2 concentration.

During the last glacial maximum, the model suggests "total above-ground carbon storage in Amazonia was half preindustrial values, indicative of rain forests with markedly lower canopy densities and simpler structures due to lowered CO_2 levels, corroborating modeling studies by Cowling (2004) and Cowling *et al*. (2001)." Thereafter, they write, "biome

557

shifts in ecotonal areas since the last glacial maximum ["the competitive replacement of drought-adapted vegetation (e.g. savanna or deciduous/ semideciduous dry forest) by rain forest"] were driven predominantly by climate change, while coincident, increased ecosystem carbon storage throughout the Amazon Basin was driven largely by CO_2."

As to the contemporary relevance of these findings, Beerling and Mayle write, "the underlying cause for the observed trend of increasing biomass in long-term Amazonian forest plots over recent years, despite drought-induced El Niño events (Phillips *et al.*, 1998; Baker *et al.*, 2004a), has been a subject of considerable debate (Baker *et al.*, 2004a; Wright, 2005)," and they conclude "this biomass increase is part of a long-term historical trend driven by anthropogenically induced rising CO_2 levels since the 19th century."

Ichii *et al.* (2005) "simulated and analyzed 1982–1999 Amazonian, African, and Asian carbon fluxes using the Biome-BGC prognostic carbon cycle model driven by National Centers for Environmental Prediction reanalysis daily climate data" and "calculated trends in gross primary productivity (GPP) and net primary productivity (NPP)." They found solar radiation variability to be the primary factor responsible for inter-annual variations in GPP, followed by temperature and precipitation variability. In terms of GPP trends, they report, "recent changes in atmospheric CO_2 and climate promoted terrestrial GPP increases with a significant linear trend in all three tropical regions." In the Amazonian region, the rate of GPP increase was highest, at 0.67 PgC year[-1] per decade, and in Africa and Asia it was about 0.3 PgC year[-1] per decade. As Beerling and Mayle found, Ichii *et al.* say carbon dioxide was the major cause of increased growth, reporting, "CO_2 fertilization effects strongly increased recent NPP trends in regional totals."

This finding is especially interesting because many scientists over the past century believed old-growth forests, such as those of Amazonia, were close to dynamic equilibrium. Just the opposite, however, has been observed repeatedly by several groups of researchers over the past two decades.

Phillips and Gentry (1994) analyzed the turnover rates—close correlates of net productivity (Weaver and Murphy, 1990)—of 40 tropical forests from around the world. They report the growth rates of

these already highly productive forests have been rising since at least 1960, and they have undergone an apparent acceleration in growth rate sometime after 1980. Pimm and Sugden (1994) report the consistency and simultaneity of the forest growth trends Phillips and Gentry documented on several continents led them to conclude "enhanced productivity induced by increased CO_2 is the most plausible candidate for the cause of the increased turnover."

Phillips *et al.* (1998) analyzed forest growth rate data for the years 1958 to 1996 for several hundred plots of mature tropical trees around the world, finding tropical forest biomass, as a whole, increased substantially over the period of record (Figure 4.2.2.6.1). The increase in the neotropics (tropical Central and South America) was equivalent to approximately 40% of the missing terrestrial carbon sink of the entire globe. They identify the aerial fertilization effect of the ongoing rise in atmospheric CO_2 content as one of the primary factors likely to be responsible for this phenomenon.

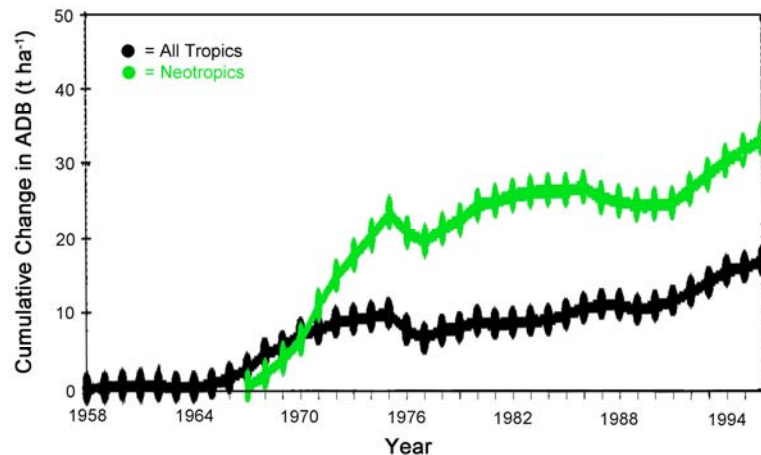

Figure 4.2.2.6.1. Cumulative aboveground dry biomass change (ADB) per year in humid forests in the entire Tropics since 1958 and in the Neotropics (tropical Central and South America) since 1967. Adapted from Phillips *et al.* (1998).

Laurance *et al.* (2004a) reported accelerated growth in the 1990s relative to the 1980s for the large majority (87%) of tree genera in 18 one-hectare plots spanning an area of about 300 km[2] in central Amazonia, and Laurance *et al.* (2004b) observed similarly accelerated tree community dynamics in the 1990s relative to the 1980s. Laurance *et al.* (2005) suggest these "pervasive changes in central Amazonian tree communities were most likely caused by global- or regional-scale drivers, such as increasing atmospheric CO_2 concentrations (Laurance

et al., 2004a,b)." They "interpreted these changes as being consistent with an ecological 'signature' expected from increasing forest productivity (cf., Phillips and Gentry, 1994; Lewis *et al.* 2004a,b; Phillips *et al.*, 2004)." Noting Nelson (2005) challenged this conclusion, they considered his arguments in some detail, dismantling each one.

Lewis (2006) reports the increasing dynamism and productivity of intact tropical forests has had a long history, noting "across the paleotropics forest dynamism has been steadily increasing for five decades (Phillips and Gentry, 1994)." Among 50 old-growth plots across tropical South America, for example, he notes "stem recruitment, stem mortality, and biomass growth, and loss, all increased significantly (Lewis *et al.*, 2004a)." He reports "over approximately the last 20 years, long-term monitoring of 59 plots showed that above-ground biomass increased by 0.6 ± 0.2 tonnes C ha^{-1} a^{-1}, or a relative increase of $0.50 \pm 0.17\%$ a^{-1} (mean $\pm$ 95% confidence interval; Baker *et al.*, 2004a)." This rate of increase "is slightly higher than that documented by Phillips *et al.* (1998)." Lewis concludes there is no question "over the past two decades these forests have shown concerted changes in their ecology, becoming, on average, faster growing—more productive—and more dynamic, and showing a net increase in above-ground biomass."

Lewis states "the results appear to show a coherent fingerprint of increasing net primary productivity across tropical South America, caused by a long-term increase in resource availability (Lewis *et al.*, 2004a,b)." The four resources he identifies are increases in solar radiation, air temperature, nutrient deposition, and atmospheric CO_2 concentration. After analyzing each of them in detail, he concludes "the most parsimonious explanation is the increase in atmospheric CO_2, because of the undisputed long-term historical increase in CO_2 concentrations, the key role of CO_2 in photosynthesis, and the demonstrated positive effects of CO_2 fertilization on plant growth rates including experiments on whole temperate-forest stands (Ainsworth and Long, 2005)." He writes, the explanation is in "the anthropogenic increase in atmospheric carbon dioxide concentrations, increasing forest net primary productivity leading to accelerated forest growth and dynamics."

In spite of the forest growth optimism inherent in the studies cited above, some pessimists remained. Gloor *et al.* (2009) write, "analysis of earlier tropical plot data has suggested that large-scale changes in forest dynamics are currently occurring in Amazonia (Phillips and Gentry, 1994; Phillips *et al.*, 2004a), and

an increase in aboveground biomass has occurred, with increases in mortality tending to lag increases in growth (Phillips *et al.*, 1998; Baker *et al.*, 2004a,b; Lewis *et al.*, 2004a)." They state this conclusion had been challenged by an overzealous application of the "Slow in, Rapid out" dictum, which relates to the fact that forest growth is a slow process, whereas mortality can be dramatic and singular in time, so sampling over relatively short observation periods may miss the more severe events, leading to positively biased estimates of aboveground biomass trends when either no trend or negative trends actually exist.

Gloor *et al.* statistically characterized the disturbance process in Amazon old-growth forests as recorded in 135 forest plots of the RAINFOR network up to 2006, as well as other independent research programs, exploring the consequences of sampling artifacts using a data-based stochastic simulator. The authors report, "over the observed range of annual aboveground biomass losses, standard statistical tests show that the distribution of biomass losses through mortality follow an exponential or near-identical Weibull probability distribution and not a power law as assumed by others." They write, "the simulator was parameterized using both an exponential disturbance probability distribution as well as a mixed exponential-power law distribution to account for potential large-scale blow-down events," and "in both cases, sampling biases turn out to be too small to explain the gains detected by the extended RAINFOR plot network." Gloor *et al.* conclude their results lend "further support to the notion that currently observed biomass gains for intact forests across the Amazon are actually occurring over large scales at the current time, presumably as a response to climate change."

Bonal *et al.* (2011) write, "the impact of global change during the last century on the biology of tropical rainforest trees is largely unknown," but "an increase in tree radial growth increment over recent decades in Amazonian tropical rainforests has been observed, leading to increased above-ground biomass at most study sites," citing Phillips *et al.* (1998, 2009) and Malhi *et al.* (2004). They note "the stimulating impact on photosynthesis of increased CO_2 concentrations in the air (Ca) could explain these growth patterns (Lloyd and Farquhar, 2008)."

Bonal *et al.* assessed the impacts of historical environmental changes "on leaf morphological (stomatal density, stomatal surface, leaf mass per unit area) and physiological traits (carbon isotope composition, $\delta^{13}C$leaf, and discrimination, $\Delta^{13}C$leaf, oxygen isotope composition, $\delta^{18}O$leaf) of two tropical

rainforest species (*Dicorynia guianensis*; *Humiria balsamifera*) that are abundant in the Guiana shield (Northern Amazonia)," working with leaf samples from different international herbariums that covered a 200-year period (AD 1790–2004).

The 11 researchers found "a clear response of leaf physiological characteristics to increasing Ca for both species," consistent with the findings of previous studies "from different ecosystems (Penuelas and Azcon-Bieto, 1992; Beerling *et al.*, 1993; Van de Water *et al.*, 1994; Pedicino *et al.*, 2002; Penuelas *et al.*, 2008), and with data from tree rings in Europe (Bert *et al.*, 1997; Duquesnay *et al.*, 1998; Saurer *et al.*, 2004), Africa (Gebrekirstos *et al.*, 2009) and in tropical rainforests (Hietz *et al.*, 2005; Silva *et al.*, 2009; Nock *et al.*, 2011)." They say their results indicate "an increase in water-use efficiency over recent decades of about 23.1 and 26.6% for *Humiria* and *Dicorynia*, respectively," driven mostly by increases in leaf photosynthesis. They write, "the range of change in water-use efficiency for these two species was consistent with many results observed not only in tropical forests (Hietz *et al.*, 2005; Nock *et al.*, 2011), but in boreal (Saurer *et al.*, 2004) and temperate forests (Francey and Farquhar, 1982; Penuelas and Azcon-Bieto, 1992; Bert *et al.*, 1997; Duquesnay *et al.*, 1998)." Bonal *et al.* further state the responses of the two tree species to increasing Ca appear to be "simply related to the availability of CO_2 in the air (fertilization effect)," and they note "this trend seems to be consistent with recent tree growth patterns in the Amazonian region."

Silva *et al.* (2009) studied tree-ring data obtained from *A. angustifolia* trees growing in forest and grassland sites in southern Brazil, comparing changes in intrinsic water use efficiency—iWUE, defined as the ratio of the rate of CO_2 assimilation by the trees' needles to their stomatal conductance—with concomitant historical changes in temperature, precipitation, and atmospheric CO_2 concentration over the past century. During the past several decades, the four researchers report, "iWUE increased over 30% in both habitats" (see Figure 4.2.2.6.2), and "this increase was highly correlated with increasing levels of CO_2 in the atmosphere." Over the latter period, tree growth remained rather stable because of lower-than-normal precipitation and higher-than-normal temperatures, which would normally tend to depress the growth of this species; Katinas and Crisci (2008) describe *A. angustifolia* as being "intolerant of dry seasons and requiring cool temperatures." Silva *et*

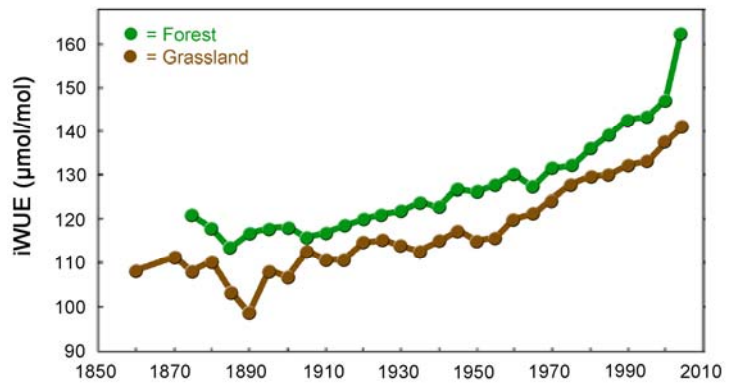

Figure 4.2.2.6.2. Intrinsic water-use efficiency (iWUE) in Araucaria angustifolia trees established into forest and grassland in southern Brazil (means of individuals per site in five-year total values). Adapted from Silva *et al.* (2009).

al. conclude the "climatic fluctuations during the past few decades," which would normally be expected to have been deleterious to the growth of *A. angustifolia*, seem to have had their growth-retarding effects "compensated by increases in atmospheric CO_2 and changes [i.e., increases] in iWUE."

Phillips *et al.* (2009) investigated what effect a severe drought might have on South America's surprisingly spry-for-its-age tropical mega-forest, especially a drought of the type the models predict will occur if anthropogenic CO_2 emissions are not significantly abated. The international team of scientists sought to determine whether such a decline in the availability of water might wipe out the super ecosystem's biomass gains of prior decades, thereby fulfilling one of the worst-case catastrophic scenarios of the models.

Focusing their attention on the Amazonian drought of 2005, which they describe as "one of the most intense droughts of the past 100 years" and "a possible analog of future events," the 66 researchers (who had monitored a host of forest plots across the Amazon basin over the prior quarter-century) utilized tree diameter, wood density, and allometric models to compute the basin's woody biomass at each time of measurement, both before and after the drought. They derived the results plotted in Figure 4.2.2.6.3.

As Figure 4.2.2.6.3. shows, the Amazonian drought of 2005 only slightly impacted the strong upward trend of tree biomass accumulation that was exhibited over the prior two decades, which had occurred, as Phillips *et al.* note, through a multi-decadal period spanning both wet and dry episodes, the latter of which are not even detectable in their wood biomass data. Hence it would appear that
Figure 4.2.2.6.3. The post-1980 cumulative biomass increase of Amazon trees ≥10 cm in diameter as a function of the mid-date of each forest-plot census interval, portrayed as a 50-interval moving mean. Adapted from Phillips *et al.* (2009).

although extremely severe drought conditions can indeed stop biomass accumulation in old-growth tropical forests—and sometimes even lead to minor reductions in biomass due to selective tree mortality—the vast majority of the aged trees are able to regain their photosynthetic prowess and add to their prior store of biomass once the moisture stress subsides, thanks in large measure to the enhanced growth (Lin et al., 1998) and water use efficiency (Hietz *et al.*, 2005) of nearly all woody plants as the atmospheric CO_2 content rises.

Lloyd and Farquhar (2008) provide additional support for this attribution, concluding, "the magnitude and pattern of increases in forest dynamics across Amazonia observed over the last few decades are consistent with a CO_2-induced stimulation of tree growth." Phillips *et al.* (2008) add still more support for the premise, concluding the simplest explanation for the phenomenon is "improved resource availability has increased net primary productivity, in turn increasing growth rates," and "the only change for which there is unambiguous evidence that the driver has widely changed and that such a change should accelerate forest growth is the increase in atmospheric CO_2," because of "the undisputed long-term increase in [its] concentration, the key role of CO_2 in photosynthesis, and the demonstrated effects of CO_2 fertilization on plant growth rates."

The voluminous and undeniable real-world observations reported in the studies described above indicate forest productivity has been increasing along with the increasing CO_2 content of the air wherever tropical forests have not been decimated by the direct destructive actions of man, such as the felling and burning of trees. This productivity increase has persisted in spite of all concomitant changes in atmospheric, soil, and water chemistry and the twentieth-century global warming. Real-world evidence suggests the anthropogenic-induced increase in the atmospheric CO_2 content is primarily responsible for this beneficial state of affairs.

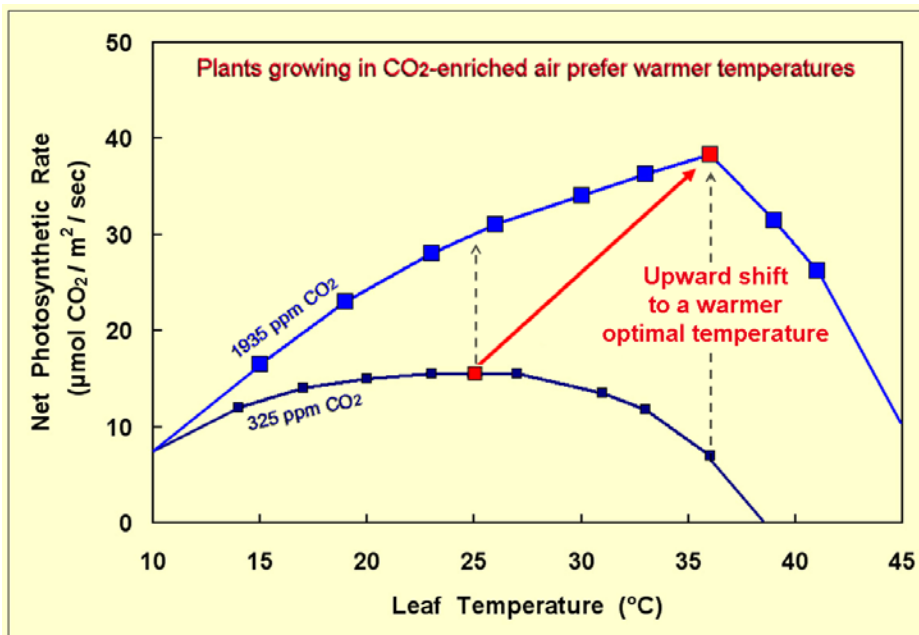
4.2.3 Rising Temperatures and Biospheric Productivity

- It is likely the greening of the planet will continue in the future, even if the largest temperature increases predicted by the models occur, because the optimum temperature for plant growth and development typically rises with increasing levels of atmospheric CO_2. This response, coupled with expected increases in plant photosynthetic rates from the rise in the air's CO_2 concentration, is more than enough to compensate for any temperature-induced plant stress caused by global warming.

In spite of the overwhelming amount of evidence, presented in Section 4.2 of this report, demonstrating rising atmospheric CO_2 concentrations and warmer temperatures have enhanced the productivity of the biosphere, some scientists have expressed concern these trends will gradually decline—and eventually reverse—if temperatures rise toward the upper limits

projected in model-based scenarios of future global warming.

It is more likely, however, that the greening of the planet will continue in the future, even if the largest temperature increases predicted by the models do occur. This is because the optimum temperature for plant growth and development typically rises with increasing levels of atmospheric CO_2. This response, coupled with expected increases in plant photo-synthetic rates from the rise in the air's CO_2 concentration, is more than enough to compensate for any temperature-induced plant stress caused by global warming.

Jurik *et al*. (1984) exposed bigtooth aspen leaves to atmospheric CO_2 concentrations of 325 and 1,935 ppm and measured their photosynthetic rates at a number of temperatures. Figure 4.2.3.1 below reproduces their results and slightly extends the two relationships defined by their data to warmer and cooler conditions.


where the net photosynthetic rate of the leaves exposed to 1,935 ppm CO_2 is maximal, the extra CO_2 boosts the net photosynthetic rate of the foliage by 450%. The extra CO_2 increases the optimum temperature for net photosynthesis in this species by about 11°C: from 25°C in air of 325 ppm CO_2 to 36°C in air of 1935 ppm CO_2.

The warm-temperature extensions of the two relationships at the right-hand side of the figure show the transition from positive to negative net photosynthesis—which denotes a change from life-sustaining to life-depleting conditions—likely occurs somewhere in the vicinity of 39°C in air of 325 ppm CO_2 but somewhere in the vicinity of 50°C in air of 1935 ppm CO_2. Thus not only was the optimum temperature for the growth of bigtooth aspen greatly increased by the extra CO_2 of this experiment, so too was the temperature above which life cannot be sustained also increased, and by about the same amount: 11°C.

Figure 4.2.3.1. Net photosynthesis of big tooth aspen leaves growing under two concentrations of atmospheric carbon dioxide at various temperatures. Adapted from Jurik *et al*. (1984).

Other researchers have documented this important CO_2-induced plant benefit in other agricultural, grassland, and woody plant species. Nearly all of these studies indicate a 300 ppm increase in the atmospheric CO_2 content increases a plant's optimum temperature for growth and development by a mean of approximately 6°C (Bjorkman *et al*., 1978; Berry and Bjorkman, 1980; Nilsen *et al*., 1983; Jurik *et al*., 1984; Seeman *et al*., 1984; Harley *et al*., 1986; Stuhlfauth and Fock, 1990; McMurtrie *et al*., 1992; McMurtrie and Wang, 1993; Idso *et al*., 1995; Cowling and Sykes, 1999; Gutierrez *et al*., 2009). This response is more than enough to compensate fully for any temperature-induced plant stress caused by the worst-case scenario of climate-model-predicted CO_2-induced global warming. Additional research indicates plants may be able to boost their optimum temperature for photosynthesis as the temperature warms, even in the absence of a concurrent increase in atmospheric CO_2.

As the figure illustrates, at 10°C, elevated CO_2 has essentially no effect on net photosynthesis in this particular species, as Idso and Idso (1994) have demonstrated is characteristic of plants in general. At 25°C, however, where the net photosynthetic rate of the leaves exposed to 325 ppm CO_2 is maximal, the extra CO_2 of this study boosts the net photosynthetic rate of the foliage by nearly 100%, and at 36°C,

Gunderson *et al*. (2010) investigated the "photosynthetic sensitivity to temperature and the

potential for acclimation in relation to the climatic provenance of five species of deciduous trees, *Liquidambar styraciflua* [sweetgum], *Quercus rubra* [northern red oak], *Quercus falcata* [southern red oak], *Betula alleghaniensis* [yellow birch] and *Populus grandidentata* [bigtooth aspen]." They conducted their experiment out-of-doors in open-top chambers at three temperature regimes—ambient, ambient plus 2°C, and ambient plus 4°C—for three years. The five scientists report, "warming treatments resulted in a shift in the temperature response curves for CO_2 assimilation, such that leaves in warmer treatments had higher temperature optima [T_{opt}]." An example of this phenomenon is depicted in Figure 4.2.3.2 for *Q. rubra* seedlings during one specific month.

Figure 4.2.3.2. Net CO_2 assimilation rate vs. leaf temperature in Quercus rubra seedlings during June of 2003 in the ambient (A) and elevated (A+2°C and A+4°C) temperature treatments. Adapted from Gunderson *et al*. (2010).

As Figure 4.2.3.2 illustrates, the trees growing in progressively warmer environments had progressively higher T_{opt} values, and there was a tendency for the net CO_2 assimilation rates at those higher T_{opt} values to be a bit higher as well. Gunderson *et al*. found this adjustment in photosynthetic response was typically accomplished over a period of as little as two days, noting "others have found all or most acclimation within 2–6 days (Veres and Williams, 1984; Hill *et al*., 1988; Battaglia *et al*., 1996; Turnbull *et al*., 2002; Froux *et al*., 2004)." They state a similar "adjustment of thermal optima was confirmed in all species, whether temperatures varied with season or treatment,

and regardless of climate in the species' range or provenance of the plant material," and the "responses to the temperature manipulation were not different from the seasonal acclimation observed in mature indigenous trees."

These observations indicate plants will be able to adjust their physiology to accommodate a warming of the magnitude and rate of rise IPCC predicts to accompany the projected future increase in atmospheric CO_2 content. If the planet's flora can adjust their physiology to not only survive a modest instantaneous warming of 2–4°C, but to actually benefit from it, as has been demonstrated to be true of several trees examined by Gunderson *et al*., there is every reason to believe they would respond to a similar warming projected to develop over a century or more. When one factors in the aerial fertilization effect of rising atmospheric CO_2 concentrations, plus the transpiration-reducing effect that boosts plant water use efficiency, plus CO_2's ability to also raise the T_{opt} values of most plants, it is clear the world's vegetation is well-prepared for future warming. The recent greening of the planet should continue in the years and decades to come, notwithstanding model-based concerns to the contrary.

4.3 Biodiversity

- Highly CO_2-responsive genotypes of a wide variety of plants—ranging from food crops to lumber crops—could be chosen to take advantage of their genetic ability to optimize growth in response to projected future increases in the atmospheric CO_2 content. Doing so is probably essential to the well-being of mankind and to the survival of much of the world's wildlands.

As human population grows, the demand for food rises as well, as does the need for land and water to grow that food. Unless something is done to enhance the per-acre productivity of the terrestrial biosphere, some species of plants and animals may be pushed out of existence by the midpoint of the current century.

A number of real-world experiments demonstrate many of Earth's food- and lumber-producing plants possess the genetic potential to grow better while using less water as atmospheric CO_2 content rises. In an important paper by 32 researchers from 12 countries, Ainsworth *et al.* (2008) made the case for breeding varieties of major food crops to best take advantage of the ongoing rise in the atmospheric CO_2 content. They note, "the growing world population, increasing demands for grains for animal feeds, land loss to urban expansion and demand for bioenergy production are exerting more and more pressure on global agricultural productivity," so "a major challenge for plant biologists, agronomists and breeders will be to provide germplasm and seed material that maximize future crop production," particularly in the context of rising atmospheric CO_2 concentrations that

provide, in their words, "a unique opportunity to increase the productivity of C_3 crops."

The scientists point out "only a fraction of available germplasm of crops has been tested for CO_2 responsiveness" and "further research is needed to elucidate the mechanisms of yield response to CO_2, to assess the genetic diversity available for improving responsiveness and to devise efficient schemes for selection for adaptation to rising ambient CO_2, whether based on conventional plant breeding or systems biology approaches for selecting and engineering improved genetics." They conclude, "because it may take 10–15 years to move from discovery of new advantaged genetics to commercial cultivars of annual grain crops, developing a robust strategy and supporting the planned work with the best possible facilities should be an urgent priority."

Ziska *et al*. (1996) grew well-watered and well-fertilized plants of 17 cultivars of rice (*Oryza sativa* L.) from seed to maturity in glasshouses maintained at atmospheric CO_2 concentrations of either 373 ppm (ambient) or 664 ppm (elevated) in 24-L pots filled with local soil at two sets of day/night temperatures (29/21°C and 37/29°C), afterwards measuring total plant biomass and grain biomass. They found the degree of CO_2-induced enhancement of total plant biomass and the number of cultivars showing significant yield enhancement with elevated CO_2 decreased at the higher and more stressful set of growth temperatures, dropping from 12 of 17 cultivars with a mean biomass stimulation of 70% at the lower set of temperatures to eight of 17 cultivars with a mean biomass stimulation of 23% at the higher set of temperatures.

At the lower set of temperatures, a few cultivars exhibited no significant changes in response to the atmospheric CO_2 enrichment employed in the study, but the most responsive cultivar—a tropical japonica type from Brazil—exhibited a 265% increase in total plant biomass and a 350% increase in grain biomass.

The wide range of productivity enhancement exhibited in response to atmospheric CO_2 enrichment by the 17 cultivars of rice examined in this experiment indicates the tremendous potential in selecting rice varieties to take advantage of the aerial fertilization effect of atmospheric CO_2. That endeavor, Ziska *et al*. write, "could maximize productivity as CO_2 concentration increases." Such a selection process likely will be an essential element of the race to feed humanity in the year 2050 without usurping vast tracts of tropical and temperate forests, savannas, and grasslands or commandeering all of the planet's remaining freshwater resources and destroy-ing most of the world's remaining wildlands.

Bunce (2008) grew adequately fertilized plants of four varieties of the common garden bean (*Phaseolus vulgaris* L.)—Matterhorn (a great northern bean), Jaguar (a black bean), Red Hawk (a kidney bean), and Brown Beauty (a snap bean)—from seed to maturity under standard field conditions at Beltsville, Maryland (USA) in open-top chambers, making photosynthetic measurements of mature upper-canopy leaves in full sunlight at midday during the pod-filling stages of four growing seasons and assessing final seed yields and other plant characteristics at harvest. They found the extra 180 ppm of CO_2 in the CO_2-enriched chambers (a concentration increase of close to 50% during daylight hours) resulted in a mean long-term stimulation of midday net photosynthesis of approximately 18% in the Matterhorn and Jaguar bean varieties and an increase of 36% in the Red Hawk and Brown Beauty cultivars. The Matterhorn variety increased dry mass seed yield by about 39%, followed by Red Hawk at 21%, Brown Beauty at 18%, and Jaguar with a 10% decline in seed yield. As Bunce reported, "the highest yielding variety at ambient CO_2 [Jaguar] was out-yielded by a different variety at elevated CO_2 [Matterhorn]."

These findings demonstrate there is significant variability in seed yield response to atmospheric CO_2 enrichment among the four bean varieties Bunce tested. There was no *a priori* way of knowing which of the four cultivars would respond best, or that one of them would respond negatively. Bunce's work demonstrates the need to perform experiments on the world's most important crop plants to identify which of their many varieties should be selected for crop breeding work, to take full advantage of the increase in the atmosphere's CO_2 concentration likely to occur over the next several decades.

Yang *et al*. (2009) write, "rice (*Oryza sativa* L.) is unequivocally one of the most important food crops that feed the largest proportion of the world's population" and "the demand for rice production will continue to increase in the coming decades, especially in the major rice-consuming countries of Asia, Africa and Latin America, due to the population explosion and cropland reduction." They note, "as sufficient intraspecific variation in yield response exists under field conditions, there is a pressing need to identify genotypes which would produce maximum grain yield under projected future CO_2 levels."

Working at the National Institute for Agro-Environmental Sciences in Tsukuba, Japan, Lou *et al*. (2008) grew plants of four rice cultivars—Dular (a traditional indica variety), IR72 (an improved indica

variety), Koshihikari (a temperate japonica variety), and IR65598 (a new variety not yet released to farmers)—in growth chambers in submerged pots filled with a fertilized soil collected from the plough layer of a paddy field in Chiba Prefecture, Japan, at two atmospheric CO_2 concentrations: ambient (~370 ppm) and elevated (~570 ppm). They found the extra 200 ppm of CO_2 reduced the ultimate grain yield of Dular (by 0.7%) and increased the final grain yield of IR72 by 8.0%, of Koshihikari by 13.4%, and of IR65598 by 17.7%.

Yang *et al*. (2009) focused on a single two-line inter-subspecific hybrid rice variety (Liangyoupeijiu) produced as part of "a nationwide mega project" to develop what they called "super" hybrid cultivars that would "further break the yield ceiling." In their three-year CO_2-enrichment study at the FACE facility at Yangzhou City, Jiangsu Province, China, which employed the same CO_2 levels as the study of Lou *et al*., they found a much greater grain yield stimulation: a 28.4% CO_2-induced increase under a low nitrogen fertility treatment of 12.5 g N m^{-2} and a 31.7% CO_2-induced increase under a high nitrogen fertility treatment of 25 g N m^{-2}.

Yang *et al*. state their hybrid cultivar "appears to profit much more from elevated CO_2 than inbred japonica cultivars." Both the Japanese and Chinese FACE studies of inbred japonica cultivars found CO_2-induced grain yield enhancements on the order of only 13% for a 200 ppm increase in the air's CO_2 concentration. Noting "there is a pressing need to identify genotypes which could optimize harvestable yield as atmospheric CO_2 increases," Yang *et al*. conclude, "on the basis of available FACE data on rice," the hybrid rice cultivar Liangyoupeijiu appeared "to be particularly promising."

Mycroft *et al*. (2009) grew seedlings of 29 well-watered and fertilized white spruce (*Picea glauca* (Moench) Voss) tree genotypes in 2.83-liter pots filled with a mixture of peat and vermiculite between 10 May and 23 September 2006 in glasshouse com-partments maintained at either ambient (370 ppm) or elevated (740 ppm) atmospheric CO_2 concentrations. They assessed plant performance by measuring final plant height, basal stem diameter, and total biomass production, including roots.

They found, "depending upon genotype, the increase in biomass at elevated CO_2 as a percentage of that at ambient CO_2 ranged from 23% to 108%, while increases in height ranged from 4% to 48%," and "in the case of stem diameter, the effect of elevated CO_2 varied from a non-significant decrease of 6% to an increase of 32% depending upon

genotype." The four researchers write, "similar to previous studies (e.g. Bazzaz *et al*., 1995; Lindroth *et al*., 2001; Moya *et al*., 1998; Steinger *et al*., 1997; Volk and Korner, 2001)," they discovered "significant genotype x CO_2 interactions for size-related traits." They note their CO_2-induced biomass increases (+23% to +108%) were of a range similar to those Mohan *et al*. (2004) obtained for red maple (0% to +93%) and Wang *et al*. (2000) found for quaking aspen (-29% to +94%).

These observations demonstrate highly CO_2-responsive genotypes of a wide variety of plants, ranging from food crops to lumber crops, could be selected to take advantage of their genetic ability to optimize growth in response to projected future increases in atmospheric CO_2 content. Such measures probably will prove essential to the well-being of mankind and to the survival of much of the world's wildlands.

4.4 Extinction

Real-world observations reveal plants have many ways of adjusting to changes in climate in addition to their ability to spread from places of rising warmth to cooler habitats, and these observations suggest the planet's current assemblage of plants is likely to be around a good deal longer than many theoretical models have predicted. One of the great horror stories associated with predictions of CO_2-induced global warming is of warming so fast and furious that many species of plants will not be able to migrate towards cooler regions—poleward in latitude, or upward in elevation—quickly enough to avoid extinction. Real-world observations of plants show they have many

ways of adjusting to changes in climate in addition to their ability to move from places of rising warmth to cooler habitats. These observations suggest the planet's current assemblage of plants is likely to be around longer than many theoretical models have predicted.

Under-yielding species appear to be buffered from extinction because growth enhancements of smaller plants tend to diminish the relative biomass advantages of larger plants in crowded conditions, and when species are rare in a local area, they have a higher survival rate than when they are common, resulting in the enrichment of rare species and increasing diversity with age and size class in complex ecosystems. In addition, diversity should increase as a group of individuals ages, because more common species are selectively removed by pathogens and predators, especially those commonly associated with them.

Also, individuals of a species compete more intensively with conspecifics than with individuals of other species, and diversity may increase if an individual benefits nearby non-conspecifics, as such facilitation makes interspecific interactions more positive than intraspecific interactions and thus provides an advantage to locally rare species. Similarly, common trees growing closer together are more prone to deadly infections, and they may also face stiffer competition for certain resources, whereas rarer trees, by depending on slightly different sets of resources, may not have this problem.

4.4.1 Migrating Plants

If Earth warms by a significant amount, for whatever reason, the best thing that could happen to the planet would be for the air's CO_2 concentration to rise concurrently, or shortly thereafter, because that would obviate the need for plants to migrate to cooler regions or at least reduce the required rate of migration and/or distance of travel well below what overly simplistic coupled climate-biology models have suggested. In a CO_2-enriched world, as air temperature increases, so too would the temperature at which most plants function at their optimum. Plants thus would be able to grow and reproduce in close proximity to where they grew when the air temperature first began to increase.

This is exactly how nature appears to operate during and after a glacial-to-interglacial transition. In response to the air temperature increase during such transitions, Earth's atmospheric CO_2 concentration

typically has risen by an amount sufficient to enable plants to cope with the warming of the globe. Cowling and Sage (1998) indicate a typical 180 ppm rise in atmospheric CO_2 concentration from a base level characteristic of glacial conditions can raise plant optimum growth temperature by about 4°–5°C, the temperature increase typically experienced during glacial terminations.

Cowling and Sykes (1999) conducted a review of the literature on the interactive effects of concurrent increases in atmospheric CO_2 and air temperature on plant growth and development. They report, "increases in CO_2 from 350 to 650 ppm are estimated to result in up to a 5°C rise in T_{opt} [plant optimal growth temperature], primarily because of a reduction in the rate of photorespiration at high temperatures." They also state, "experiments with *Phaseolus vulgaris* [common garden bean] exposed to low CO_2 T_{opt} can decrease by approximately 4°–5°C with a reduction in CO_2 from 380 to 200 ppm," citing Cowling and Sage (1998).

Cannariato *et al*. (1999) investigated the character, magnitude, and speed of biotic responses of benthic foraminifera to millennial-scale climate oscillations reconstructed from data obtained from a northeast Pacific Ocean sediment core that extended back in time some 60,000 years. This history revealed a number of rapid climatic switches throughout the record, representing periods of what they call "extreme environmental variability." They report they observed no extinctions, and the benthic ecosystems "appear to be both resilient and robust in response to rapid and often extreme [changes in] environmental conditions." They report faunal turnovers occurred within decades throughout the record "without extinction or speciation," which led them to conclude "broad segments of the biosphere are well adapted to rapid climate change."

Allen *et al*. (1999) examined an even longer period of time. After analyzing sediment cores from a lake in southern Italy and from the Mediterranean Sea, they developed high-resolution climate and vegetation datasets for this region covering the last 102,000 years. Their efforts revealed rapid changes in vegetation correlated well with rapid changes in climate, such that complete shifts in natural ecosystems would sometimes occur over periods of less than 200 years. They also report, over the warmest portion of the record (the Holocene), the total organic carbon content of the vegetation reached its highest level, more than doubling values experienced over the rest of the record, and during the more productive woody-plant period of the Holocene,

the increased vegetative cover also led to less soil erosion. As the 15 researchers state, "the biosphere was a full participant in these rapid fluctuations, contrary to widely held views that vegetation is unable to change with such rapidity." They learned warmer was always better in terms of vegetative productivity.

Other studies based on more modern data have continued to demonstrate the unlikelihood of warming-induced plant extinctions. In July/August 2003, for example, Walther *et al*. (2005) resurveyed the floristic composition of the uppermost 10 meters of 10 mountain summits in the Swiss Alps, applying the same methodology used in earlier surveys of the same mountain tops by Rubel (1912), conducted in 1905, and Hofer (1992), conducted in 1985. Their analyses covered the bulk of the Little Ice Age-to-Current Warm Period transition (1905–2003), the warming IPCC claims to have been unprecedented over the past millennium or more in terms of both the rate of temperature rise and the level to which Earth's temperature rose.

Whereas the mean increase in species numbers recorded by Hofer (1992) for the time interval 1905 to 1985 was 86%, "species numbers recorded in 2003 were generally more than double (138%) compared to the results by Rubel (1912) and 26% higher than those reported by Hofer (1992)." Walther *et al*. write, "the rate of change in species richness (3.7 species per decade) was significantly greater in the later period compared to the Hofer resurvey (1.3 species per decade)." They note "the observed increase in species numbers does not entail the replacement of high alpine specialists by species from lower altitudes, but rather has led to an enrichment of the overall summit plant diversity."

In spite of the apparent reasonableness of the global warming extinction hypothesis, in which high-altitude species are expected to be "squeezed out of existence"—or "pushed off the planet," as NASA's James Hansen once described it, by other species migrating upwards from lower altitudes to escape the increasing stress of rising temperatures, Walther *et al*. could find no sign of this dire consequence over a century of supposedly unprecedented warming in the Swiss Alps.

Kullman (2007) analyzed the changing behavior of alpine and subalpine plants, together with shifts in their geographical patterns over the past century (when air temperatures rose by about 1°C in the Scandes of west-central Sweden), based on "repeat photography, individual age determinations and analyses of permanent plots." Kullman reports, "at all

levels, from trees to tiny herbs, and from high to low altitudes," as he describes it, "the results converge to indicate a causal association between temperature rise and biotic evolution," indicating "this appears to be an ecosystem on the brink of profound and imminent transformation."

Kullman reports treeline advance since the early twentieth century varied between 75 and 130 meters, depending on species and site, and subalpine and alpine plant species shifted upslope by an average of 200 meters. He writes, "present-day repetitions of floristic inventories on two alpine mountain summits reveal increases in plant species richness of 58 and 67%, respectively, since the early 1950s," and "no species have yet become extinct from the highest elevations." He states his results "converge with observations in other high-mountain regions worldwide," citing Grabherr et al. (1994), Keller et al. (2000), Kullman (2002), Virtanen et al. (2003), Klanderud and Birks (2003), Walther et al. (2005), and Lacoul and Freedman (2006).

Kullman concludes the rapidity with which the observed ecosystem transformations occurred "contrasts with earlier assumptions and theoretical generalizations, stressing significant time-lags or inertial adaptations to changed climatic conditions." His results demonstrate the capacity for vegetation to respond rapidly to climate change in dramatic ways that avert species extinctions and in fact can lead to increases in ecosystem species richness.

Three years later, Kullman reaffirmed his findings in additional works (Kullman, 2010a, 2010b, 2010c). In one of these (Kullman, 2010b), he describes how the post-Little Ice Age warming has broken "a multi-millennial trend of plant cover retrogression" and "floristic and faunal impoverish-ment, all imposed by progressive and deterministic neo-glacial climate cooling." He says "alpine plant life is proliferating, biodiversity is on the rise and the mountain world appears more productive and inviting than ever."

Similar observations led Kullman to conclude (Kullman, 2010c), "the alpine flora appears to be more adaptive and responsive to climate change than generally believed," and "overall, a richer, greener and more productive alpine world has emerged in the wake of the recent climate warming episode (Kullman, 2010a, 2010b)." He makes it very clear that "in contrast to model predictions, no single alpine plant species has become extinct, neither in Scandinavia nor in any other part of the world in response to climate warming over the past century" (Kullman, 2010b), citing, in addition to his own prior

studies, Pauli et al. (2001, 2007), Theurillat and Guisan (2001), and Birks (2008). As for the future, Kullman opines, "continued modest warming over the present century will likely be beneficial to alpine biodiversity, geological stability, resilience, sustainable reindeer husbandry and aesthetic landscape qualities" (Kullman, 2010b).

Holzinger et al. (2008) revisited areas of 12 mountains with summits between elevations of 2,844 and 3,006 meters in the canton of Grisons (Switzerland). In 2004 they made complete inventories of all vascular plant species they encountered, which they compared with similar inventories made by other researchers in 1885, 1898, 1912, 1913, and 1958, following the ascension paths of the earlier investigators "as accurately as possible." The four researchers report mean summer temperatures in the studied region increased by at least 0.6°C between the time of the first study and the one they conducted in 2004.

Holzinger et al. detected plant upward migration rates of several meters per decade, and their data suggest vascular plant species richness increased by 11% per decade over the past 120 years on the mountain summits (defined as the upper 15 meters of the mountains) in the alpine-nival ecotone. This finding, they write, "agrees well with other investigations from the Alps, where similar changes have been detected (Grabherr et al., 1994; Pauli et al., 2001; Camenisch, 2002; Walther, 2003; Walther et al., 2005)." Regarding the ominous prediction of "the extinction of a considerable number of high-alpine species" in "the context of climate warming," they conclude this "outstanding threat for species to become out-competed 'beyond the summits' can neither be confirmed nor rejected with our data," suggesting the threat may not be quite as outstanding as the climate models have typically made it out to be.

Erschbamer et al. (2009) documented and analyzed changes (from 2001 to 2006) in plant species number, frequency, and composition along an altitudinal gradient crossing four summits from the treeline ecotone to the subnival zone in the South Alps (Dolomites, Italy), where minimum temperatures increased by 1.1–2.0°C during the past century with a marked rise over the last decades. The four researchers report, "after five years, a re-visitation of the summit areas revealed a considerable increase of species richness at the upper alpine and subnival zone (10% and 9%, respectively) and relatively modest increases at the lower alpine zone and the treeline ecotone (3% and 1%, respectively)." They note, "during the last five years, the endemic species of the

research area were hardly affected," and "at the highest summit, one endemic species was even among the newcomers." The Austrian scientists conclude, "at least in short to medium time scales, the southern alpine endemics of the study area should not be seriously endangered."

Kelly and Goulden (2008) compared two vegetation surveys (one made in 1977 and the other in 2006–2007) of the Deep Canyon Transect in Southern California's (USA) Santa Rosa Mountains that spans several plant communities and climates, rising from an elevation of 244 meters to 2,560 meters over a distance of 16 km "through desert scrub, pinyon-juniper woodland, chaparral shrubland, and conifer forest." They found "the average elevation of the dominant plant species rose by ~65 meters," The 30-year mean temperature measured at seven stations around Deep Canyon rose by 0.41°C between 1947–1976 and 1977–2006, and the same metric rose by 0.63°C in the climate regions straddled by the transect, and by 0.77°C at the two weather stations nearest Deep Canyon. They conclude "surprisingly rapid shifts in the distribution of plants can be expected with climate change."

Alsos *et al.* (2007) analyzed DNA fingerprinting (amplified fragment-length polymorphism) of 4,439 samples from most of the geographic ranges of nine plant species native to the Arctic, studying the Svalbard Archipelago—the islands of which were almost entirely glaciated during the last glacial maximum of 20,000 years ago. They used the genetic data thereby obtained to reconstruct past plant colonization patterns, determining "the frequency of effective long-distance dispersal events, [identifying] the source areas, and [assessing] whether dispersal ability is more limiting than establishment in a new area."

The nine researchers found long-distance colonization of the Svalbard Archipelago "has occurred repeatedly and from several source regions," with probable propagule dispersal vectors being "wind, drift wood and drifting sea ice, birds, and mammals." They write, "the genetic effect of restricted colonization was strongly correlated with the temperature requirements of the species, indicating that establishment limits distribution more than dispersal."

Given that dispersal mechanisms in existence during the early and mid-Holocene (from 9,500 to 4,000 years before present, when "the climate was 1 to 2°C warmer than today," as Alsos *et al.* report) are probably "still operating," they conclude "Arctic species seem to be able to track their potential niche

and … unlimited dispersal models may be appropriate to estimate long-term range shifts for Arctic regions."

Le Roux and McGeoch (2008) examined patterns of altitudinal range changes in the entire native vascular flora of sub-Antarctic Marion Island (46°54'S, 37°45'E) in the southern Indian Ocean, which warmed by 1.2°C between 1965 and 2003. Between 1966 and 2006, there was "a rapid expansion in altitudinal range," with species expanding their upper elevational boundaries by an average of 70 meters. Because "the observed upslope expansion was not matched by a similar change in lower range boundaries," they emphasize "the flora of Marion Island has undergone range expansion rather than a range shift." They note "the expansion of species distributions along their cooler boundaries in response to rising temperatures appears to be a consistent biological consequence of recent climate warming," citing several other studies that have observed the same type of response.

Another consequence of the stability of lower range boundaries together with expanding upper range boundaries is a greater overlapping of ranges, resulting in greater local biodiversity. Le Roux and McGeoch report, "the present species composition of communities at higher altitudes is not an analogue of past community composition at lower altitudes, but rather constitutes a historically unique combination of species," indicating a world significantly richer, ecologically speaking, than the old one.

Stocklin *et al.* (2009) provide some insight into why plants in the real world tend to undergo a proliferation of species instead of extinction as temperature and atmospheric CO_2 concentration rise. They studied the consequences of the Swiss Alps' highly structured alpine landscape for evolutionary processes in four plants (*Epilobium fleischeri, Geum reptans, Campanula thyrsoides,* and *Poa alpina*), testing for whether genetic diversity within their populations was related to altitude and land use while also seeking to determine whether genetic differentiation among populations was more related to different land use or to geographic distances.

The three Swiss scientists found within-population genetic diversity of the four species was high and mostly unrelated to altitude or population size. They also report genetic differentiation among populations was pronounced and strongly increased with distance, implying "considerable genetic drift among populations of alpine plants." Stocklin *et al.* conclude "phenotypic plasticity is particularly pronounced in alpine plants," and "because of the high heterogeneity of the alpine landscape, the pronounced

capacity of a single genotype to exhibit variable phenotypes is a clear advantage for the persistence and survival of alpine plants." They write, "the evolutionary potential to respond to global change is mostly intact in alpine plants, even at high altitude." These results make it much easier to understand why, despite significant twentieth-century global warming, no species of plants have been observed to have been pushed off the planet, especially in alpine regions.

In an invited paper in *Quaternary Science Reviews*, Vegas-Vilarrubia *et al.* (2011) write, "current extinction estimates for the near-future should be revised in light of palaeoecological information," which in their view "shows that spatial reorganizations and persistence in suitable micro-refugia have been more common than extinction during the Quaternary." The four researchers conclude "an interesting consequence is the possibility of new unknown species combinations with no modern analogues."

Vegas-Vilarrubia *et al.* (2011) note the global warming that occurred at the end of the Younger Dryas (~13,000 to 11,500 years ago) is one of the more powerful analogues of projected future global warming "because both magnitude and rates of change parallel those predicted for the present century." Although this prior real-world transformation "seems to have consisted of ecological reorganizations and changes in community composition because of differential species migration patterns and rates," the four researchers point out "so far, it has not been possible to associate large-scale extinctions to the Younger Dryas climatic reversal." Instead of a model-inspired increase in atmospheric CO_2 triggering catastrophic changes in climate, real-world data from the past suggest rising atmospheric CO_2 will help plants avoid climatic-induced extinctions.

Two phenomena come into play in these eco-system transformations, according to the Spanish scientists: acclimation and adaptation, "with the first relying on phenotypic plasticity and the second involving genetic changes of potential evolutionary significance," which have been proposed as "possible reactions to future global warming and as alternatives to extinction by habitat loss." Vegas-Vilarrubia *et al.* note "some authors propose that spatial reorganizations without extinction will be the dominant biotic response to the near-future global changes." They add, "it is also possible that ecosystems never attain equilibrium," and "transient states perpetuate because of the recurrent action of environmental change." They suggest "one of the main lessons to be learned from these considerations is that ecosystems may

express their resilience when confronted with environmental shifts by attaining several possible equilibrium states, as manifested in changes in biodiversity and/or composition, without losing their ecological functions."

Willis and MacDonald (2011) note key research efforts have focused on extinction scenarios derived from "a suite of predictive species distribution models (e.g., Guisan and Thuiller, 2005)"—most often referred to as bioclimatic envelope models—that "predict current and future range shifts and estimate the distances and rates of movement required for species to track the changes in climate and move into suitable new climate space." They report one of the most-cited studies of this type—that of Thomas *et al.* (2004)—"predicts that, on the basis of mid-range climatic warming scenarios for 2050, up to 37% of plant species globally will be committed to extinction owing to lack of suitable climate space."

In contrast, Willis and MacDonald write, "biotic adaptation to climate change has been considered much less frequently." This phenomenon— sometimes referred to as evolutionary resilience—they describe as "the ability of populations to persist in their current location and to undergo evolutionary adaptation in response to changing environmental conditions," citing Sgro *et al.* (2010). They note this approach to the subject "recognizes that ongoing change is the norm in nature and one of the dynamic processes that generates and maintains biodiversity patterns and processes," citing MacDonald *et al.* (2008) and Willis *et al.* (2009).

Willis and MacDonald examined the effects of significant and rapid warming on plants during several previous intervals of the planet's climatic history that were as warm as, or even warmer than, what climate models typically predict for the next century. These intervals included the Paleocene-Eocene Thermal Maximum, the Eocene climatic optimum, the mid-Pliocene warm interval, the Eemian interglacial, and the Holocene.

In stark contrast to what IPCC typically does, this approach relies on empirical (as opposed to theoretical), data-based (as opposed to model-based) reconstructions (as opposed to projections) of the past (as opposed to the future). Willis and MacDonald found "persistence and range shifts (migrations) seem to have been the predominant terrestrial biotic response (mainly of plants) to warmer intervals in Earth's history," and "the same responses also appear to have occurred during intervals of rapid climate change." They note "evidence for global extinctions or extinctions resulting from reduction of population

sizes on the scale predicted for the next century owing to loss of suitable climate space (Thomas *et al.*, 2004) is not apparent." They report an increase in local biodiversity sometimes has been observed.

Feurdean *et al.* (2012) note species distribution models run at finer scales (Trivedi *et al.*, 2008; Randin *et al.*, 2009) or including representations of plant demography (Hickler *et al.*, 2009) and more accurate dispersal capability (Engler and Guisan, 2009) tend to predict much smaller habitat and species loss in response to climate model predictions than do more coarse-scale models (Thomas *et al.*, 2004; Thuiller *et al.*, 2005; Araujo *et al.*, 2008).

The German and Romanian researchers analyzed "seven fossil pollen sequences from Romania situated at different elevations … to examine the effects of climate change on community composition and biodiversity between 15,000 and 10,500 cal. yr BP in this biogeographically sensitive region of Europe." This period "was characterized by large-amplitude global climate fluctuations occurring on decadal to millennial time scales (Johnsen *et al.*, 1992; Jouzel *et al.*, 2007)," which enabled them to explore "how repeated temperature changes have affected patterns of community composition and diversity" and to analyze "recovery processes following major disruptions of community structure."

The four scientists report "community composition at a given time was not only the product of existing environmental conditions, but also the consequence of previous cumulative episodes of extirpation and recolonization." They found "many circumpolar woody plants were able to survive when environmental conditions became unfavorable," and "these populations acted as sources when the climate became more favorable again." The latter behavior, they write, "is in agreement with modeling results at the local scale, predicting the persistence of suitable habitats and species survival within large-grid cells in which they were predicted to disappear by coarse-scale models."

The findings of Feurdean *et al.* thus add to the growing number of studies demonstrating the shortcomings of "climate envelope" models of both vegetation and animal responses to rising temperatures, which are often used to predict massive species extinctions as a result of the "unprecedented" CO_2-induced global warming predicted by equally deficient climate models.

Dobrowski *et al.* (2013) write, "anthropogenic climate change is considered a threat to ecosystem services and to global biodiversity because of its magnitude, the potential for novel climatic conditions (Williams *et al.*, 2007), and the rate at which it is occurring (Parmesan and Yohe, 2003; Montoya and Rafaelli, 2010)." They note, "species have always been subject to changing climatic regimes and have responded through adaptation (Davis and Shaw, 2001; Hoffman and Sgro, 2011), changes in phenology (Cleland *et al.*, 2007), range shifts (Davis and Shaw, 2001), and the use of climate refugia (Dobrowski, 2011; Hampe and Jump, 2011)." They write, "the fossil record suggests that widespread extinctions of plant species were rare during periods of rapid warming (~2–10°C/century) such as the Pleistocene-Holocene transition (Willis and MacDonald, 2011)," noting instead of species disappearing, "ecological turnover and range shifts were common responses to rapid climate changes of the past (Botkin *et al.*, 2010; Hof *et al.*, 2011; Willis and MacDonald, 2011)."

The seven U.S. scientists assessed "climate velocity (both climate displacement rate and direction) for minimum temperature, actual evapotranspiration, and climatic water deficit over the contiguous U.S. during the 20th century (1916–2005)." They discovered "a complex picture of the climate in the contiguous U.S.," where "velocity vectors vary regionally, show variable and opposing directions among the variables considered, and shift direction through time."

Dobrowski *et al.* found "T_{min} vectors calculated over decadal and century scales demonstrate complex dynamics (e.g. northerly and southerly directions, direction reversal through time) that vary regionally," and "climate displacement vectors for metrics of the water balance were predominantly oriented toward the west and south, showing regional variability." They report "divergent climate vectors between temperature and water balance may help explain why roughly 10–30% of species assessed in previous climate change studies have not shifted their ranges whereas nearly 25% of species have shifted their ranges in a direction counter to expectations (Parmesan and Yohe, 2003; Chen *et al.*, 2011; Crimmins *et al.*, 2011)."

Dobrowski *et al.* say these results "suggest that the expectation of poleward and upward shifts associated with all taxa, previously referred to as a 'globally coherent fingerprint' (Parmesan and Yohe, 2003), may be derived from an oversimplification of the climate dynamics that have been observed over the 20th century." They conclude their findings imply "a more full understanding of changes in multiple climatic factors, in addition to temperature, may help explain unexpected or conflicting observational evidence of climate-driven species range shifts." They

say "moving away from viewing climate as simple monotonic changes in temperature is a necessary step in advancing our understanding of how species have and will respond to climate shifts."

4.4.2 Stationary Plants

- A major cause of biodiversity reductions is not rising atmospheric CO_2 concentrations, but instead the direct encroachment of man upon the world of nature. Anthropogenic global warming, to whatever extent it exists, is helping plants overcome these assaults and thrive despite the growing human presence.

The "acid test" for any extinction hypothesis is to examine what appears to be happening—or to have

happened—in the real world. Here we discuss studies of plants fighting to survive under experimental settings or real-world locations where they periodically face threats to their survival and are unable to spread to other areas to escape competition, predation, high temperatures, or other threats.

An experiment that broached the subject of plants threatened by external biological and climatic factors was established in spring 1994 at the Cedar Creek Natural History Area in central Minnesota (USA), where a decade later Lambers *et al*. (2004) quantified the temporal evolution of the productivity and "staying power" of 14 species of plants across an experimental grassland diversity gradient. Over the course of that long-term study, the five researchers learned certain species were over-yielders—plants that grow better and produce more biomass when grown in competition with other species than when grown by themselves. They found six such species: a C_3 grass, three C_4 grasses, and two legumes. The five researchers note these "over-yielding species were either superior N competitors (C_4 grasses) or N fixers (legumes)." They also found five under-yielding species, four of which were forbs that typically grew less robustly when in the presence of other species. The scientists report the over-yielding species were not displacing the under-yielding species over time.

Lambers *et al*. conclude diversity-promoting interactions played a role in this experiment, and "under-yielding species appear to be buffered from extinction." No one knows how common this phenomenon is, but its operation in this study suggests plants may be much better "buffered from extinction" than many have long supposed. More research should be directed toward elucidating the "diversity-promoting interactions" that maintain the existence of under-yielding species in the face of what might logically be presumed to be significant competitive pressure from average and over-yielding species.

Stinson and Bazzaz (2006) grew well-watered stands of ragweed (*Ambrosia artemisiifolia*) out-of-doors in open-top-chambers maintained at either 360 or 720 ppm CO_2 from their seedling stage to the onset of senescence, then harvested the plants and determined the dry masses of their shoots, roots, and reproductive structures. Prior to this time—at 14, 33, and 52 days after the start of the experiment—they also measured the heights and numbers of leaves of all the plants. The scientists found doubling the atmosphere's CO_2 concentration increased the mean stand-level biomass of the shoots of the ragweed plants by 44% and increased the biomass of their

roots and reproductive structures by 46% and 94%, respectively, for a total CO_2-induced biomass increase of 70%. They also found the extra CO_2 "reduced the coefficients of variation for all aspects of plant growth, especially reproductive biomass," so the CO_2-induced growth enhancements were "more pronounced in small, rather than large plants." They report, "growth enhancements to smaller plants diminished the relative biomass advantages of larger plants in increasingly crowded conditions," and "CO_2-induced growth gains of subordinate *A. artemisiifolia* plants minimize differences in the reproductive output of small and large plants."

The Harvard University scientists conclude, "more homogeneous reproduction between subordinates and dominants also implies that a larger number of individuals will contribute propagules to future generations." This phenomenon, they write, "could in turn affect evolutionary and population dynamics."

An international team of 33 researchers (Wills *et al*., 2006) analyzed seven forest dynamics plots located throughout the New and Old World tropics, with a wide range of species richness and tree densities, all of which had been visited and "censused" more than once over the past few decades. For all of the plots they studied, they found "rare species survive preferentially, which increases diversity as the ages of the individuals increase" and "when species were rare in a local area, they had a higher survival rate than when they were common, resulting in enrichment for rare species and increasing diversity with age and size class in these complex ecosystems."

The researchers offer several explanations for their findings. They note "diversity should increase as a group of individuals ages, because more common species are selectively removed by pathogens and predators," especially those commonly associated with them. They also note "individuals compete more intensively with conspecifics than with individuals of other species" and "diversity may increase if an individual facilitates (benefits) nearby nonconspecifics." This facilitation may have "the effect of making interspecific interactions more positive than intraspecific interactions and thus provides an advantage to locally rare species."

Similarly, in a commentary on these important findings and the phenomena underpinning them, Pennisi (2006) write, "being closer together, common trees are more prone to deadly infections," and "they may also face stiffer competition for certain resources," whereas "rarer trees, by depending on

slightly different sets of resources, may not have this problem." Pennisi quotes Scott Armbruster of the UK's University of Portsmouth as saying the fact "these patterns are found to be so consistent across so many distant tropical forests suggests to me that the conclusion may eventually be found to hold for other diverse ecosystems as well."

Londre and Schnitzer (2006) write, woody vines (lianas) around the globe are "competing intensely with trees and reducing tree growth, establishment, fecundity, and survivorship," possibly because "increasing levels of CO_2 may enhance growth and proliferation of temperate lianas more than of competing growth forms (e.g., trees)," and possibly because "warmer winter temperatures may also increase the abundance and distribution of temperate lianas, which are limited in their distribution by their vulnerability to freezing-induced xylem embolism in cold climates." The two researchers investigated whether these phenomena had impacted liana abundance and distribution over the prior 45 years in 14 temperate deciduous forests of southern Wisconsin (USA), during which time (1959–1960 to 2004–2005) the atmosphere's CO_2 concentration rose by 65 ppm, mean annual air temperature in the study region rose by 0.94°C, mean winter air temperature rose by 2.40°C, and mean annual precipitation did not change.

Contrary to their initial hypothesis, the researchers found "liana abundance and diameter did not increase in the interiors of Wisconsin (USA) forests over the last 45 years." They report *Toxicodendron radicans*—a liana popularly known as poison ivy, which "grew markedly better under experimentally elevated CO_2 conditions than did competing trees (Mohan *et al*., 2006)"—decreased in abundance over this period, and did so significantly.

Londre and Schnitzer write, "the lack of change in overall liana abundance and diameter distribution in [the] study suggests that lianas are limited in the interiors of deciduous forests of Wisconsin by factors other than increased levels of CO_2," suggesting it was likely the interior-forest lianas were limited by the enhanced tree growth provided by the CO_2 increase, which likely resulted in the trees becoming more competitive with the vines because of CO_2-induced increases in tree leaf numbers, area, and thickness. These factors would have reduced the amount of light being transmitted to the lianas growing beneath the forest canopy, negating the enhanced propensity for growth provided to the vines by the historical increase in the atmosphere's CO_2 concentration.

In support of this net-zero competing effects

hypothesis, Londre and Schnitzer found, "compared to the forest interior, lianas were >4 times more abundant within 15 m of the forest edge and >6 times more abundant within 5 m of the forest edge," and this "strong gradient in liana abundance from forest edge to interior was probably due to light availability." They report their results "are similar to findings in tropical forests, where liana abundance is significantly higher along fragmented forest edges and within tree fall gaps," and where the interior tropical trees have not suffered what some have claimed would be the negative consequences of CO_2-induced increases in liana growth, as described in the review of the study of Phillips *et al*. (2002).

Londre and Schnitzer write, because "forest fragmentation (and thus edge creation) has increased significantly over the last half-century, particularly in the northeastern and midwestern United States (e.g., Ritters and Wickham, 2003; Radeloff *et al*., 2005), liana abundance has likely increased in temperate forests due to forest fragmentation." Consequently, "as forest fragmentation continues, liana abundance will also likely continue to increase, and the effects of lianas on temperate forests, such as intense competition with trees (Schnitzer *et al*., 2005), reduced tree growth rates and biomass sequestration (Laurance *et al*., 2001), and the incidence of arrested gap-phase regeneration (Schnitzer *et al*., 2000) may become even more pronounced."

These latter observations remind us that a major cause of biodiversity reductions is not rising atmospheric CO_2 concentrations, but instead the direct encroachment of man upon the world of nature (Waggoner, 1995; Tilman *et al*., 2001, 2002; Raven, 2002). Such encroachment could deplete the globe's forests and drive innumerable species of both plants and animals to extinction, unless we can dramatically increase the water use efficiency of our crop plants so we are not forced to encroach further upon forests to obtain the additional land and water resources (Wallace, 2000) we will otherwise need to grow the greater quantities of food required to sustain the growing human population.

Regarding this challenge, Feeley and Silman (2009) write, "ongoing development of the Amazon, including natural gas and oil production, large-scale cattle ranching, soy farming, extended networks of improved roads, and the various synergistic activities that invariably accompany increased access, is causing the rapid loss and degradation of natural habitat," which can lead to the extinctions of species that live there. The two researchers used various collections of pertinent data to map the potential

ecoregion-based distributions of the more than 40,000 vascular plant species for which collections were available from the Amazon. They estimated rates of habitat loss due to future land-use changes, based on projections made by Soares-Filho *et al.* (2006) of areas that will be deforested by 2050 under business-as-usual and more-optimistic governance scenarios, which they translated into estimated extinction risks for the year 2050.

By AD 2050, they found, human land-use practices will have reduced the habitat available to Amazonian plants by approximately 12–24%, resulting in 5–9% of species becoming "committed to extinction" at that time.

Some regions will suffer more than others. For the largest Amazonian ecoregion—the seasonal Cerrado savannahs of southwestern Brazil that cover about two million square kilometers—Feeley and Silman calculated a habitat loss of 1.5%/year as characteristic of the past three decades, but "habitat loss in the Cerrado has actually accelerated to 3.1–4.3%/year." They state if they include "historic habitat loss and use a contemporary habitat loss rate of 3.7%, extinction risk for Cerrado species rises to more than 2 times greater than for non-Cerrado species."

The Cerrado has been losing "natural habitat to agricultural and pastoral land over the past three decades," Feeley and Silman note, and with the push for greater biofuel production, those habitat losses will accelerate. These incursions, not the ongoing rise in atmospheric CO_2 content, are the great threat to the Amazon's biodiversity.

Short *et al.* (2011) write about a different species of plants facing extinction threats. They write, "seagrasses, a functional group of marine flowering plants rooted in the world's coastal oceans, support marine food webs and provide essential habitat for many coastal species, playing a critical role in the equilibrium of coastal ecosystems and human livelihoods." Seagrasses are also "a component of more complex ecosystems within marine coastal zones, contributing to the health of coral reefs and mangroves, salt marshes and oyster reefs," they write, citing Dorenbosch *et al.* (2004), Duke *et al.* (2007), Heck *et al.* (2008) and Unsworth *et al.* (2008).

They report that for the first time, "the probability of extinction [has been] determined for the world's seagrass species under the Categories and Criteria of the International Union for the Conservation of Nature (IUCN) Red List of Threatened Species." They describe this effort as "a four-year process involving seagrass experts internationally, compila-

tion of data on species' status, populations, and distribution, and review of the biology and ecology of each of the world's seagrass species."

The 26 seagrass experts from 11 countries determined 10 seagrass species (comprising 14% of all seagrass species) are at elevated risk of extinction, with three other species qualifying as endangered. They identified several possible causes of the problem, including suspended sediments and siltation (Dennison *et al.*, 1993; de Boer, 2007), coastal construction, land reclamation, shoreline hardening, and dredging (Erftemeijer and Lewis, 2006), damaging fisheries practices such as trawling and aquaculture (Pergent-Martini *et al.*, 2006), mechanical damage from boats, boat moorings and docks (Burdick and Short, 1999; Kenworthy *et al.*, 2002), introduced species (Williams, 2007) that compete for space and resources (Heck *et al.*, 2000), and certain diseases (Rasmussen, 1997). They conclude "the most common threat to seagrasses is human activity," not CO_2-induced global warming or ocean acidification.

Mosses offer another example of species under threat of extinction due to human activity, but not CO_2. Gerdol and Vicentini (2011) write, "*Sphagnum* mosses are a fundamental component of bog vegetation in northern regions, where these plants play a major role in controlling important ecosystem processes." Noting "heat waves are expected to become increasingly intense and frequent, especially in cold territories," they attempted to ascertain the ability of the mosses to survive such conditions.

The two researchers collected cores of two *Sphagnum* species—*S. fuscum* and *S. magellanicum*—from three mountain heights in the southeastern Alps of the Italian province of Bolzano above sea level: low (1,090 m), intermediate (1,780 m), and high (2,100 m). The locations spanned, they write, "almost the whole altitudinal range known for these species in mountainous regions of central-southern Europe." In the laboratory, they grew portions of the six cores for four consecutive days at three 12-hour daytime temperature levels—ambient temperature (AT, 25°C), medium temperature (MT, 36°C), and high temperature (HT, 43°C)—and measured net CO_2 exchange and chlorophyll *a* fluorescence, as well as plant tissue chemistry.

The two Italian scientists report normalized net CO_2 exchange rates did not vary among species nor with altitude. Net CO_2 exchange rates in the plants under the MT treatment declined during treatment but recovered noticeably six days after treatment stopped. Despite receiving "severe damage," the plants experiencing the HT treatment also exhibited a

capacity to recover six days after the conclusion of the temperature treatment. Noting their study suggests "the two *Sphagnum* species possess moderate altitudinal plasticity to increased temperature," they conclude, "heat waves, even stronger than ever recorded, will unlikely bring about die-off of *Sphagnum* mosses in bog ecosystems unless high temperatures are coupled with drought."

4.5 Evolution

- As good as things currently are for world agriculture, and as significantly better as they are expected to become as the atmosphere's CO_2 content continues to rise, there may be additional substantial room for natural selection and bio-engineering to remove the remaining constraints of low CO_2 adaptation in several important agricultural crops and thereby create novel genotypes able to exploit high CO_2 conditions.

4.5.1 A Major Opportunity

Sage and Coleman (2001) reviewed what is known about plant responses to increases and decreases in atmospheric CO_2 content. They note plants generally photosynthesize at reduced rates and produce less biomass at lower-than-current atmospheric CO_2 levels, and they photosynthesize at enhanced rates and produce more biomass at higher-than-current CO_2 concentrations. At optimal temperatures for C_3-plant photosynthesis, for example, the two researchers write, "reducing atmospheric CO_2 from the current level to 180 ppm [an approximate 50% reduction at that time] reduces photosynthetic capacity by approximately half" and "causes biomass to decline by 50%." Doubling the atmosphere's CO_2 concentration typically increases photosynthesis and biomass production by 30 to 50%.

Sage and Coleman also report, "high CO_2 concentrations reduce the impact of moderate drought, salinity and temperature stress, and can indirectly reduce low nutrient stress by promoting root growth, nitrogen fixation and mycorrhizal infection." These phenomena boost the basic CO_2-induced productivity increase still more, as Idso and Idso (1994) noted in an earlier review of the literature. These observations are common knowledge among plant biologists and serve merely as intro-ductory material for Sage and Coleman's hypothesis that modern bioengineering techniques might help make plants even more responsive to increases in atmospheric CO_2 content.

Their reasoning is as follows. During the peak of the last ice age, and throughout the bulk of all prior ice ages of the past two million years, atmospheric

CO_2 concentrations tended to be approximately 180 ppm. This value, according to Sage and Coleman, might not be much above the "critical CO_2 threshold at which catastrophic interactions occur." Thus they speculated plants of the late Pleistocene "might have been adapted to lower CO_2 concentrations than currently exist." And in light of the short period of evolutionary time that has elapsed since the last of these low-CO_2 conditions prevailed, the two researchers suggest "many if not most plants might still be adapted to CO_2 levels much lower than those that exist today."

Literally thousands of laboratory and field experiments have demonstrated Earth's vegetation responds in dramatic positive fashion to atmospheric CO_2 enrichment far above what is characteristic of the CO_2 conditions of the present. Hence Sage and Coleman conclude as good as things currently are, and as significantly better as they are expected to become as the atmospheric CO_2 content continues to rise, there may be additional "substantial room for natural selection and bioengineering to remove the constraints [of low CO_2 adaptation], thereby creating novel genotypes able to exploit high CO_2 conditions to best advantage."

That such is possible and even probable is borne out by Ziska *et al*. (1996), who grew well-watered and well-fertilized plants of 17 cultivars of rice from seed to maturity in glasshouses maintained at atmospheric CO_2 concentrations of either 373 or 664 ppm in soil-filled pots kept at two different sets of day/night temperatures (29/21°C and 37/29°C), after which they measured total plant biomass and grain biomass. They report the degree of CO_2-induced enhancement of total plant biomass and the number of cultivars showing significant enhancement with elevated CO_2 decreased at the higher and more stressful set of growth temperatures, dropping from 12 of 17 cultivars with an average biomass stimulation of 70% at the lower set of temperatures to eight of 17 cultivars with a mean biomass stimulation of 23% at the higher set of temperatures. A few cultivars exhibited no significant changes in response to the atmospheric CO_2 enrichment employed in the study, while the most responsive cultivar exhibited a 265% increase in total plant biomass and a 350% increase in grain biomass. The variability in productivity enhancement exhibited by the 17 rice cultivars clearly demonstrates the selection of rice varieties has tremendous potential to take advantage of the aerial fertilization effect of rising atmospheric CO_2 content, which "could maximize productivity as CO_2 concentration increases," Ziska *et al*. write.

Also noting there is "considerable variability among current rice cultivars in their responses to CO_2 and temperature (Ziska and Teramura, 1992; Ziska *et al*., 1996; Moya *et al*., 1998) leading to the possibility of selecting rice cultivars against these two environmental variables for yield increases and/or stability in a possibly warmer, but almost certainly higher future CO_2 world," Baker (2004) grew the Southern United States rice cultivars Cocodrie, Jefferson, and Cypress for an entire season in outdoor, naturally sunlit, controlled-environment chambers at a constant day/night temperature of 28°C at CO_2 concentrations of 350 and 700 ppm. In the following year he grew the cultivar Lamont under the same conditions, but at day/night temperatures of 27/23°C, as a main crop and ratoon (stubble) crop.

In the first of these experiments, grain yield per plant rose by 46%, 57%, and 71% in response to the doubling of the atmospheric CO_2 content in the Cocodrie, Jefferson, and Cypress cultivars, respectively. In the second experiment, with the Lamont cultivar, it rose by 12% when the rice was grown as a main crop but by 104% when it was grown as a ratoon crop. Baker concludes, "the wide range in grain yield responsiveness to CO_2 enrichment found among these four US rice cultivars points to the potential for selecting or developing high yielding US rice cultivars with the ability to take advantage of expected future global increases in CO_2," noting "CO_2 enrichment could have potentially large positive effects on ratoon crop yields."

Sage and Coleman note the low CO_2 levels of the past "could have had significant consequences for much of the Earth's biota." They suggest the origin of agriculture itself "might have been impeded by reduced ecosystem productivity during low CO_2 episodes of the late Pleistocene." Since then, the increase in atmospheric CO_2 content has essentially doubled the biological prowess of the planet's vegetation, and projected increases in atmospheric CO_2 content could readily lead to a tripling of the productivity of Earth's ice-age past. In addition, the three studies reviewed above suggest there may be other opportunities to improve plant performance even more by using modern bioengineering techniques to overcome genetic constraints linked to adaptations to low levels of CO_2 that may persist in many plants. For agriculture, Sage and Coleman suggest, "this could be a major opportunity to improve crop productivity and the efficiency of fertilizer and water use."

These studies demonstrate we are living in an age of unparalleled biological promise. The fullness of

that promise has yet to be achieved, and how effectively we exploit the opportunities to do so, as Sage and Coleman write, "will depend on our ability to conduct the basic research [needed] to identify the genes controlling acclimation and adaptation to CO_2 variation."

4.5.2 CO_2 -Induced

- The ongoing rise in atmospheric CO_2 content likely is exerting significant selection pressure on Earth's naturally occurring terrestrial plants, which should improve their resistance to various environmental stressors via the process of micro-evolution as the air's CO_2 concentration continues to rise in the years and decades ahead.

The ongoing rise in atmospheric CO_2 content likely is exerting significant selection pressure on Earth's naturally occurring terrestrial plants, which should improve their resistance to various environmental stressors via the process of micro-evolution. Plants may be much better prepared than we have commonly believed to meet whatever climatic challenges, including global warming, the future may pose for them. Moreover, evidence continues to accumulate for substantial heritable variation of ecologically important plant traits, including root allocation, drought tolerance, and nutrient plasticity, which suggests rapid evolution based on epigenetic variation alone should be possible.

Two decades ago, Root and Schneider (1993) wrote CO_2-induced changes in global climate were expected to occur "too fast for evolutionary processes such as natural selection to keep pace," and this phenomenon "could substantially enhance the probability of extinction of numerous species." This famous but unsubstantiated declaration has pervaded the publications of IPCC ever since … but it never has been proven correct. It is more likely to be incorrect, especially as it pertains to CO_2-induced changes in natural (i.e., non-agricultural) terrestrial vegetation, the topic examined in the scientific studies reviewed below.

Rae *et al*. (2007) note various studies "are beginning to identify genes that appear sensitive to elevated CO_2 (Gupta *et al*., 2005; Taylor *et al*., 2005; Ainsworth *et al*., 2006)," while "leaf growth responses to elevated CO_2 have been found in *Populus*" and "quantitative trait loci (QTL) for this response [have been] determined (Rae *et al*., 2006)." Continuing this endeavor, they studied a three-generation *Populus* pedigree generated by the hybridization of two contrasting *Populus* species—where two full-siblings from the resulting F1 family were crossed to form an F2 family—growing cuttings of the different generations for 152 days out-of-doors in open-top chambers maintained at either the ambient CO_2 concentration or concentrations on the order of 600 ppm. They measured various plant properties and physiological processes and determined QTL for above- and below-ground growth and genotype-by-environment interactions.

The four UK researchers report, "in the F2 generation, both above- and below-ground growth showed a significant increase in elevated CO_2," and "three areas of the genome on linkage groups I, IX and XII were identified as important in determining above-ground growth response to elevated CO_2, while an additional three areas of the genome on linkage groups IV, XVI and XIX appeared important in determining root growth response to elevated CO_2." Consequently, stating their results "quantify and identify genetic variation in response to elevated CO_2 and provide an insight into genomic response to the changing environment," they conclude further work in this area "should lead to an understanding of

micro-evolutionary response to elevated CO_2," as subsequent studies have further demonstrated.

Springer *et al*. (2008) grew well-watered and well-fertilized plants of two closely related out-crossed genotypes (SG and CG) of *Arabidopsis thaliana*, generated via artificial selection, in controlled-environment chambers maintained at atmospheric CO_2 concentrations of either 380 or 700 ppm. They selected genotype SG for high seed number at elevated CO_2 over five generations, and they randomly chose genotype CG to serve as a control. They measured time to flowering, number of leaves at flowering, and total biomass at flowering, as well as foliar sugar concentrations. In a second experiment conducted under the same growing conditions, they characterized the expression patterns of several floral-initiation genes.

They found "SG delayed flowering by 7–9 days, and flowered at a larger size (122% higher biomass) and higher leaf number (81 more leaves) when grown at elevated versus current CO_2 concentration," but "flowering time, size and leaf number at flowering were similar for CG plants grown at current and elevated CO_2." They note "SG plants had 84% higher foliar sugar concentrations at the onset of flowering when grown at elevated versus current CO_2, whereas foliar sugar concentrations of CG plants grown at elevated CO_2 only increased by 38% over plants grown at current CO_2." They report, "SG exhibited changes in the expression patterns of floral-initiation genes in response to elevated CO_2, whereas CG plants did not."

Noting "delayed flowering increases production of vegetative resources that can be subsequently allocated to reproductive structures," the researchers conclude "such evolutionary responses may alter total carbon gain of annual plants if the vegetative stage is extended, and may potentially counteract some of the accelerations in flowering that are occurring in response to increasing temperatures." Their results demonstrate the ability of elevated CO_2 to alter the expression of plant genes in ways that may enable plants to take better advantage of the ongoing rise in atmospheric CO_2 content.

Lau *et al*. (2008) measured the amount of pathogen damage caused by *Pythium* or *Fusarium* spp. to the common prairie legume *Lespedeza capitata* growing in ambient and elevated (560 ppm) CO_2 treatments in the seventh and eighth full years (2004 and 2005) of the BioCON study (Reich *et al*., 2001) conducted at the Cedar Creek Natural History Area in Minnesota (USA), where they applied the CO_2 treatments during the daylight hours of each

growing season. They found disease incidence was lower in the elevated CO_2 environment (down by 10% in 2004 and 53% in 2005). "Because disease caused major reductions in reproductive output," the five researchers conclude, "the effects of CO_2 on disease incidence may be important for *L. capitata* evolution and population dynamics." They note Strengbom and Reich (2006), "working in the same experimental site ... also found that elevated CO_2 ... reduced disease incidence on *Solidago rigida*."

Kaligaric *et al*. (2008) investigated fluctuating asymmetry (FA), which describes the magnitude of random deviations from perfect symmetry in morphological traits of both plants and animals that "offers a unique tool for comparative studies of developmental stability (Moller and Swaddle, 1997)" and has been used as "an indicator of genetic and environmental stress (Martel *et al*., 1999; Cornelissen and Stiling, 2004)" in plants. They measured the degree of FA in "undamaged (not grazed, not visibly attacked by herbivores or pathogens) fully developed leaves" of the Mediterranean shrub *Myrtus communis* growing along an atmospheric CO_2 gradient (570, 530, 490, 450, 410, and 370 ppm) moving away from a natural CO_2 spring (I Borboi) near Lajatico (Pisa, Tuscany, Italy) at distances of 2, 18, 34, 50, 66, and 82 meters, respectively, from the CO_2 source.

The four researchers found "a significant and negative correlation between CO_2 concentration and leaf FA," such that "with increased CO_2 concentration the leaf FA decreased." This result, they write, "confirms what was obtained by Cornelissen *et al*. (2004) on *Quercus myrtifolia* and *Quercus geminata* (in a short-term experiment)." They report, "*Myrtus communis*, grown under elevated CO_2 concentration at 'I Borboi,' showed a reduction in xylem embolism and an increase in hydraulic efficiency (Tognetti *et al*., 2001)," stating "improved water relations could represent a good explanation for the observed reduction in leaf FA" as the atmospheric CO_2 content increased. They conclude "adaptation and selection could explain the tendency towards decreased leaf FA in plants from the CO_2 spring relative to ambient conditions," because "the more symmetrical leaves under long-term elevated CO_2 concentration were more developmentally stable in these conditions."

Onoda *et al*. (2009) write the ongoing rise in atmospheric CO_2 content "is likely to act as a selective agent" among plants, citing Woodward *et al*. (1991), Thomas and Jasienski (1996), Ward *et al*. (2000), Kohut (2003), Ward and Kelly (2004), and Lau *et al*. (2007). They report, "evolutionary responses have been found in selection experiments

with short-lived organisms, such as *Arabidopsis thaliana* (e.g. development rate and biomass production; Ward *et al*., 2000) and *Chlamydomonas reinhardtii* (e.g. photosynthesis and cell size; Collins and Bell, 2004)." They add, "the evolutionary response of wild plants (especially long-lived plants) is, in general, difficult to evaluate using growth experiments," because of the long time spans needed to evaluate the phenomenon properly. They avoid this problem by studying plants growing around natural CO_2 springs, where they "have been exposed to a CO_2-enriched atmosphere over many generations," providing what the researchers call "a unique opportunity to explore the micro-evolutionary response of wild plants to elevated CO_2."

Onoda *et al*. write, "the adaptation of leaf photosynthesis to elevated CO_2 was tested by a common garden experiment with herbaceous species originating from three different natural CO_2 springs in Japan: Nibu, Ryuzin-numa and Yuno-kawa," where "several genotypes were collected from each high-CO_2 area (spring population) and nearby control areas (control population), and each genotype was propagated or divided into two ramets, and grown in pots at 370 and 700 ppm CO_2." They assessed the plants' photosynthetic nitrogen use efficiency (PNUE), water use efficiency (WUE), and the degree of carbohydrate accumulation in the plants' leaves, which if too large can lead to down-regulation of photosynthesis.

Onoda *et al*. report, "high CO_2 concentration directly and greatly increased PNUE and WUE, suggesting that plants will show higher growth rates at a given resource availability." They also identify "a significant reduction in stomatal conductance, which contributed to higher WUE, and a trend of reduced down-regulation of photosynthesis with a lower starch accumulation," and they note these results suggest "there is substantial room for plant evolution in high-CO_2 environments." They write, a molecular study "also found relatively large genetic differentiation across the CO_2 gradient in these plants." As a result of their own work and "the increasing number of studies on CO_2 springs (e.g. Fordham *et al*., 1997; Polle *et al*., 2001; Schulte *et al*. 2002) and selection experiments (Ward *et al*., 2000; Collins and Bell, 2004)," Onoda *et al*. conclude "high CO_2 will act as a selection agent" as atmospheric CO_2 content continues to rise. This phenomenon should enable plants to fare even better in the CO_2-enriched air of the future than they do today.

Cseke *et al*. (2009) note certain perceived "genetic and environmental bottlenecks" may limit a plant's capacity to allocate assimilated carbon to greater biomass production. However, it is plausible that numerous species may possess the genetic diversity needed to overcome these potential roadblocks and thereby benefit more than is commonly anticipated from the enhanced growth known to be possible in a CO_2-enriched atmosphere.

Working at the Aspen FACE site near Rhinelander, Wisconsin (USA), Cseke *et al*. grew two quaking aspen (*Populus tremuloides* Michx.) clones (216 and 271) from the seedling stage in replicate plots maintained at either 372 or 560 ppm CO_2 throughout each year's growing season (May–September), assessing their stem volume (a surrogate for biomass) annually for a period of eight years. They measured the trees' maximum light-saturated rates of leaf net photosynthesis, the transcriptional activity of leaf elevated-CO_2-responsive genes, and numerous leaf primary and secondary carbon-based compounds. The CO_2-induced increase in the maximum light-saturated rate of leaf net photosynthesis in clone 216 was more than twice as great as that of clone 271 (37% vs. 17%, as best as can be determined from Cseke *et al*.'s bar graphs); they found just the opposite relationship in the CO_2-induced increases in the trees' stem volumes, which increased only 0–10% for clone 216 but. 40–50% for clone 271.

The researchers' transcript abundance and carbon/nitrogen biochemistry data suggest "the CO_2-responsive clone (271) partitions carbon into pathways associated with active defense/response to stress, carbohydrate/starch biosynthesis and subsequent growth," whereas "the CO_2-unresponsive clone (216) partitions carbon into pathways associated with passive defense and cell wall thickening." The seven scientists conclude there was "significant variation in expression patterns between different tree genotypes in response to long-term exposure to elevated CO_2," and "future efforts to improve productivity or other advantageous traits for carbon sequestration should include an examination of genetic variability in CO_2 responsiveness." As the atmosphere's CO_2 concentration continues to rise, manifestations of these fitness-promoting traits will appear on their own, brought forth naturally by the changing environment, as plants appear to be genetically programmed to respond positively to atmospheric CO_2 enrichment. Plants are innately well-prepared to use the ongoing rise in the air's CO_2 concentration to their advantage.

Nakamura *et al*. (2011) suggest "evolutionary responses to elevated CO_2 in wild plants are, in general, difficult to detect using growth experiments, because the duration of experiments is often too short

compared to the time required for evolution." They note areas around natural CO_2 springs—and locations nearby but beyond the influence of the additional CO_2—provide ideal sources of plants for such studies, as the plants near the springs have "been exposed to high CO_2 over an evolutionary time scale," citing Miglietta *et al.* (1993) and Raschi *et al.* (1999).

Nakamura *et al.* conducted experiments designed to reveal numerous characteristics of *Plantago asiatica* plants (a C_3 rosette perennial herb) acquired from locations at different distances from a stream emerging from a CO_2-emitting spring situated at the foot of Mount Gassan (Japan), where the plants had been exposed to normal ambient (370 ppm) and several elevated (726, 771, 1,044, and 5,339 ppm) CO_2 concentrations, as measured in late August and early September in two years presumed to have been typical of CO_2 concentrations at those locations over what they called "an evolutionary time scale."

The six scientists "found phenotypic differences between populations in areas with high and normal CO_2, some of which were heritable," indicating "an evolutionary differentiation occurred in the *P. asiatica* population across a CO_2 gradient." One of these differences was in plant relative growth rate, which, they write, "was higher in parent plants that originated in areas with higher CO_2, suggesting that plants from higher-CO_2 populations had an inherent potential for higher productivity." They conclude "a higher potential of biomass production contributes to fitness and has selective advantages."

Noting their results are "consistent with those of previous experiments, wherein artificial selection increased seed production under the respective CO_2 condition compared to non-selected plants (Ward *et al.*, 2000; Ward and Kelly, 2004)," Nakamura *et al.* conclude their study "clearly shows that phenotypic and genetic differences have occurred between high and normal CO_2 populations."

The scientific findings described above indicate the ongoing rise in atmospheric CO_2 content is exerting significant selection pressure on naturally occurring terrestrial plants, which should improve their resistance to environmental stressors via the process of micro-evolution as atmospheric CO_2 concentrations continue to rise.

4.5.3 Warming-Induced

- Plants may exhibit a rapid evolutionary response to temperature modifications, making them much better prepared than scientists have long believed to meet whatever possible challenge higher temperatures might pose.

IPCC contends CO_2-induced global warming will result in mass plant extinctions because many species will not be able to migrate poleward in latitude or upward in altitude fast enough to find temperature regimes suitable for their continued existence. That scenario assumes plants cannot evolve quickly enough to increase their ranges to keep up with the effects of warming, and that they cannot adjust their inner workings to be able to tolerate more heat than they seem capable of enduring at present. The papers reviewed below explore those possibilities.

Gunter *et al.* (2000) note many models of actual or attempted range shifts in response to global warming lack a thorough understanding of "the role that acclimation and genetic adaptation may have in a species' response to predicted climate regimes," stating if populations "have a greater capacity for adjustment to higher temperatures, and if they are not

constrained by complete genetic isolation from other populations, then the effects of global warming will probably be less severe than what may be predicted from a simple temperature-response curve applied without regard to spatial or temporal genetic variation."

The four researchers employed random amplified polymorphic DNA markers to evaluate population-level genetic structure as an indirect indicator of the capacity for response to environmental change by sugar maple trees from three geographical locations representing a north-south gradient of that species' current distribution. They found "genetic diversity, as indicated by estimates of percent polymorphic loci, expected heterozygosity, fixation coefficients, and genetic distance, is greatest in the southern region, which consists of populations with the maximum potential risk due to climate change effects." They say "the high degree of variation within sugar maple implies that it may contain genetic mechanisms for adaptation."

Gunter *et al*. note sugar maple range shift potentials derived by the Goddard Institute for Space Studies (Hansen *et al*., 1983) and NASA's Geophysical Fluid Dynamics Laboratory (Manabe and Wetherald, 1987)—as described by Davis and Zabinski (1992)—"assume that a species grows only in a climate with temperature and precipitation identical to its current range." In a significant rebuff of those studies and their alarmist implications, Gunter *et al*. note existing "high levels of genetic variation among families indicate that vegetational models designed to predict species' responses to global-scale environmental change may need to consider the degree and hierarchical structure of genetic variation when making large-scale inferences." The ability of species to adapt to a changing environment may be far greater than what is presumed by the outdated climate envelope approach.

Hamrick (2004) also noted concerns that "expected changes may be of such an extent that tree species will not have adequate genetic variation to adapt to the modified conditions (Critchfield, 1984; Davis and Zabinski, 1992)"; "environmental changes may occur at such a rapid rate that trees, with their long generation times, could not adapt quickly enough to keep pace with predicted changes (Davis and Shaw, 2001)"; and trees "may not be capable of dispersing into newly available habitats quickly enough to match the rate of environmental change (Clark, 1998)."

In reviewing the findings of several studies that focused on the responses of trees to conditions analogous to those of computer-generated simulations of rapid global warming, Hamrick found "trees combine life-history traits and levels of genetic diversity that will allow them to adapt relatively quickly to environmental changes," noting they have high genetic mobility via pollen. The plant biology and genetics professor also notes "tree species have faced large-scale global environmental changes many times during their evolutionary histories," and even though these changes "occurred quite quickly, most tree species have survived," maintaining traits that "may allow many tree species to survive predicted global climatic changes while preserving much of their genetic diversity."

Jump *et al*. (2006) write, "one of the basic assumptions in the study of plant adaptation to environment (genecology) is that natural selection in different environments generates genetic clines that correlate with environmental clines." They point out "temperature is of major importance as a selective agent causing population differentiation over altitudinal and latitudinal clines (Saxe *et al*., 2001)," and "temporal changes in gene frequency that result from global warming should therefore mirror spatial changes observed with decreasing altitude and latitude." These changes, they write, are typically manifest in particular alleles that "may be confined to, or occur preferentially in, different sites with contrasting environmental conditions."

The four researchers "combined population genomic and correlative approaches to identify adaptive genetic differentiation linked to temperature within a natural population of the tree species *Fagus sylvatica* L. [European beech] in the Montseny Mountains of Catalonia, northeastern Spain," concentrating on three areas: the upper treeline (high *Fagus* limit, HFL), the lower limit of *F. sylvatica* forest (low *Fagus* limit, LFL), and an area of the forest interior.

Jump *et al*. note the 648-meter altitudinal difference that separates the HFL and LFL locations "equates to a mean temperature difference of 3°C ... based on the altitudinal lapse rate of 0.51°C per 100 meters reported by Peñuelas and Boada (2003) for Montseny." Regarding the change in temperature due to the region's manifestation of twentieth-century global warming, they write, "by 2003, temperatures had increased by approximately 1.65°C when compared with the 1952–1975 mean," and this temperature change, they remark, was "likely to represent a strong selection pressure."

Numerous tests conducted by Jump *et al*. on the data they collected reveal the frequency of a

particular *F. sylvatica* allele shows a predictable response to both altitudinal and temporal variations in temperature, with a declining frequency and probability of presence at the HFL site the Spanish research team determined to be "in parallel with rising temperatures in the region over the last half-century." They say their work "demonstrates that adaptive climatic differentiation occurs between individuals within populations, not just between populations throughout a species geographic range," which further suggests "some genotypes in a population may be 'pre-adapted' to warmer temperatures (Davis and Shaw, 2001)."

Jump *et al.* also contend "the increase in frequency of these genotypes," which occurred in their study in parallel with rising temperatures, "shows that current climatic changes are now imposing directional selection pressure on the population," and "the change in allele frequency that has occurred in response to this selection pressure also demonstrates that a significant evolutionary response can occur on the same timescale as current changes in climate," citing Davis *et al.* (2005), Jump and Peñuelas (2005), and Thomas (2005).

Jump *et al.* conclude an evolutionary response to global warming of the type they describe is likely already "underway," which further suggests many species of plants probably will not be forced to migrate either poleward in latitude or upward in altitude in response to global warming, as climate models suggest they will be forced to do. Instead, they will adjust their ranges (meaning, expand them) at the cold-limited boundaries of their ranges, and they may not be forced to make any major changes at the heat-limited boundaries of their ranges.

Keller *et al.* (2011) note "studies on the evolution of plant populations during historical fluctuations in climate can reveal the capacity for and constraints on adaptive evolution and may help inform predictions about evolutionary responses to future environments." They tested for adaptive variation in 13 ecophysiology and phenology traits on clonally propagated genotypes of balsam poplar (*Populus balsamifera* L.) trees originating from a range-wide sample of 20 subpopulations that developed during the warming of climate conditions that marked the end of the last glacial maximum (~18 thousand years ago), when there was a rapid environmental change that increased population sizes and led to range expansions in many plant species. This "wave of migrations," they write, "affected genomic diversity within populations, as colonists sub-sampled alleles from the ancestral gene pool during the process of expansion," as described

by Lascoux *et al.* (2004), Petit *et al.* (2004), and Savolainen and Pyhajarvi (2007). The six scientists report, "evidence for divergence in excess of neutral expectations was present for eight of thirteen traits," noting "strong correlations were present between traits, geography [extending across the whole of Canada from the Atlantic to Pacific Oceans], and climate." These results, they conclude, reveal "a general pattern of northern subpopulations adapted to shorter, drier growing seasons compared with populations in the center or eastern regions of the range."

Keller *et al.* say their study "demonstrates pronounced adaptive variation in ecophysiology and phenology among balsam poplar populations," suggesting "as this widespread forest tree species expanded its range since the end of the last glacial maximum, it evolved rapidly in response to geographically variable selection." It is likely to do so again if circumstances warrant; as they conclude, "balsam poplar is both highly variable and capable of a broad range of adaptive physiological responses to a changing climate."

Niu *et al.* (2012) write, "it is well documented that plants (Mooney *et al.*, 1978; Berry and Bjorkman, 1980; Atkin and Tjoelker, 2003), animals (Parmesan, 2006), and microbes (Bradford *et al.*, 2008) acclimate and/or adapt to prevailing environmental conditions in a way that can optimize their functioning under varying temperatures, which is collectively termed optimality (Parker and Maynard Smith, 1990)." They hypothesize "the integrated response of an ecosystem, as an assemblage of interacting organisms, might also demonstrate thermal optimality under temperature change," citing Loreau (2010).

Niu *et al.* "compiled data from 169 globally distributed sites of eddy covariance and quantified the temperature response functions of net ecosystem exchange (NEE), an ecosystem-level property, to determine whether NEE shows thermal optimality and to explore the underlying mechanisms."

The team of 68 researchers from 19 countries writes, "the temperature response of NEE followed a peak curve, with the optimum temperature (corresponding to the maximum magnitude of NEE) being positively correlated with annual mean temperature over years and across sites." They state, "shifts of the optimum temperature of NEE were mostly a result of temperature acclimation of gross primary productivity (upward shift of optimum temperature) rather than changes in the temperature sensitivity of ecosystem respiration." They report, "extended growing seasons,

increased nitrogen mineralization, and enhanced root growth (Peñuelas and Filella, 2001; Churkina *et al.*, 2005; Luo *et al.*, 2009) may also have contributed to the increased CO_2 uptake under higher temperatures, leading to the upward shift in the optimum temperature of gross primary productivity in warmer years."

Pluess and Weber (2012) write, "with increasing temperatures and dryer summers [as predicted by various climate models], areas nowadays covered by beech forests are expected to shrink tremendously," but "if individuals at the dry distribution limits [of the species: *Fagus sylvatica* L.] are adapted to lower moisture availability, *F. sylvatica* might contain the genetic variation for the continuation of beech forests under climate change," even in areas predicted to become devoid of the trees.

The two researchers used an AFLP (amplified fragment length polymorphism) genome scan approach designed to explore the "neutral and potentially adaptive genetic variation in *Fagus sylvatica* in three regions [in the lowland forests of Switzerland] containing a dry and mesic site each," after which they "linked this dataset with dendrochronological growth measures and local moisture availabilities based on precipitation and soil characteristics." They found a "potential for adaptation to water availability" reflected in observed outlier alleles that "indicated micro-evolutionary changes between mesic and dry stands." They also note, "while Rose *et al.* (2009) found adaptation to drought in a common garden experiment with seedlings originating from provenances which were more than 1000 km apart," their own work found genetic differentiation in relation to water availability in neighboring stands. Pluess and Weber conclude "dispersal across large distances is thereby not needed for the spread of 'pre-adapted' genes in *F. sylvatica*," for the trees apparently have the genetic material needed for "the continuation of beech forests under climate change," even in areas that have been predicted to become too dry for *F. sylvatica* trees to survive.

Hahn *et al.* (2012) note "altitudinal gradients comprise an assemblage of environmental, especially climatic, variables which influence the distribution of plant species and, potentially, population genetic variation." They also note some scientists argue climate change may alter species distributions such that, locally, certain species "might become extinct," citing Sala *et al.* (2000) and Thomas *et al.* (2004). The basis for this prediction, the six scientists write, are the observations, "habitat suitability typically decreases at the upper edge of the altitudinal range

where population size might decline," and "in small populations genetic diversity is often reduced and inbreeding may increase (Lynch *et al.*, 1995; Young *et al.*, 1996)," with the result that "low genetic diversity and high inbreeding potentially cause loss of fitness due to fixation of deleterious alleles and inbreeding depression (Ouborg *et al.*, 1991; Lynch *et al.*, 1995; Young *et al.*, 2002), which could affect future population persistence."

Hahn *et al.* investigated patterns of population genetic variation in three common plants of semi-dry grasslands—*Briza media*, a wind-pollinated grass, and *Trifolium montanum* and *Ranunculus bulbosus*, two insect-pollinated herbs—at upper peripheral and lower more central altitudes in the Swiss Alps using the AFLP technique. The Swiss researchers determined, contrary to what many had long supposed, altitude had not affected genetic diversity in the grassland species they studied. They report their results indicate "populations at the upper periphery are not genetically depauperate or isolated" and thus may be "important populations for migration under climate change." Hahn *et al.* conclude what they call the "potentially pre-adapted genes" of the three plant species might "spread easily across altitudes," which would help to prevent their local extinction in a warming world.

Thompson *et al.* (2013) write, "in addition to changes in distribution and plasticity, an evolutionary response to climate change may occur if species evolve a genetically-based adaptation to climate change," citing Chevin *et al.* (2010) and Hoffmann and Sgro (2011). They note "it is important to distinguish this genetic response from a plastic response of individuals if we are to fully understand the evolutionary potential of species to evolve with climate change," as has been described by Gienapp *et al.* (2008).

To test the hypothesis that phenolic chemotypes (thymol and carvacrol) of Mediterranean wild thyme (*Thymus vulgaris*) now occur in sites where they were previously absent or have increased their frequency in transitional sites due to a relaxation of selection normally associated with extreme early winter freezing, the team of eight researchers compared the chemotype composition of populations observed in the early 1970s (Vernet *et al.*, 1977) to that found in 2009–2010 for 36 populations sampled along six transects in and around the Saint Martin-de-Londres basin, which covers an area of about 80 km^2 with southern limits about 20 km north of Montpellier in the Mediterranean climate region of southern France.

The eight French researchers discovered "a rapid

and probably ongoing spatial reorganization of a genetic polymorphism that is closely associated with a warming of extreme winter freezing events on a highly localized spatial scale," observing "both a significant appearance of freezing-sensitive phenolic chemotypes in sites where they were historically absent and an increase in their frequency in previously mixed populations." Thompson *et al*. conclude their study, "done over a similar time span as work reporting ecological changes in plant species distribution, illustrates that a rapid evolutionary response to temperature modifications can occur where genetic variation is combined with a change in a previously strong selection pressure, even for a perennial woody plant."

Matter *et al*. (2013) write, "gene flow connects populations, maintains genetic diversity, prevents inbreeding and facilitates the spread of adaptive genes across a species range," citing Slatkin (1985, 1987) and Ellstrand and Elam (1993). They further state, "understanding how plant populations are connected by gene flow, particularly across altitudinal gradients in mountain regions, will improve our understanding of how they will respond to future environmental change." The four Swiss scientists studied patterns of historic gene flow, flowering phenology, and contemporary pollen flow in two common herbs (*Ranunculus bulbosus* and *Trifolium montanum*) along an altitudinal gradient of 1200–1,800 meters a.s.l. over a distance of 1 km among five alpine meadows in Switzerland.

"Historic gene flow was extensive," they write, with their data suggesting "contemporary pollen flow is not limited across altitudes in either species." They conclude "high levels of pollen flow among altitudes in both *R. bulbosus* and *T. montanum* should facilitate exchange of genes which may enhance adaptive responses to rapid climate change."

The observations discussed above suggest plants may be much better prepared to meet upcoming climatic challenges than most scientists once believed.

4.5.4 Drought-Induced

- Evidence continues to accumulate for substantial heritable variation of ecologically important plant traits, including root allocation, drought tolerance, and nutrient plasticity, which suggests plants should be capable of rapid evolution based on epigenetic variation alone.

One generally thinks of evolution as acting over very long spans of time. This section explores whether evolution can occur more quickly to help plants cope with the rapid climatic changes IPCC predicts will be caused by continued increases in the atmosphere's CO_2 content.

Franks *et al*. (2007) compared "phenotypic and fitness values of ancestral, descendant, and ancestral x descendant hybrid genotypes [of field mustard (*Brassica rapa*)] grown simultaneously" under conditions that mimicked those before and after a real-world switch from above-average to below-average precipitation in southern California (USA), which led to abbreviated growing seasons from 2000 to 2004. They had "collected *B. rapa* seed in 1997, before the drought, and then again in 2004 from two populations," a dry site and a wet site. Hence they could grow—at the same time and under the same circumstances, in a new set of experiments—plants that had experienced extended drought conditions (descendants) and plants that had not experienced such conditions (ancestors), as well as hybrids of the two, and thus could see whether flowering times (FT) differed, as is likely from life history theory, which "predicts that the optimal FT in annual plants will be shorter with shorter growing seasons," such as those that were imposed by the extended drought that occurred between the two times of their seed collecting.

The three researchers found, as predicted, "the abbreviated growing seasons caused by drought led to the evolution of earlier onset of flowering," as plant descendants "bloomed earlier than ancestors, advancing first flowering by 1.9 days in one study population and 8.6 days in another." They state, "the intermediate flowering time of ancestor x descendant hybrids supports an additive genetic basis for divergence." They conclude, "natural selection for drought escape thus appears to have caused adaptive evolution in just a few generations," further noting, "abundant evidence has accumulated over the past several decades showing that natural selection can cause evolutionary change in just a few generations (Kinnison and Hendry, 2001; Reznick and Ghalambor, 2001)."

Franks *et al*. write their findings "provide evidence for a rapid, adaptive evolutionary shift in flowering phenology after a climatic fluctuation," which "adds to the growing evidence that evolution is not always a slow, gradual process but can occur on contemporary time scales in natural populations" and in response to real-world climatic changes.

In a follow-up study conducted with the same plant material, Franks and Weis (2008) report several life-history traits "differed between the ancestral genotypes collected before and descendant genotypes collected after the natural drought," stating "this shows directly that an evolutionary change in the life-history traits has occurred during a 5-year drought."

They also report "the evolutionary changes in trait levels following the drought are consistent with predictions from life-history theory" because "the drought selected for individuals that flowered earlier, continued to flower for longer given sufficient resources, and produced a more consistent, evenly distributed pattern of flowering over time." These changes, they write, constitute "a true genetically based evolutionary change rather than an expression of phenotypic plasticity."

Jump *et al.* (2008) studied *Fumana thymifolia* (a small shrub that occurs around the Mediterranean Basin) at Spain's Garraf Natural Park, seeking to determine whether reduced seedling establishment observed as a consequence of climate manipulation is a random or selective process, in an attempt to answer what they called "the key question": Does climate change provoke evolutionary change within natural populations?

As an unaltered control treatment, the seven scientists' study had a drought treatment that employed automatically activated transparent plastic shields that covered a third of the plots in response to rainfall and retreated when rainfall stopped (which decreased soil moisture by approximately 20%), and a warming treatment employing reflective covers that reduced nighttime re-radiation of energy received from the Sun during the prior daylight hours from another one-third of the plots (which increased temperature by about 1°C).

Over the seven-year period 1999–2005, Jump *et al.* report, mean yearly seedling density per treatment was significantly reduced in the drought and warming treatments compared with the control treatment, and "when compared against control samples, high single-locus genetic divergence occurred in drought and warming treatment samples, with genetic differentiation up to 37 times higher than background (mean neutral locus) genetic differentiation."

The researchers say the significant reduction in seedling survival in the drought and warming treatments "results from an episode of selection for individuals tolerant of the modified climatic conditions and is not due simply to a random reduction in plant establishment." This implication, they write, "reinforces results reported by other authors that show that genetic variability for climate-related traits exists within natural plant populations (Hamrick and Holden, 1979; Cobb *et al.*, 1994; Kelly *et al.*, 2003; Mitton and Duran, 2004; Franks *et al.*, 2007)."

Jump *et al.* conclude contemporary climate change "is driving changes in gene frequency within natural plant populations," and these changes "are occurring on the same time scale as current climatic changes, based on preexisting genetic variability within populations," citing Jump and Peñuelas (2005), Thomas (2005), Jump *et al.* (2006), and Reusch and Wood (2007). They state this ability to adapt rapidly to rapid climate change may increase the persistence of species "beyond that predicted under a species-based climate envelope approach," such as IPCC typically uses to justify predictions of impending extinctions of species.

In a conclusion that clearly repudiates the catastrophic extinction scenario, Jump *et al.* state their results demonstrate "that rapid evolution in response to climate change may be widespread in natural populations, based on genetic variation already present within the population." The accumulating evidence suggests plants are likely to be much more resilient to rising temperatures and reductions in precipitation than people have long been led to believe.

Franks and Weis (2009) write, "one rigorous way to determine if evolution has occurred in a natural population is to collect propagules before and after an environmental change and raise them under common conditions," noting "this approach was used previously to show that *Brassica rapa* [a self-incompatible weedy winter annual] evolved drought escape through earlier flowering following a series of recent dry years in Southern California, and that early flowering results in higher fitness under drought conditions (Franks *et al.*, 2007)," and "a related study showed that multiple phenological traits and their interactions evolved in response to the drought (Franks and Weis, 2008)."

Working with the same pre- and post-drought collection lines as were used in the Franks *et al.* (2007) experiment, the two researchers set out to estimate the amount of assortative mating within, and the degree of phenological isolation between, two *B. rapa* populations. They found "climate change can alter plant phenology, which can change patterns of assortative mating within populations," and "this assortative mating can directly change genotype frequencies and can also increase the rate of evolution by interacting with selection." Their work demonstrates "climatically driven changes in phenology can potentially influence gene flow among populations due to changes in overlap in flowering schedules," and "these changes in gene flow can also influence both the rate and pattern of evolutionary change."

The two scientists conclude "the high degree of

interdependence of flowering time, assortative mating, selection and gene flow make predicting evolutionary responses to changes in climate particularly complex and challenging." This great degree of complexity suggests that among the multiplicity of outcomes there is a good chance one or more will be just what plants need to respond successfully to the climate change that elicited the changes.

Vigouroux *et al.* (2001) write, "one important phenomenon that is often overlooked and is poorly documented is the ability of agro-systems to rapidly adapt to environmental variations." Such adaptations, they note, can occur by the adoption of new varieties or by the adaptation of existent varieties to a changing environment. Working in "one of the driest agro-ecosystems in Africa, the Sahel," they "analyzed samples of pearl millet landraces collected in the same villages in 1976 and 2003 throughout the entire cultivated area of Niger," to see how the agro-system had responded to recurrent drought over that time. They studied "phenological and morphological differences in the 1976 and 2003 collections by comparing them over three cropping seasons in a common garden experiment."

The 15 researchers write, "compared to the 1976 samples, samples collected in 2003 displayed a shorter lifecycle and a reduction in plant and spike size." They also report an early flowering allele "increased in frequency between 1976 and 2003," and this increase "exceeded the effect of drift and sampling, suggesting a direct effect of selection for earliness on this gene." Vigouroux *et al.* conclude "recurrent drought can lead to selection for earlier flowering in a major Sahelian crop," reinforcing the earlier findings of Franks *et al.* (2007), Franks and Weis (2008, 2009), and Jump *et al.* (2008).

Pluess and Weber (2012) note, "with increasing temperatures and dryer summers [as predicted by various climate models], areas nowadays covered by beech forests are expected to shrink tremendously," but "if individuals at the dry distribution limits [of the species: *Fagus sylvatica* L.] are adapted to lower moisture availability, *F. sylvatica* might contain the genetic variation for the continuation of beech forests under climate change," even in areas predicted to become devoid of the trees.

Pluess and Weber employed an AFLP genome scan approach designed to explore the "neutral and potentially adaptive genetic variation in *Fagus sylvatica* in three regions [within the lowland forests of Switzerland] containing a dry and mesic site each." They "linked this dataset with dendrochronological

growth measures and local moisture availabilities based on precipitation and soil characteristics."

The two Swiss scientists report a "potential for adaptation to water availability" was reflected in observed outlier alleles that "indicated micro-evolutionary changes between mesic and dry stands." They note, "while Rose *et al.* (2009) found adaptation to drought in a common garden experiment with seedlings originating from provenances which were more than 1000 km apart," Pluess and Weber found genetic differentiation in relation to water availability in neighboring stands. They conclude, "dispersal across large distances is thereby not needed for the spread of 'preadapted' genes in *F. sylvatica*," for the trees apparently contain the genetic material needed for "the continuation of beech forests under climate change," even in areas predicted to become too dry for *F. sylvatica* trees to survive.

Zhang *et al.* (2012) note "a key question in ecology and evolution is to what degree variation in ecologically important traits is heritable, because heritability determines the potential for evolutionary change of traits (Fisher, 1930; Falconer and MacKay, 1996)," and this phenomenon significantly enhances the ability of a species "to adapt to changing environments (Visser, 2008; Hoffmann and Sgro, 2011)." Zhang *et al.* conducted a glasshouse experiment in which they tested the response of a large number of epigenetic recombinant inbred lines, or epiRILs (lines that are nearly isogenic but highly variable at the level of DNA methylation, which can stably alter the gene expression pattern in cells) of *Arabidopsis thaliana* to drought and increased nutrient conditions.

The four researchers found "significant heritable variation among epiRILs both in the means of several ecologically important plant traits and in their plasticities to drought and nutrients." They state the significant selection gradients of the several mean traits and plasticities they discovered "suggest that selection could act on this epigenetically based phenotypic variation." They conclude their study "provides evidence that variation in DNA methylation can cause substantial heritable variation of eco-logically important plant traits, including root allocation, drought tolerance and nutrient plasticity, and that rapid evolution based on epigenetic variation alone should thus be possible."

These findings bode well for the future of terrestrial plants, even if a significant degree of global warming resumes after its ongoing decade-and-a-half hiatus.

Terrestrial Animals

Key Findings

The following bullet points summarize the main findings of this chapter:

- The Intergovernmental Panel on Climate Change's (IPCC's) view of future species extinction relies on a narrow view of the literature that is highly selective and based almost entirely on model projections as opposed to real-world observations. The latter often contradict the former.

- Numerous shortcomings are inherent in the models used to predict the impact of climate on the health and distributions of animal species. Assumptions and limitations make those models unreliable in projecting the future in this regard.

- As in past species extinctions, future species losses are unlikely to be directly attributable to climate changes that act over long terms and to which species are well adapted. Species losses in the future are more likely to be attributable to the novel, relatively rapid twentieth and twenty-first century anthropogenic processes of habitat loss and the transportation-mediated dispersal of pathogens and predators (including man) into previously isolated populations.

- The planet's animal species have inherent abilities enabling them to cope with climate changes over a period of a few generations, a single generation, or even in real time.

- Research suggests amphibian populations will

suffer little, if any, harm from projected CO_2-induced global warming, and they may even benefit from it.

- Enhanced plant productivity driven by elevated levels of atmospheric CO_2 tends to support greater abundance of soil microarthropods.

- Although some changes in bird populations and their habitat areas have been documented in the literature, linking such changes to CO_2-induced global warming remains elusive. Also, when there have been changes, they often are positive, as many species have adapted and are thriving in response to rising temperatures of the modern era.

- Published research indicates rising temperatures will not likely increase, and may decrease, plant damage from leaf-eating herbivores, as rising atmospheric CO_2 boosts the production of certain defensive compounds in plants that are detrimental to animal pests.

- Global warming is creating opportunities for butterflies to expand their populations and ranges, just the opposite of alarmist projections of range contractions and butterfly species demise in response to a CO_2-induced warming of Earth.

- The warming-induced extinctions of mammals that have been predicted to occur are highly unlikely to be realized in nature, and warming in fact opens new territories for mammal range expansions. In addition, rising atmospheric CO_2 concentrations may produce changes in the palatability of the trunk and branch tissues of certain trees that may protect them from being killed by hares and rabbits.

- The likely net effect of climate change on the spread of parasitic and vector-borne diseases is complex and at this time difficult to predict. Rising temperatures increase the mortality rates as well as the development rates of many parasites, and temperature is only one of many variables that influence the range of viruses and other sources of diseases.

- Polar bears have survived historic changes in climate that have exceeded those of the twentieth century or are forecast by computer models to occur in the future. In addition, some populations of polar bears appear to be stable despite rising temperatures and summer sea ice declines. The biggest threat they face is not from global warming, but commercial hunting by humans, which historically has taken a huge toll on polar bear populations.

- Studies of the effects of rising temperatures on reptiles find they often are able to tolerate a greater range of environmental conditions than they have been exposed to in the recent past, demonstrate abilities to thermo-regulate to achieve body temperatures close to their preferred temperatures, and often benefit from warmer temperatures.

- It appears earthworms and soil nematodes respond to increases in the air's CO_2 content, via a number of plant-mediated phenomena, in ways that further enhance the positive effects of atmospheric CO_2 enrichment on plant growth and development, while helping to sequester more carbon more securely in the soil and thereby reducing the potential for CO_2-induced global warming.

Introduction

The draft Summary for Policymakers from the Intergovernmental Panel on Climate Change's (IPCC) Working Group II contribution to the *Fifth Assessment Report* makes the following claims about the impact of climate change on species:

> In response to ongoing climate change, terrestrial and marine species have shifted their ranges, seasonal activities, migration patterns, and abundance, have demonstrated altered species interaction (*high confidence*). Increased tree mortality, observed in many places worldwide, has been attributed to climate change in some regions. While recent warming contributed to the extinction of many species of Central American amphibians (*medium confidence*), most recent observed terrestrial-species extinctions have not been attributed to recent climate change, despite some speculative efforts (*high confidence*). Natural climate change at rates much slower than current anthropogenic change has led to significant ecosystem shifts, including species emergences and extinctions, in the past million years (IPCC-II, 2014, p. 3).

While this language is somewhat more nuanced than

past IPCC reports, the necessary qualifications and uncertainties are missing from this language appearing later in the same draft report:

> A large fraction of terrestrial and freshwater species faces increased extinction risk under projected climate change during and beyond the 21st century, especially as climate change interacts with other pressures, such as habitat modification, over-exploitation, pollution, and invasive species (*high confidence*). Extinction risk is increased under all RCP scenarios, with risk increasing with both magnitude and rate of climate change. Many species will be unable to move fast enough during the 21st century to track suitable climates under mid- and high-ranges rates of climate change (i.e., RCP4.5, 6.0, and 8.5) (*medium confidence*). See Figure SPM.5. Management actions can reduce, but not eliminate, risks to ecosystems and can increase ecosystem adaptability, for example through reduction of other stresses and habitat (Ibid., pp. 8–9).

These conclusions are overly alarmist and unsupported by scientific research. The primary error made by IPCC's authors is to ignore the growing anomaly between climate model simulations and real-world observations of global temperature. The world in fact is not warming as fast as IPCC predicts, the twentieth century warming was not as "unprecedented" as IPCC previously thought, transient climate response is likely to be less than once thought, the risk of damaging increases in drought or tropical cyclones is lower, and so on (Idso *et al.,* 2013a; Idso *et al.,* 2013b). All of these concessions and walk-backs have implications for the impacts of climate change on terrestrial animals, all of them seemingly positive, yet Working Group II's Summary for Policymakers makes no concessions. A large body of research thus must be treated with considerable caution because of the resulting exaggeration of species range shifts and erroneous climate projections at regional scales.

Even assuming IPCC climate models were unbiased and reasonably accurate at regional scales, the material presented in this chapter reveals IPCC's view of future species extinction relies on a narrow view of the literature that is highly selective. It is based almost entirely on "climate envelope" model projections that often contradict real-world observations. It is clear the SAR-based (species-area-relationship) extinction estimates pioneered by Thomas *et al.* (2005) exaggerate future extinction rates due to the inherent bias of structural errors (He and Hubbell, 2012) and by systematically disregard-

ing any species that benefit from climate change (Stockwell, 2004). IPCC also improperly characterizes the adaptive responses (e.g., range shifts, phenotypic or genetic adaptations) of many species as supporting its model-based extinction claims. In reality such adaptive responses provide documentary evidence of species *resilience*, proving their ability to cope with present and future climate changes as they have so often done throughout the historic and geologic past.

The findings cited in this chapter make it clear that when confronted with climate change or other challenges, terrestrial animals ranging from amphibians and arthropods to insects, polar bears, and worms exhibit opportunistic and highly adaptive behaviors. Ranges do not suddenly shrink as wildlife passively endures changes to its habitat, as is often projected in model-based studies. Instead, the species fortify themselves against the possibility of extinction, behaving as resilient evolutionary survivors and colonizing new habitat as it becomes available, strengthening their populations against the myriad challenges associated with environmental change.

This chapter begins with a review and analysis of the IPCC-based species extinction claim, highlighting many of the problems inherent in the models on which such claims are based and examples from the paleoecological record where species responded to and survived climate changes similar to or greater than those forecast by IPCC. Model projections are then evaluated against real-world observations of how various animal species responded to what IPCC has called the unprecedented rise in atmospheric CO_2 and temperature of the twentieth and twenty-first centuries. Although there likely will be some changes in species population dynamics in the decades and centuries ahead, few if any species are likely to be driven even close to extinction by global warming. In several instances, real-world data indicate warmer temperatures and higher atmospheric CO_2 concentrations will be highly beneficial, favoring a proliferation of species. IPCC continues to ignore in its reports such positive externalities of rising temperature and atmospheric CO_2.

5.1 The Extinction Hypothesis

- IPCC's view of future species extinction relies on a narrow view of the literature that is highly selective and based almost entirely on model projections as opposed to real-world observations. The latter often contradict the former.

5.1.1 Model Shortcomings

The species extinction hypothesis began to appear in the discussion of potential impacts of CO_2-induced global warming in the late twentieth and early twenty-first centuries. Thomas *et al*. (2004), for example, developed projections of future habitat distributions for more than a thousand plant and animal species. Using those projections, they produced estimates of extinction probabilities associated with climate change scenarios for the year 2050 promoted by IPCC (IPCC, 2007). Their ominous projections (the extinction of more than a million species if anthropogenic CO_2 emissions were not quickly and dramatically reduced) were widely disseminated to the popular media even before the research was published. The projections were typically portrayed as well-founded scientific predictions of what was bound to occur.

The 19 authors first determined the "climate envelopes" of 1,103 species, each envelope representing the current climatic conditions under which a given species was found in nature. Then, after selecting those species where the habitat area would be expected to decrease in response to an increase in temperature, they used an empirical power-law relationship that relates species number to habitat area size to determine extinction probability calculations.

At first blush, their procedure seems reasonable enough, all else being equal. But all else is rarely equal when something changes in the real world. Stockwell (2004) provided an entirely different analysis of the available data, noting most climate change effects research accentuates the "losers" while deprecating the "winners." Stockwell notes Thomas *et al*.'s approach to the issue "ignores species that are currently threatened with extinction by non-climatic factors, and which could therefore benefit from an expanded potential habitat and so escape extinction in the new CO_2/climate regime." As Stockwell describes it, "a CO_2- or climate-driven range expansion would clearly help species that are threatened with extinction due to increasing habitat loss attributable to expanding urbanization and agricultural activities; while it may help other species that are threatened with extinction by habitat fragmentation to cross geographical barriers that were previously insurmountable obstacles to them." Consequently, he continues, "by neglecting the many species that fall into these and other like categories, no decrease in extinctions is possible under Thomas *et al*.'s approach to the problem, even under [a] free dispersal scenario, with the result that a massive increase in extinctions is a foregone conclusion."

Stockwell further notes, "the no dispersal scenario also forces an unrealistic decrease in range with any climatic change that shifts habitat area without reducing it; while 'overfitting' reduces ranges even more, producing systematic errors on the order of 10–20%, particularly with smaller data sets, deficiencies in data sampling and modeling methods, and the inclusion of irrelevant variables (Stockwell and Peterson 2002a; 2002b; 2003)."

With respect to Bakkenes *et al*. (2002), one of the studies relied on by Thomas *et al.,* for example, Stockwell writes, "two independent climate variables adequately explain 93% of the variation in their dependent variable; while the use of more climate variables ends up incorporating more random variation than it does actual signal, leading to a contraction of the climate envelope and a systematic bias towards smaller predicted ranges." It should come as no surprise, therefore, as Stockwell continues, "that in this study and that of Peterson *et al*. (2002)—which comprise two of the six major studies on which the analysis of Thomas *et al*. is based—the use of only two climate variables by the two studies yields extinction percentages of 7% and 9%, while the four additional studies upon which Thomas *et al*. rely (which use from 3 to 36 independent variables) yield extinction percentages

ranging from 20% to 34%, consistent with what would be expected from errors associated with statistical over-fitting."

Because these ecological models are so unreliable, the common-sense response should be to attempt to verify model-based projections with independent data. However, Stockwell notes, "their single attempt to do so with a real-world extinction supposedly caused by global warming (Pounds *et al*., 1999) has been satisfactorily explained by changes in local weather patterns due to upwind deforestation of adjacent lowlands (Lawton *et al*., 2001)." Stockwell concludes, "Thomas *et al*. have a dearth of pertinent hard data to support their contentions; and while the absence of evidence does not necessarily disprove a claim, the lack of any real extinction data to support the results of their analysis certainly suggests that the models they are using are not 'tried and true'."

Stockwell concludes, "Thomas *et al*. (2004) seek to create the impression of impending ecological disaster due to CO_2-induced global warming, claiming their results justify mandating reductions of greenhouse gas emissions," but their findings "are forced by the calculations, confounded with statistical bias, lack supporting real-world evidence, and are perforated with speculation." Stockwell concludes "their doctrine of 'massive extinction' is actually a case of 'massive extinction *bias*'."

It may be argued Thomas *et al*. provide a service to conservation by raising awareness of the potential for species extinction due to climate change, but promoting biased methods that are poorly developed and unsupported by evidence is not scientifically responsible. The discrepancy between the forecasts of future impacts that include large-scale range reduction has yet to be reconciled with the relatively few extinctions from quite large and rapid climate changes in the past (Moritz and Agudo, 2013).

Botkin *et al*. (2007) are highly critical of the application of such methods, particularly when the results are at variance with the evidence provided by the fossil record. And in another critique of the Thomas *et al*. paper, Dormann (2007) found it important to "review the main shortcomings of species distribution models and species distribution projections" such as those employed and derived by Thomas *et al*. He carefully analyzed three aspects of what he described as "problems associated with species distribution models."

The first of these aspects is general species distribution model issues, under which Dormann listed four major problems. The second is extrapolation issues, where he found five major problems; and the third is statistical issues, where he listed six major problems. The methods employed and findings claimed by studies such as Thomas *et al*., Dormann writes, "have been challenged for conceptual and statistical reasons" by many other researchers, including Buckley and Roughgarden (2004), Harte *et al*. (2004), Thuiller *et al*. (2004), Lewis (2006), and Botkin *et al*. (2007). Dormann thus concludes, "projections of species distributions are not merely generating hypotheses to be tested by later data" but instead are being presented as "predictions of tomorrow's diversity, and policy makers and the public will interpret them as forecasts, similar to forecasts about tomorrow's weather," which he clearly believes is unwarranted and unwise.

Detailed intercomparative studies have borne out these concerns about the quality of species' distribution models. Forecasts of the future geographic distribution of six species of Falco from northern Europe ranged from a contraction in 80% of the species to no net loss in any species, seriously hampering their efficacy in conservation practices (Rodriguez-Castaneda *et al*. 2012).

The most effective criticism has been of the method used to estimate extinction rates by reversing the species-area accumulation curve, a species-area relationship (SAR) used to estimate extinction rates before they are actually observed, the so-called "extinction debt" owing to reduction in habitat and population size during a climate change. Researchers He and Hubbell (2011) show Thomas *et al*. (2005) overestimate the extinction debt from habitat loss largely due to a sampling artifact.

Pereira *et al*. (2012) responded by claiming He and Hubbell's SAR estimates are themselves biased. Thomas and Williamson (2012) report extinction is caused by many factors, not just habitat loss, and species already have responded to climate change in a manner consistent with high future extinction risks. In reply, He and Hubbell (2012) show the Pereira *et al*. (2012) claims are not substantiated and the SAR method of Thomas *et al*. (2005) is not appropriate for estimating extinction rates caused by habitat loss of any kind, concluding, "this so-called backward SAR method is a method for estimating endemic species, not 'extinction debt.' The backward SAR method has nothing to do with, and does not measure, extinction debt." Subsequent debate has clarified the proofs and results are general and explain the widely recognized overestimation of extinction by the backward SAR method, which should not be used to estimate species extinction in practice (He and Hubbell, 2013).

Despite the multitude of problems associated with

the Thomas *et al*. paper, the extinction hypothesis was revived by Parmesan (2006). In reviewing 866 papers addressing the subject of ecological and evolutionary responses to the global warming of the prior few decades, Parmesan raised new concerns about the ability of Earth's many species of plants and animals to maintain a viable foothold on the planet if temperatures continue to rise. But much of the evidence cited by Parmesan actually weighs *against* this concern.

Parmesan notes "most observations of climate-change responses have involved alterations of species' phenologies." She reports, for example, many species had exhibited "advancement of spring events," such that there was "a lengthening of vegetative growing season in the Northern Hemisphere," which is something most would consider a positive phenomenon. She also reports "summer photosynthetic activity increased from 1981–1991"—another positive response—and the growing season throughout the United States "was unusually long during the warm period of the 1940s," but "since 1996, growing season length has increased only in four of the coldest, most-northerly zones (42°–45° N latitude), not in the three warmest zones (32°–37° N latitude)."

The negativity Parmesan associates with these mostly positive warming-induced phenological changes arises from the possibility there may be "mismatches" across different trophic levels in natural ecosystems, such as between the time each year's new crop of herbivores appears and the time of appearance of the plants they depend on for food. Eleven plant-animal associations were studied intensively in this regard, and in seven of them, Parmesan states, "they are more out of synchrony now than at the start of the studies."

Of course there always will be winners and losers (some big and some small) in such animal-plant matchups during periods of climate change, and probably many "draws." In addition, the paucity of pertinent data at the time of the Parmesan study precluded a valid determination of which of the three alternatives is the most likely to predominate. As one example of a "big loser" in the face of recent global warming, Parmesan reports, "field studies have documented that butterfly-host asynchrony has resulted directly in population crashes and extinctions." But population extinctions are not species extinctions, and she acknowledges the local extinctions to which she referred merely resulted in "shifting [the] mean location of extant populations northward [in the Northern Hemisphere] and

upward." Newer research conducted since the publication of Parmesan's study suggests there could be many more wins and draws than losses as species cope with and adapt to such trophic mismatches.

A second major biological response to global warming addressed by Parmesan is species migration, often said to lead to range restrictions that make it difficult for species to maintain the minimum viable population size required for their continued existence. For example, it is often claimed global warming will be so fast and furious that many species will not be able to migrate poleward in latitude or upward in altitude rapidly enough to avoid extinction, or if located on mountaintops they will run out of suitable new habitat to which they can flee when faced with rising temperatures. On this subject, Parmesan essentially rehashed the earlier findings of the meta-analyses of Root *et al*. (2003) and Parmesan and Yohe (2003), which predominantly portrayed species ranges as expanding in the face of rising temperatures, since warming provides an opportunity for species to expand their ranges at their cold-limited boundaries while often providing a much reduced impetus for them to retreat at the heat-limited boundaries of their ranges. An example of this phenomenon cited by Parmesan occurred in the Netherlands between 1979 and 2001, where she reports "77 new epiphytic lichens colonized from the south, nearly doubling the total number of species for that community."

Parmesan also reports "increasing numbers of researchers use analyses of current intraspecific genetic variation for climate tolerance to argue for a substantive role of evolution in mitigating negative impacts of future climate change," additionally noting the fossil record contains "a plethora of data indicating local adaptation to climate change at specific sites." In addition, she states, there is evidence many existing species during earlier periods of dramatic climate change "appeared to shift their geographical distributions as though tracking the changing climate." In both of these situations the outcomes were clearly positive.

The greatest push by Parmesan for a decisively negative consequence of global warming is her claim that "documented rapid loss of habitable climate space makes it no surprise that the first extinctions of entire species attributed to global warming are mountain-restricted species," "many cloud-forest-dependent amphibians have declined or gone extinct on a mountain in Costa Rica (Pounds *et al*., 1999, 2005)," and "among harlequin frogs in Central and South American tropics, an astounding 67% have

disappeared over the past 20–30 years," citing Pounds *et al*. (2006) regarding the latter. Such claims subsequently were shown by several researchers to be incorrect (see Amphibians, Section 5.2), as all the extinctions and disappearances of the amphibian species to which Parmesan referred had nothing at all to do with "rapid loss of habitable climate space" at the tops of mountains. As Pounds *et al*. (2006) note, the loss of these species "is largest at middle elevations, even though higher-elevation species generally have smaller ranges." In addition, as noted in an earlier review of the subject by Stuart *et al*. (2004), many of the amphibian species declines "took place in seemingly pristine habitats," which had not been lost to global warming nor even modestly altered. The extinctions and species disappearances appeared not to have been due to rising temperatures *per se*, but to the fungal disease chytridiomycosis, which is caused by *Batrachochytrium dendrobatidis*, as noted by both Stuart *et al*. (2004) and Pounds *et al*. (2006).

The fallacy of the montane range restriction assumption was shown by Tingley *et al.* (2012) in a study of breeding ranges of birds across three elevational transects in the Sierra Nevada Mountains (USA). While rising temperature over the past century pushed species upslope, they found increased precipitation pulled them downslope, resulting in range shifts that were heterogeneous within species and among regions. Thus despite increasing temperature in montane environments, the highly variable precipitation regimes create highly heterogeneous responses by species at range margins.

Other studies have poked further holes in the model-based animal extinction hypothesis, some for similar reasons, others for new ones.

Noting "climate envelopes (or the climatic niche concept) are the current methods of choice for prediction of species distributions under climate change," Beale *et al*. (2008) state, "climate envelope methods and assumptions have been criticized as ecologically and statistically naive (Pearson and Dawson, 2003; Hampe, 2004)," and "there are many reasons why species distributions may not match climate, including biotic interactions (Davis *et al*., 1998), adaptive evolution (Thomas *et al*., 2001), dispersal limitation (Svenning and Skov, 2007), and historical chance (Cotgreave and Harvey, 1994)."

Beale *et al*. evaluated the degree of matchup of species distributions to environment by generating synthetic distributions that retained the spatial structure of observed distributions but were randomly placed with respect to climate. They report, "using data on the European distribution of 100 bird species, we generated 99 synthetic distribution patterns for each species," and "for each of the 100 species, we fitted climate envelope models to both the true distribution and the 99 simulated distributions by using standard climate variables." They determined the goodness-of-fit of the many distribution patterns, because, as they note, "there has been no attempt to quantify how often high goodness-of-fit scores, and hence ostensibly good matches between distribution and climate, can occur by chance alone."

The three U.K. researchers determined "species-climate associations found by climate envelope methods are no better than chance for 68 of 100 European bird species." And, they write, "because birds are perceived to be equally strongly associated with climate as other species groups and trophic levels (Huntley *et al*., 2004)," their results "cast doubt on the predictions of climate envelope models for all taxa." They further state, "many, if not most, published climate envelopes may be no better than expected from chance associations alone, questioning the implications of many published studies." The researchers conclude, "scientific studies and climate change adaptation policies based on the indiscriminate use of climate envelope methods irrespective of species sensitivity to climate may be misleading and in need of revision."

These results are not so surprising in view of the well-known ecological principle that critical life-history events and interspecies relationships often can be the major factor limiting the spread of a species. Correspondingly, seasonal climate and ecosystem productivity variables have been found to be more statistically significant determinants of range than the broader annual climate variables typically used in ecological niche models (Stockwell, 2006).

Nogues-Bravo (2009) states climate envelope models "are sensitive to theoretical assumptions, to model classes and to projections in non-analogous climates, among other issues." He reviewed the pertinent scientific literature to determine how appropriate existing models were for determining whether a species will be driven to extinction by hypothesized planetary warming. He explains, "the studies reviewed: (1) rarely test the theoretical assumptions behind niche modeling such as the stability of species climatic niches through time and the equilibrium of species with climate; (2) they only use one model class (72% of the studies) and one paleoclimatic reconstruction (62.5%) to calibrate their models; (3) they do not check for the occurrence of non-analogous climates (97%); and (4) they do not

use independent data to validate the models (72%)."

Nogues-Bravo notes, "ignoring the theoretical assumptions behind niche modeling and using inadequate methods for hindcasting" may produce "a cascade of errors and naïve ecological and evolutionary inferences." He concludes, "there are a wide variety of challenges that [climate envelope models] must overcome in order to improve the reliability of their predictions through time."

Randin *et al*. (2009) focused their attention on the quality of species distribution models (SDMs). They note, "the mean temperature interpolated from local stations at a 20-meter resolution contains more variability than expressed by the mean temperature within a 50-km x 50-km grid cell in which variation in elevation is poorly represented." Or, as they describe elsewhere in their paper, "climatic differences along elevation gradients, as apparent at 25-m x 25-m resolution, allow plant species to find suitable climatic conditions at higher elevation under climate change," whereas "models at a 10' x 10' resolution [10 minutes of latitude x 10 minutes of longitude, which correspond to 16-km x 16-km cells in the Swiss Alps, where they carried out their analyses] reflect the mean climatic conditions within the cell, and thus provide imprecise values of the probability of occurrence of species along a thermal gradient."

In testing this "local high-elevation habitat persistence hypothesis," Randin *et al*. assessed "whether climate change-induced habitat losses predicted at the European scale (10 x 10' grid cells) are also predicted from local-scale data and modeling (25-m x 25-m grid cells)." For 78 mountain species modeled at both European and local scales, they found the "local-scale models predict persistence of suitable habitats in up to 100% of species that were predicted by a European-scale model to lose all their suitable habitats in the area."

Randin *et al*. suggest the vastly different results they obtained when using fine and coarse grid scales might help explain what they call the Quaternary Conundrum: "why fewer species than expected went extinct during glacial periods when models predict so many extinctions with similar amplitude of climate change (Botkin *et al*., 2007)." In addition, they note, "coarse-resolution predictions based on SDMs are commonly used in the preparation of reports by the Intergovernmental Panel on Climate Change," which are then used by "conservation planners, managers, and other decision makers to anticipate biodiversity losses in alpine and other systems across local, regional, and larger scales."

Willis and Bhagwat (2009) discuss other problems that arise from coarse model scales. In a "perspective" published in *Science* the two raised a warning flag, stating, "coarse spatial scales fail to capture topography or 'microclimatic buffering' and they often do not consider the full acclimation capacity of plants and animals," citing Botkin *et al*. (2007).

As an example of this model-based deficiency, Willis and Bhagwat cite Randin *et al*. (2009), noting for alpine plant species growing in the Swiss Alps, "a coarse European-scale model (with 16 km by 16 km grid cells) predicted a loss of all suitable habitats during the 21st century, whereas a model run using local-scale data (25 m by 25 m grid cells) predicted persistence of suitable habitats for up to 100% of plant species." The two Europeans note Luoto and Heikkinen (2008) "reached a similar conclusion in their study of the predictive accuracy of bioclimatic envelope models on the future distribution of 100 European butterfly species," finding "a model that included climate and topographical heterogeneity (such as elevational range) predicted only half of the species losses in mountainous areas for the period from 2051 to 2080 in comparison to a climate-only model."

Another problem was the models' failure to consider the capacity of plants and animals to acclimatize to warmer temperatures. Willis and Bhagwat note "many studies have indicated that increased atmospheric CO_2 affects photosynthesis rates and enhances net primary productivity—more so in tropical than in temperate regions—yet previous climate-vegetation simulations did not take this into account." They cite Lapola *et al*. (2009), who developed a new vegetation model for tropical South America, the results of which indicate "when the CO_2 fertilization effects are considered, they overwhelm the impacts arising from temperature," so "rather than the large-scale die-back predicted previously, tropical rainforest biomes remain the same or [are] substituted by wetter and more productive biomes."

"Another complexity," note Willis and Bhagwat, is the fact that "over 75% of the Earth's terrestrial biomes now show evidence of alteration as a result of human residence and land use," which has resulted in "a highly fragmented landscape" that has been hypothesized to make it especially difficult for the preservation of species. Nevertheless, they report Prugh *et al*. (2008) have "compiled and analyzed raw data from previous research on the occurrence of 785 animal species in >12,000 discrete habitat fragments on six continents," and "in many cases, fragment size

and isolation were poor predictors of occupancy." They further note "this ability of species to persist in what would appear to be a highly undesirable and fragmented landscape has also been recently demonstrated in West Africa," where "in a census on the presence of 972 forest butterflies over the past 16 years, Larsen [2008] found that despite an 87% reduction in forest cover, 97% of all species ever recorded in the area are still present."

Suggitt *et al.* (2011) note "most multi-cellular terrestrial organisms experience climate at scales of millimeters to meters," yet "most species-climate associations are analyzed at resolutions of kilometers or more," in what is "commonly known as the 'bio-climate approach' or 'climate envelope' modeling." They write, "because individuals experience hetero-geneous microclimates in the landscape, species sometimes survive where the average background climate appears unsuitable," which the vast majority of bioclimate studies do not consider in their analyses.

Suggitt *et al.* recorded temperatures in numerous microsites at two locations where the vegetation was relatively homogenous (the Lake Vyrnwy Royal Society for the Protection of Birds reserve in Wales, and High Peak in the Peak District National Park in England) in September 2007 and January 2008, and in numerous microsites within three habitat types (woodland, heathland, and grassland) in Skipwith Common in North Yorkshire, UK, in September 2008 and January 2009. The seven scientists report, "thermal differences between habitats, and slope and aspects, were of the same order of magnitude as projected increases in global average surface temperatures," and in some cases, microclimate temperature variations exceeded estimates of warm-ing under all of IPCC's emissions scenarios, "which range from 1.1 to a 6.4°C rise in global mean temperatures (IPCC, 2007)."

Suggitt *et al.* add, "these large temperature differences provide opportunities for individual organisms that are able to move short distances to escape unfavorable microclimates," and, hence, "populations may shift microhabitats (slopes, aspects and vegetation density) in response to inter-annual variation in the climate." They state their results indicate "the incorporation of habitat and topo-graphical information is essential for species that (a) have some level of flexibility in their habitat associations, and (b) are at least partially limited by temperature extremes." In the real world of nature, the "bioclimate approach" and "climate envelope" modeling are not adequate for describing how species will respond to future changes in climate.

Sears *et al.* (2011) analyzed how spatial heterogeneity can impact biological responses to thermal landscapes at scales more relevant to organ-isms than the (much larger) scales typically employed by standard climate envelopes. They examined the effects of topographic relief on the range of operative temperatures available for behavioral thermo-regulation of animals within various parts of an area described by a given climate envelope. Their results indicated "empirical studies alone suggest that the operative temperatures of many organisms vary by as much as 10–20°C on a local scale, depending on vegetation, geology, and topography," and even this variation in abiotic factors "ignores thermoregulatory behaviors that many animals use to balance heat loads." Through a set of simulations of these phenomena, they "demonstrate how variability in elevational topography can attenuate the effects of warming climates." They found "identical climates can produce very different microclimates at the spatial scales experienced by organisms"; "greater topographic relief should decrease selective pressure on thermal physiology for organisms that use behavior to avoid thermal extremes in heterogeneous environments," citing Huey *et al.* (2003); and "topographic diversity should buffer the impacts of climate change by facilitating behavioral thermo-regulation."

Sears *et al.* say well-known relationships in biophysical ecology show "no two organisms experience the same climate in the same way," and "changing climates do not always impact organisms negatively." They conclude, "when coupled with thermoregulatory behavior, variation in topographic features can mask the acute effect of climate change in many cases," rendering the climate envelope approach to assessing species responses to climate change rather useless if not downright deceptive.

Dobrowski (2011) writes, "the response of biota to climate change of the past is pertinent to understanding present day biotic response to anthropogenic warming," and "one such adaptive response garnering increased attention is the purported utilization of climatic refugia by biota." Historically, these refugia were "typically thought of as large regions in which organisms took refuge during glacial advances and retreats during the Pleistocene, which then acted as sources for colonization during more favorable climatic periods." But "in addition to these large-scale refugia," he writes, "there is compelling evidence that climatic refugia occurred at local scales during the Last Glacial Maximum and were also utilized during

interglacial warm periods, including the current interglacial (Willis and Van Andel, 2004; Birks and Willis, 2008)."

Dobrowski notes, "modeling using global climate models (GCMs) and regional climate models (RCMs) is done at scales of tens to hundreds of kilometers, whereas research suggests that temperature varies at scales of < 1 km in areas of complex terrain (Urban *et al*., 2000; Fridley, 2009)." He reports, "Hijmans *et al*. (2005) showed that there can be temperature variation of up to 33°C within one 18-km raster cell." In addition, "GCMs and RCMs can simulate free-air conditions but fail to accurately estimate surface climate due to terrain features that decouple upper atmospheric conditions from boundary layer effects (Grotch and Maccracken, 1991; Pepin and Seidel, 2005)."

Dobrowski points out many researchers "have recently commented on the potential of topographically driven meso- or micro-climatic variation in mountain environments for providing refugia habitats for populations of species threatened by climate warming," citing Luoto and Heikkinen (2008), Randin *et al*. (2009), and Seo *et al*. (2009). And he notes these researchers "point to lower rates of predicted habitat loss and lower predicted extinction probabilities from species distribution models when using finely resolved climate data as compared with coarse scaled data," stating, "they suggest that this is evidence of 'local scale refugia' (Randin *et al*., 2009) or 'reserves to shelter species' (Seo *et al*., 2009)."

Dobrowski concludes, "microrefugia are likely to be found in terrain positions that promote the consistent decoupling of the boundary layer from the free-atmosphere," and "these terrain positions are likely to have climate states and trends that are decoupled from regional averages," which is "a requisite for microrefugia to persist through time." Thus, he concludes, "convergent environments (local depressions, valley bottoms, sinks, and basins) are primary candidates for microrefugia based on these criteria," which bodes well for the once-considered-impossible survival of many species of plants and animals in a possible further warming of the planet.

Lande (2009) writes, "the primary mechanisms of phenotypic adaptation are Darwinian evolution by natural selection on genetic variation, and phenotypic plasticity through environmental influence on individual development," further stating, "rapid phenotypic adaptation may be necessary to prevent [the] extinction of modern species subject to anthropogenic global warming, especially those

[species] with long generations such as large-bodied vertebrates and perennial plants." Against this backdrop and while noting "genetic variance in plasticity within and/or among populations has commonly been observed (Scheiner, 1993, 2002)," Lande employed "quantitative genetic models of phenotypic plasticity to analyze the dynamics of phenotypic adaptation to a sudden extreme environmental change" that is "beyond the usual range of background environmental fluctuations."

Lande's model suggests, "during the first generation in the new environment the mean fitness suddenly drops and the mean phenotype jumps towards the new optimum phenotype by plasticity," after which "adaptation occurs in two phases." First, "rapid evolution of increased plasticity allows the mean phenotype to closely approach the new optimum," after which the new phenotype "undergoes slow genetic assimilation, with reduction in plasticity compensated by genetic evolution of reaction norm elevation in the original environment." Such findings suggest there is a sound observational and mechanistic basis for concluding Earth's flora and fauna are genetically capable of coping with the type of rapid CO_2-induced global warming IPCC contends will drive innumerable plant and animal species to extinction.

5.1.2 Paleoecological Records

- As in past species extinctions, future species losses are unlikely to be directly attributable to climate changes that act over long terms and to which species are well adapted. Species losses in the future are more likely to be attributable to the novel, relatively rapid twentieth and twenty-first century anthropogenic processes of habitat loss and the transportation-mediated dispersal of pathogens and predators (including man) into previously isolated populations.

Most of the world's major species "body types" were laid down during the Cambrian period 600 million years ago (Levinton, 1992). These species have dealt successfully through the ages with new pest enemies, new diseases, ice ages, and global temperature swings greater than that predicted to result from CO_2-induced global warming.

During the Paleocene-Eocene Thermal Maximum (PETM), some 56 million years ago, it is believed, large amounts of carbon were released to the ocean-atmosphere system and global temperatures

may have risen by 5–8°C, although more recent climate modelling indicates changes in cloud properties and an increase in shortwave radiation played a much greater role in the warm PETM period than previously believed (Kiehl and Shields, 2013).

McInerney and Wing (2011) reviewed much of the scientific literature on the insights being sought by biologists concerned about potential species extinctions due to CO_2-induced global warming, and they give their assessment of the current status of the grand enterprise in which many scientists have been involved since the early 1990s, when the PETM and its significance first began to be recognized (Kennett and Stott, 1991; Koch et al., 1992).

Although there was a major extinction of benthic foraminifera in the world's oceans, the two researchers write, "most groups of organisms did not suffer mass extinction." In fact, they say, "it is surprising that cool-adapted species already living at higher latitudes before the onset of the PETM are not known to have experienced major extinctions," and "this absence of significant extinction in most groups is particularly interesting in light of the predictions of substantial future extinction with anthropogenic global warming." In addition, "low levels of extinction in the face of rapid environmental change during the Quaternary pose a similar challenge to modeled extinctions under future greenhouse warming," citing Botkin et al. (2007). Finally, they observe, "rapid morphological change occurred in both marine and terrestrial lineages, suggesting that organisms adjusted to climate change through evolution as well as dispersal."

McInerney and Wing conclude by noting "research on the PETM and other intervals of rapid global change has been driven by the idea that they provide geological parallels to future anthropogenic warming." The many research results they review seem to suggest Earth's plants and animals, both on land and in the sea, may be much better equipped to deal with the environmental changes that may occur in response to anthropogenic CO_2 emissions than what many students of the subject have long believed.

Hof et al. (2011) present evidence demonstrating "recent geophysical studies challenge the view that the speed of current and projected climate change is unprecedented." In one such study, for example, they report Steffensen et al. (2008) showed temperatures in Greenland warmed by up to 4°C/year near the end of the last glacial period. They state this change and other rapid climate changes during the Quaternary (the last 2.5 million years) did not cause a noticeable level of broad-scale, continent-wide extinctions of species. Instead, these rapid changes appeared to "primarily affect a few specific groups, mainly large mammals (Koch and Barnosky, 2006) and European trees (Svenning, 2003)," so "few taxa became extinct during the Quaternary (Botkin et al., 2007)."

How were the bulk of Earth's species able to survive a climatic change that many today believe is unsurvivable? Hof et al. suggest "species may have used strategies other than shifting their geographical distributions or changing their genetic make-up." They note, for example, "intraspecific variation in physiological, phenological, behavioral or morphological traits may have allowed species to cope with rapid climatic changes within their ranges (Davis and Shaw, 2001; Nussey et al., 2005; Skelly et al., 2007)," based on "preexisting genetic variation within and among different populations, which is an important prerequisite for adaptive responses," noting "both intraspecific phenotypic variability and individual phenotypic plasticity may allow for rapid adaptation without actual microevolutionary changes." Hof et al. conclude, "species are probably more resilient to climatic changes than anticipated in most model assessments of the effect of contemporary climate change."

Indeed, as shown in the subsections below, model-based projections of animal extinctions in response to rising temperature and atmospheric CO_2 suffer a major loss of credibility when tested against real-world data. Although there likely will be some changes in species population dynamics, few if any species will be driven to extinction. In contrast, a number of studies indicate many animal species will benefit from a warming climate and rising atmospheric CO_2 concentrations, resulting in a proliferation, as opposed to extinction, of species.

Vegas-Vilarrubia et al. (2011) contend "current extinction estimates for the near-future should be revised in light of palaeoecological information, which shows that spatial reorganizations and persistence in suitable microrefugia have been more common than extinction during the Quaternary." As a result, they say, "an interesting consequence is the possibility of new unknown species combinations with no modern analogues."

The two phenomena that come into play in these ecosystem transformations are acclimation and adaptation, "with the first relying on phenotypic plasticity and the second involving genetic changes of potential evolutionary significance." Vegas-Vilarrubia et al. note "some authors propose that spatial reorganizations without extinction will be the dominant biotic response to the near-future global

changes." But "it is also possible that ecosystems never attain equilibrium," they write, and "transient states perpetuate because of the recurrent action of environmental change." They note "one of the main lessons from this is that ecosystems may express their resilience when confronted with environmental shifts by attaining several possible equilibrium states, as manifested in changes in biodiversity and/or composition, without losing their ecological functions."

Vegas-Vilarrubia *et al.* cite the global warming that occurred at the end of the Younger Dryas (~13,000 to 11,500 years ago), which serves as one of the more powerful analogs of projected global warming "because both magnitude and rates of change parallel those predicted for the present century." This prior real-world transformation "seems to have consisted of ecological reorganizations and changes in community composition because of differential species migration patterns and rates," but they note, "so far, it has not been possible to associate large-scale extinctions to the Younger Dryas climatic reversal."

Mergeay and Santamaria (2012) continue that line of thinking in an editorial introducing nine papers in a special issue of *Evolutionary Applications.* The two special-issue editors note Shine (2012) opens the issue by "showing how evolution can rapidly modify ecologically relevant traits in invading as well as native species." Bijlsma and Loeschcke (2012) then "tackle the interaction of drift, inbreeding and environmental stress," and Angeloni *et al.* (2012) "provide a conceptual tool-box for genomic research in conservation biology and highlight some of its possibilities for the mechanistic study of functional variation, adaptation and inbreeding."

Van Dyck (2012) shows "an organism's perception of its environment is subject to selection, a mechanism that could reduce the initial impact of environmental degradation or alleviate it over the longer run." Urban *et al.* (2012) argue "certain consequences of global change can only be accounted for by interactions between ecological and evolutionary processes." And Lemaire *et al.* (2012) highlight "the important role of evolution in predator-prey interactions."

Focusing on eco-evolutionary interactions, Palkovacs *et al.* (2012) "review studies on phenotypic change in response to human activities" and "show that phenotypic change can sometimes cascade across populations, communities and even entire ecosystems." Bonduriansky *et al.* (2012) examine "non-genetic inheritance and its role in adaptation,"

dissecting "the diversity of epigenetic and other transgenerational effects." Finally, Santamaria and Mendez (2012) "build on the information reviewed in all previous papers to identify recent advances in evolutionary knowledge of particular importance to improve or complement current biodiversity policy."

"Overall," Mergeay and Santamaria (2012) conclude, "these nine papers offer compelling evidence for the role of evolutionary processes in the maintenance of biodiversity and the adaptation to global change."

Meylan *et al.* (2012) focused on "the role of hormonally mediated maternal effects in inducing phenotypic plasticity as a response to rising temperatures and extreme climatic events," citing Marquis *et al.* (2008) on lizards. The three researchers describe how the discovery of maternal androgens and glucocorticoids in egg yolks, together with the intra-clutch variation of these hormones (Groothuis and Schwabl, 2008), make it possible for the offspring phenotype to be "manipulated in response to environmental conditions experienced by the female (Weaver *et al.*, 2004)." This maternal effect can be considered a form of "intergenerational phenotypic (developmental) plasticity," which could prove crucial "in coping with unpredictable environments." They suggest "hormones are a critical link between the environment and the genome" because they "may mediate the expression of phenotypic variation, generate trait integration, shape multivariate trade-offs (Sinervo *et al.*, 2008) and either directly or indirectly shape phenotypic plasticity during ontogeny and later into adulthood (Lessells, 2008)."

Meylan *et al.* further state, "the hormonal cascades involved in organizational effects during development may be modulated by environmental stressors and the maternal response as given by the duration and magnitude of elevated glucocorticoids." They discuss "the phenotypic and population dynamic consequences of prenatal exposure to steroid hormones resulting in context-dependent expression of traits by the offspring," ultimately describing "how hormone-mediated maternal effects may enhance rapid adaptation to changing environmental conditions." Finally, the three ecologists write, "females exposed to abiotic stressors during reproduction may alter the phenotypes by manipulation of hormones to the embryos," and they conclude, "hormone-mediated maternal effects, which generate phenotypic plasticity, may be one avenue for coping with global change."

Clearly, Earth's life forms are well-endowed with complex change-management strategies, either

through behavior or otherwise. More recent developments have sought to correct or augment the limitation of static, deterministic paradigms such as niche modeling and species area curves with more dynamic and stochastic paradigms—particularly exploring the consequences of "niche assembly" vs. "dispersal assembly" on extinction risk and biodiversity management (Stockwell, 2013). It is well-known that the composition of many communities is not ruled consistently by species' ecological niches or functional roles, and that they also incorporate stochastic processes (e.g. coastal fish metacommunities, see Mouillot, 2007). Recent work is beginning to redress the incomplete "niche-based" frameworks that have produced unrealistic and counterfactual estimates of extinction loss.

The most potent of the tools has been "unified neutral theory" (UNT, Hubbell, 2001), which provides a simple yet rigorous evaluation of the role of "dispersal assembly" in communities' richness and has provided deeper insights into extinction estimates than "niche assembly" alone might offer. It is clear the SAR-based extinction estimates pioneered by Thomas *et al.* (2005) exaggerate the extinction rates, due to the inherent bias of structural errors (He and Hubbell, 2012) and through disregarding the species that benefit from climate change (Stockwell, 2004). However, it is hypothesized that habitat reductions from any cause will increase the probability of extinction, as rarity usually precedes extinction, even if the effect is not immediately apparent. This is the basis for the notion of "extinction debt." This is a dilemma, for if every environmental change increases extinctions, why haven't all species gone extinct?

A recent application of the UNT simulations of habitat reductions has identified two distinctive species area curves: imminent extinctions from habitat loss and delayed total extinctions indicative of extinction debt. The lag times for relaxation of the community into a lower species richness following habitat loss are often very large, within the order of thousands of years (Halley and Sgardeli, 2014). This suggests much of the "extinction debt" from a specific climate disruption may be redeemed by environmental or physiological changes in the intervening period between when the extinction debt is incurred and when the population has dwindled to unsustainable levels.

Another UNT simulation of two types of colonizing dispersal events—the "volcanic island" and the "land bridge" (Rosindell and Harmon, 2013) shows the stark difference between the colonization of a virgin habitat that slowly builds up diversity, and the drastic reduction of biodiversity from the sudden connection of unrelated communities via a transportation corridor. As in past species extinctions, future species losses are unlikely to be directly attributable to climate changes that act over long terms and to which species are well adapted. Species losses in the future are more likely to be attributable to the novel, relatively rapid twentieth and twenty-first century anthropogenic processes of habitat loss and the transportation-mediated dispersal of pathogens and predators (including man) into previously isolated populations.

It is clear niche-model-based projections of extinctions are riddled with assumptions and limitations that make them an unreliable guide to the impact of climate change on species. The vast majority of the predicted extinctions likely will not occur. A significant body of real-world evidence suggests most of Earth's plants and animals will be able to easily adapt, survive, and even thrive in the face of projected climate change, even under the worst-case scenarios of CO_2-induced global warming predicted by IPCC. As shown hereafter and in Chapter 4 (see Section 4.4 on Extinction), far from being a detriment to the biosphere, the air's rising CO_2 content is enhancing vegetative productivity and fostering a great proliferation of plant and animal species all around the world, helping to protect them from other anthropogenic forces that might otherwise drive them to extinction, independent of whatever the planet's climate may do.

5.1.3 Other Studies

- The planet's animal species have inherent abilities enabling them to cope with climate changes over a period of a few generations, a single generation, or even in real time.

Results of other studies also suggest the model-based species extinction hypothesis is unlikely to occur. In a review paper published in *Current Biology*, for example, Erwin (2009) explored past epochs and the myriad nooks and crannies of Earth today, searching for the primary trigger of speciation. His conclusion? Warmth is the fire that fuels the process by which species originate, whereas cold tends to destroy what warmth produced.

Headquartered in the Department of Paleobiology at the National Museum of Natural History in Washington, DC (USA), Erwin writes, "some of the best evidence for a link between biodiversity and climate comes from latitudinal gradients in diversity, which provide an avenue to explore the more general relationship between climate and evolution." In reviewing that evidence, he notes, "among the wide range of biotic hypotheses, those with the greatest empirical support indicate that warmer climates [1] have provided the energetic foundation for increased biodiversity by fostering greater population size and thus increased extinction resistance, [2] have increased metabolic scope, [3] have allowed more species to exploit specialized niches as a result of greater available energy, and [4] have generated faster speciation and/or lower extinction rates." He states, "in combination with geologic evidence for carbon dioxide levels and changing areas of tropical seas, these observations provide the basis for a simple, first-order model of the relationship between climate through the Phanerozoic and evolutionary patterns and diversity," and "such a model suggests that we should expect greatest marine diversity during globally warm intervals," as is typically also found for terrestrial diversity.

Erwin notes "the three best-studied mass extinction events are associated with sharp changes in climate and support the contention that rapid shifts in climate can reduce global diversity," which sounds much like the mantra of IPCC regarding global warming. However, the climate shifts Erwin cites consist mostly of cooling, and it is not only the shift to cooling but stagnating in a cool state that bodes ill for biodiversity. As Erwin describes it, "the long interval of stagnant evolution during the Permo-Carboniferous glaciation is consistent with studies of

modern-day latitudinal diversity that [indicate] rates of evolutionary innovation and diversification are higher in high-energy climates than in low-energy climates."

Further explaining this conceptual framework, Erwin notes "contemporary studies suggest a positive relationship between high-energy climates and [1] increased diversification rates, [2] increased number of niches because of increased metabolic scope, and [3] more specialized niches, and possibly because of [4] niche construction." He writes, "studies showing that the tropics are a cradle of diversity, pumping clade representatives into higher latitudes, as well as evidence of increased ordinal level originations in the tropics, and of the sudden appearance of several mammalian groups during the Paleocene-Eocene Thermal Maximum suggest an asymmetric pattern of innovations associated with high-energy climate regimes."

Erwin concludes, "there is an intriguing possibility that diversity does not track climate, but rather builds up during warm intervals but without falling by proportional amounts when climates turn cooler," with the result that "warmer climates may serve as an evolutionary diversification pump with higher diversity persisting [throughout following cooler periods], at least for a time."

Two generalizations clearly can be made: warmth typically begets speciation, and cold tends to lead to species extinctions.

Independent support for this thesis was provided in papers by Jaramillo *et al*. (2010) and Willis *et al*. (2010). Jaramillo *et al*. (2010) examined the Paleocene-Eocene Thermal Maximum (PETM), which occurred some 56.3 million years ago, at sites in Venezuela and Columbia. The PETM provides an interesting analog to the Current Warm Period, and it is postulated carbon dioxide rose rapidly in that era over a period of 10,000 to 20,000 years and global temperatures were elevated approximately 5 °C for 100,000 to 200,000 years.

The PETM was clearly identifiable in terms of temperature, where it was between 31 and 34 °C during the peak of global warmth. Using pollen and other organic materials, the authors were able to identify various plant species that existed during this period. In spite of the high temperatures and possibly less-moist conditions, the number of drought-tolerant plants did not increase, nor were moisture-requiring plants shown to decrease during the PETM. These facts lead the authors to speculate either rainfall or water use efficiency increased because of higher levels of atmospheric carbon dioxide, thereby compensating for the higher temperatures.

They also note the PETM brought a radical increase in diversity, measured in both absolute terms (number of species/taxa) and in evenness (relatively more even species percentages). This was achieved by addition of new taxa. The origination rate for new taxa during the PETM was two to six times higher than during the periods before and after, but extinction rates were not unusual. The species/taxa that originated, and the overall diversity, continued after the PETM. Thus the gains in plant species richness during the PETM were relatively persistent rather than transient.

It is believed tropical forests of today are currently growing in climates near the maximum temperature the plants can tolerate (~27.5 °C), and thus future global warming in tropical zones may stress plants and cause a reduction in forest growth, perhaps driving some species to extinction. However, Jaramillo *et al*. show temperatures of 31 to 34 °C seem not only to have been tolerated but to have caused a burst of speciation in the PETM, including major taxa that persist today. The high temperatures of the PETM were not detrimental to the tropical moist forests examined in this study.

Willis *et al*. (2010) identified past historical periods when climate was similar to that projected by global climate models for the next century or so, or in which the rate of temperature change was unusually rapid. These periods were examined for any climate-related extinctions.

The first period they examined was the Eocene Climatic Optimum (53–51 million years ago), when the atmosphere's CO_2 concentration exceeded 1,200 ppm and tropical temperatures were 5–10°C warmer than current values. Far from causing extinctions of the tropical flora (where the data are best), the four researchers report, "all the evidence from low-latitude records indicates that, at least in the plant fossil record, this was one of the most biodiverse intervals of time in the Neotropics." They also note "ancestors of many of our modern tropical and temperate plants evolved ... when global temperatures and CO_2 were much higher than present, ... indicating that they have much wider ecological tolerances than are predicted based on present-day climates alone."

The second period they examined consisted of two rapid-change climatic events in the Holocene—one at 14,700 years ago and one at 11,600 years ago—when temperatures increased in the mid- to high-latitudes of the Northern Hemisphere by up to 10°C over periods of less than 60 years. Many sites

show evidence of rapid plant responses to rapid warming during these events. The authors note, "at no site yet studied, anywhere in the world, is there evidence in the fossil record for large-scale climate-driven extinction during these intervals of rapid warming." They report extinctions did occur due to the cold temperatures of the glacial epoch, when subtropical species in southern Europe were driven out of their ecological tolerance zone.

Willis *et al.* also make use of recent historical data, such as the 3°C rise in temperature at Yosemite Park over the past 100 years. Comparing surveys of mammal fauna conducted near the beginning and end of this period, they detected some changes but no local extinctions. Thus they determined for all the periods they studied, there were no detectable extinctions during very warm temperatures or very rapid warming.

D'Odorico *et al.* (2008) write, "recent climate change predictions indicate that, in addition to trends in the mean values of climate variables, an increase in interannual variability is expected to occur in the near future." Also noting "environmental fluctuations are usually believed to play a 'destructive role' in ecosystem dynamics," they explore the validity of this latter assumption in the context of current climate model predictions, asking, "Can environmental variability have only 'negative' effects on ecosystem dynamics?"

After lengthy mathematical analysis, D'Odorico *et al.* determined "opportunities for species existence/coexistence are found to increase with 'moderate' values of the variance of environmental fluctuations, while they decrease when these fluctuations are relatively strong." This outcome constitutes what has come to be known as the "intermediate disturbance hypothesis," which grew out of the work of Connell (1978), who, in the words of D'Odorico *et al.*, suggested "coral reefs and rain forests maintain high levels of diversity only in a non-equilibrium state," and Huston (1979), who noted "most communities have relatively high levels of diversity because environmental variability maintains them in a non-equilibrium state."

Noting numerous real-world indications (Chapin *et al.*, 1997; Steneck *et al.*, 2002; Bengtsson *et al.*, 2003; Elmqvist *et al.*, 2003; Bellwood *et al.*, 2004; Folke *et al.*, 2004) that "biodiversity may enhance ecosystem resilience," the four researchers provide a theoretical basis for this phenomenon, demonstrating the validity of the ecological equivalent of the common dictum of physical exercise gurus: no pain, no gain. This evidence suggests what IPCC considers

unfavorable may in fact be just what is needed to increase the diversity and resilience of myriad terrestrial and aquatic ecosystems and propel them to higher levels of activity in the brave new world of our CO_2-enriched future.

In an overview of a symposium titled "Molecules to Migration: Pressures of Life," held in Africa on the Maasai Mara National Reserve of Kenya, Fuller *et al.* (2010) note the theoretical approach most commonly used to predict future species distributions in a CO_2-enriched and warmer world (the "climate envelope" approach) assumes "animals and plants can persist only in areas with an environment similar to the one they currently inhabit." This approach, they point out, "typically ignores the potential physiological capacity of animals to respond to climate change." They explain how "behavioral, autonomic, and morpho-logical modifications such as nocturnal activity, selective brain cooling, and body color may potentially serve as buffers to the consequences of climate change."

The six scientists note all organisms "have the capacity to adapt to changing environmental conditions both by phenotypic plasticity within a life span and by microevolution over a few life spans." They note, "there is evidence that microevolution—that is, heritable shifts in allele frequencies in a population (without speciation)—has occurred in response to climate warming," citing Bradshaw and Holzapfel (2006, 2008). They also point out phenotypic plasticity "is likely to represent the first response of individual organisms." They report "adaptive changes in phenotype induced by climate change have been documented, for example, in the morphology and phenology of birds (Charmantier *et al.*, 2008) and mammals (Reale *et al.*, 2003; Linnen *et al.*, 2009; Maloney *et al.*, 2009; Ozgul *et al.*, 2009)."

Fuller *et al.* cite Pincebourde *et al.* (2009), who "showed that intertidal sea stars can behaviorally regulate their thermal inertia by increasing their rate of water uptake during high tide on hot days," which is "a response that affords protection against extreme aerial temperatures during subsequent low tides." Next they note "exposure of humans to hot conditions on successive days induces an increase in sweat capacity (Nielsen *et al.*, 1993)." They state, "other adaptations also ensue, including plasma volume expansion and decreased electrolyte content of sweat," and thus "a typical unacclimatized male, who can produce about 600 ml of sweat per hour, can double that output with heat acclimatization (Henane and Valatx, 1973)." This "phenotypic adaptation (in this case, heat acclimatization) can alter physiological

tolerance (the risk of heat illness)," they note.

The Australian, South African, and U.S. scientists also cite several studies—Zervanos and Hadley (1973), Belovsky and Jordan (1978), Grenot (1992), Hayes and Krausman (1993), Berger *et al.* (1999), Dussault *et al.* (2004), Maloney *et al.* (2005), and Hetem *et al.* (2010)—of large herbivores that "increase nocturnal activity in the face of high diurnal heat loads." They state "another adaptation that may enhance plasticity in response to aridity that is available to oryx and other artiodactyls, as well as members of the cat family (Mitchell *et al.*, 1987), is selective brain cooling," in which cooling of the hypothalamus and the temperature sensors that drive evaporative heat loss "inhibits evaporative heat loss and conserves body water (Kuhnen, 1997; Fuller *et al.*, 2007)," which "is likely to be particularly valuable to animals under concurrent heat stress and dehydration." Finally, they suggest maintaining genetic diversity for a trait such as fur or feather color that adapts various organisms to different thermal environments "may provide important plasticity for future climate change," citing Millien *et al.* (2006), and "there is already evidence that, over the past 30 years as the climate has warmed, the proportion of dark-colored to light-colored Soay sheep has decreased on islands in the outer Hebrides," citing Maloney *et al.* (2009).

Clearly, the planet's animal species have inherent abilities enabling them to cope with climate changes over a period of a few generations, a single generation, or even in real time.

5.2 Amphibians

- Research suggests amphibian populations will suffer little, if any, harm from projected CO_2-induced global warming, and they may even benefit from it.

Still *et al*. (1999) and Pounds *et al*. (1999) published a pair of papers in *Nature* dealing with the cause of major decreases in frog and toad populations in the highland forests of Monteverde, Costa Rica. Those diebacks—in which 20 of 50 local species went extinct locally, or were extirpated—had occurred over the prior two decades, a period described by IPCC as having experienced unprecedented warming. Holmes (1999), in a popular science article describing the mystery's putative solution, wrote the authors of the two reports made "a convincing case blaming global climate change for these ecological events." Then came the study of Lawton *et al*. (2001), who challenged this hypothesis, presenting "an alternative mechanism [of] upwind deforestation of lowlands" as the cause of the amphibian decline.

Lawton *et al*. began their analysis by noting the trade winds that reach the Monteverde cloud-forest ecosystem flow across approximately 100 km of lowlands in the Rio San Juan basin, and that deforestation proceeded rapidly in the Costa Rican part of the basin over the past century. By 1992, only 18 percent of the original lowland forest remained. The four scientists noted this conversion of forest to

pasture and farmland altered the properties of the air flowing across the landscape. The reduced evapotranspiration that followed deforestation, for example, decreased the moisture content of the air mass, and regional atmospheric model simulations suggested there should be reduced cloud formation and higher cloud bases over such deforested areas, which would cause there to be fewer and higher-based clouds than otherwise would have been the case when the surface-modified air moved into the higher Monteverde region.

Thus there were two competing theories from which to choose a candidate mechanism for the environmental changes that had altered the Monteverde cloud-forest ecosystem: one that was global in nature (CO_2-induced warming) and one that was local (upwind lowland deforestation). Lawton *et al.* resolved the matter. Noting the lowland forests north of the San Juan River in southeastern Nicaragua had remained largely intact—providing a striking contrast to the mostly deforested lands in neighboring Costa Rica—they used satellite imagery to show "deforested areas of Costa Rica's Caribbean lowlands remain relatively cloud-free when forested regions have well-developed dry season cumulus cloud fields," noting further the prominent zone of reduced cumulus cloudiness in Costa Rica "lies directly upwind of the Monteverde tropical montane cloud forest." Consequently, they demonstrated by direct observation the effects predicted by the theory they espoused did indeed occur in the real world, alongside a "control" area identical in all respects but for the deforestation that produced the cloud effects.

Two years later, Nair *et al.* (2003) demonstrated the reduced evapotranspiration that followed prior and ongoing deforestation upwind of the Monteverde cloud forest decreased the moisture contents of the air masses that ultimately reached the tropical preserve, and regional atmospheric model simulations they conducted indicated there also should have been reduced cloud formation and higher cloud bases over these areas than there were before the deforestation began. Three years later, Ray *et al.* (2006) extended the work of Lawton *et al.* and Nair *et al.* while exploring in more detail the impact of deforestation in Costa Rican lowland and premontane regions on orographic cloud formation during the dry season month of March.

Ray *et al.* used the mesoscale numerical model of Colorado State University's Regional Atmospheric Modeling System to derive high-spatial-resolution simulations "constrained by a variety of ground based and remotely sensed observations," in order to

"examine the sensitivity of orographic cloud formation in the Monteverde region to three different land use scenarios in the adjacent lowland and premontane regions," namely, "pristine forests, current conditions and future deforestation."

This observation-constrained modeling work revealed historic "deforestation has decreased the cloud forest area covered with fog in the montane regions by around 5–13% and raised the orographic cloud bases by about 25–75 meters in the afternoon." In addition, they write, their work suggests "further deforestation in the lowland and premontane regions would lead to around [a] 15% decrease in the cloud forest area covered with fog and also raise the orographic cloud base heights by up to 125 meters in the afternoon."

As additional cases of amphibian mass mortality were reported throughout the world, Parmesan (2006) and Pounds *et al.* (2006) pointed accusing fingers at atmospheric CO_2, this time claiming global warming was promoting the spread of *Batrachochytrium dendrobatidis* (*Bd*), a non-hyphal zoosporic fungus that was the immediate cause of the amphibian declines and triggering outbreaks of chytridiomycosis via what came to be known as the climate-linked epidemic hypothesis (CLEH).

Investigating this concept in the Penalara Natural Park in the Sierra de Guadarrama of Central Spain, Bosch *et al.* (2007) looked for relationships between 20 meteorological variables and the development of chytridiomycosis infection in the area's amphibian populations, focusing on "two time periods according to the lack (1976–1996) or presence (1997–2003) of observed chytrid-related mortalities." This work revealed "a significant association between change in local climatic variables and the occurrence of chytridiomycosis," leading them to conclude, "rising temperature is linked to the occurrence of chytrid-related disease."

Being careful not to be too adamant about what their data implied, however, Bosch *et al.* note "associations between climate and disease do not necessarily imply causation." They also state, "chytrid-related declines are probably the result of a complex web of interaction, and the effects of climate will be conditional on other factors such as host density, amphibian community composition, microbial competitors and zooplankton predators, to name but a few." To disentangle this network and break it down into its key components, they say it will be necessary "to collect seasonal data on amphibian densities, contemporary and historical measurements of the prevalence and intensity of infection, seasonal

mortalities, and fine-scale meteorological conditions from a range of sites that represent altitudinal clines," and conduct "molecular epidemiological analyses."

Lips *et al*. (2008) evaluated data pertaining to population declines of frogs of the genus *Atelopus*, as well as similar data from other amphibian species, in Lower Central America and Andean South America, based on their own work and that of others recorded in the scientific literature. They sought to determine whether the documented population declines were more indicative of an emerging infectious disease or a climate-change-driven infectious disease, noting in this regard, "both field studies on amphibians (Briggs *et al*., 2005; Lips *et al*., 2006) and on fungal population genetics (Morehouse *et al*., 2003; Morgan *et al*., 2007) strongly suggest that *Bd* is a newly introduced invasive pathogen."

Lips *et al*. say their findings reveal "a classical pattern of disease spread across native populations, at odds with the CLEH proposed by Pounds *et al*. (2006)." Emphasizing the latter's "analyses and re-analyses of data related to the CLEH all fail to support that hypothesis," Lips *et al*. conclude their own analyses support "a hypothesis that *Bd* is an introduced pathogen that spreads from its point of origin in a pattern typical of many emerging infectious diseases," reemphasizing that "the available data simply do not support the hypothesis that climate change has driven the spread of *Bd* in our study area."

Although the four U.S. scientists make it clear disease dynamics are "affected by micro- and macro-climatic variables," and "such synergistic effects likely act on *Bd* and amphibians," their work clearly shows the simplistic scenario represented by the CLEH—which posits, in their words, that "outbreaks of chytridiomycosis are triggered by a shrinking thermal envelope"—paints an unrealistic picture of the role of global climate change in the much-more-complicated setting of real-world biology, where many additional factors may play even greater roles in determining amphibians' well-being.

Laurance (2008) tested the hypothesis, put forward by Pounds *et al*. (2006), that "the dramatic, fungal pathogen-linked extinctions of numerous harlequin frogs (*Atelopus* spp.) in upland rainforests of South America mostly occurred immediately following exceptionally warm years, implicating global warming as a likely trigger for these extinct-tions." He used "temperature data for eastern Australia, where at least 14 upland-rainforest frog species [had] also experienced extinctions or striking population declines attributed to the same fungal

pathogen, and where temperatures [had] also risen significantly in recent decades." This work provided "little direct support for the warm-year hypothesis of Pounds *et al*." Instead, Laurance "found stronger support for a modified version of the warm-year hypothesis," where frog declines were likely to occur only following three consecutive years of unusually warm weather; and these declines were observed "only at tropical latitudes, where rising minimum temperatures were greatest."

Laurance states many researchers "remain unconvinced that ongoing disease-linked amphibian declines are being widely instigated by rising global temperatures or associated climatic variables, as proposed by Pounds *et al*." He notes, for example, "chytrid-linked amphibian declines have been documented on several continents and at varying times" and to date, "no single environmental stressor has been identified that can easily account for these numerous population crashes." He continues, "it stretches plausibility to argue that the chytrid pathogen is simply an opportunistic, endemic micro-parasite that has suddenly begun causing catastrophic species declines as a consequence of contemporary global warming."

Rohr *et al*. (2008) provided a rigorous test of the two competing hypotheses by evaluating "(1) whether cloud cover, temperature convergence, and predicted temperature-dependent *Bd* growth are significant positive predictors of amphibian extinctions in the genus *Atelopus* and (2) whether spatial structure in the timing of these extinctions can be detected without making assumptions about the location, timing, or number of *Bd* emergences." The five scientists report, "almost all of our findings are contrary to the predictions of the chytrid-thermal-optimum hypothesis," even noting "not all of the data presented by Pounds *et al*. (2006) are consistent with the chytrid-thermal-optimum hypothesis." They write, "there was no regional temperature convergence in the 1980s when extinctions were increasing, and that convergence only occurred in the 1990s when *Atelopus spp*. extinctions were decreasing, opposite to the conclusions of Pounds *et al*. (2006) and the chytrid-thermal-optimum hypothesis." On the other hand, they report, "there is a spatial structure to the timing of *Atelopus spp*. extinctions but that the cause of this structure remains equivocal, emphasizing the need for further molecular characterization of *Bd*."

Alford *et al*. (2009) quantified four movement characteristics of three groups of radio-tracked cane toads (*Bufo marinus*) at three places in Australia: a location where the toads had been established for

some 50 years at the time of their sampling; a location where the first toads arrived about six months before sampling began in 1992 and 1993; and a location where sampling occurred for a period of 13 months, starting at the time of the toads' initial arrival in 2005. For all of the movement parameters they studied, "toads from the current invasion front differed dramatically from animals in the long-established population, while toads from the earlier invasion front were intermediate between these extremes."

The five researchers report "cane toads are now spreading through tropical Australia about 5-fold faster than in the early years of toad invasion." They state "the current invasion-front animals achieved these [high invasion speeds] by rarely reusing the same retreat site two days in succession, by travelling further each night when they did move, and by moving along straighter paths." Therefore, as they describe it, the toad invasion front "advances much more rapidly than would occur if the toads retained ancestral behaviors (less frequent relocation, with shorter movements, and fewer toads using straight paths)." And because "invasion-front toads in 1992 were more dispersive than origin-population toads in the same year, but … invasion-front toads have continued to evolve heightened dispersal ability and dispersed even more effectively in 2005 than they did in 1992," these observations suggest "as long as toads continue to invade suitable new habitat, dispersal ability will be selected upwards."

Alford *et al*. write the rapidity and magnitude of the shifts in cane toads "are truly remarkable," having been accomplished in only 50 generations (about 70 years), and they state "such a major shift over such a brief period testifies to the intense selective pressure exerted on frontal populations of range-shifting species." This development, in their words, "not only has implications for our understanding of the rates of invasion by non-native species, but also for the rate of range-shift in native taxa affected by climate change." The capacity for species to respond to changing environments may be underestimated when it is based on observations of individuals at the core of their range.

Further exploring this issue, Bustamante *et al*. (2010) exposed groups of Panamanian golden frogs (*Atelopus zeteki*) to varying dosages of zoospores of *Bd* and different temperatures and hydric environments to ascertain whether the frogs were susceptible to the pathogen and, if so, how environmental factors might affect the frogs' survival. These operations indicated "frogs exposed to a dosage of 100 *Bd* zoospores survived significantly longer than those

that had been exposed to 10^4 or 10^6 zoospores." They also found "exposed frogs housed at 23°C survived significantly longer than those that were housed at 17°C," and "exposed frogs held in dry conditions survived significantly longer than those in wet conditions."

Since their study was conducted in a laboratory, Bustamante *et al*. acknowledge their results "do not directly test hypotheses about the relation between climate change and the decline of the frogs in the field," but they note their data nevertheless "do not support the contention that rising global temperatures are necessary to cause the death of amphibians infected with this pathogen, because the pathogen was just as lethal at 17°C as at 23°C, and frogs at the warmer temperature lived significantly longer than those at the cooler one." This result is inconsistent with the climate-linked epidemic hypothesis of Pounds *et al*. (2006)—and Bustamante was a coauthor of that paper.

Anchukaitis and Evans (2010) state "widespread amphibian extinctions in the mountains of the American tropics have been blamed on the interaction of anthropogenic climate change and a lethal pathogen." However, they note, "limited meteorological records make it difficult to conclude whether current climate conditions at these sites are actually exceptional in the context of natural variability," casting doubt once again on the contention modern global warming was the primary culprit in the demise of the Monteverde golden toad (*Bufo periglenes*).

Anchukaitis and Evans developed annual proxy records of hydroclimatic variability over the past century within the Monteverde Cloud Forest of Costa Rica, based on measurements of the stable oxygen isotope ratio ($\delta^{18}O$) made on trees lacking annual rings, as described in the papers of Evans and Schrag (2004) and Anchukaitis *et al*. (2008). That work revealed, "contrary to interpretations of the short instrumental record (Pounds *et al*., 1999), no long-term trend in dry season hydroclimatology can be inferred from our $\delta^{18}O$ time series at Monteverde (1900–2002)." Instead, they found, "variability at the interannual scale dominates the isotope signal, particularly during the period of increased ENSO variance since the late 1960s," and they add, "there is no evidence of a trend associated with global warming." They emphasize "the extinction of the Monteverde golden toad appears to have coincided with an exceptionally dry interval caused by the 1986–1987 El Niño event," which they describe as "one of the longest driest periods in the last 100 years," based on their $\delta^{18}O$ chronology. In

addition, they report, there is currently no consensus on how anthropogenic climate change might influence the El Niño Southern Oscillation, and "ENSO anomalies in the most recent decades are not beyond the range of natural variability during the instrumental period (Rajagopalan *et al.*, 1997)."

Anchukaitis and Evans conclude their analysis suggests "the cause of the specific and well-documented extinction of the Monteverde golden toad was the combination of the abnormally strong ENSO-forced dryness and the lethality of the introduced chytrid fungus, but was not directly mediated by anthropogenic temperature trends, a finding from paleoclimatology that is in agreement with statistical reanalysis (Rohr *et al.*, 2008; Lips *et al.*, 2008) of the 'climate-linked epidemic hypothesis'." The latter two analyses also had revealed the chytrid-thermal-optimum hypothesis, as it alternatively has been described, to be devoid of merit. Consequently, even in the case of struggling amphibians, there are no real-world data indicating global warming is, or ever will be, responsible for driving them to extinction.

Noting "phenotypic plasticity, the capacity of a genotype to produce distinct phenotypes under different environmental conditions, is a common and powerful method of adaptation in nature," Orizaola and Laurila (2009) investigated variations in temperature-induced plasticity in larval life-history traits among populations of an isolated "meta-population" of pool frogs (*Rana lessonae*) in Central Sweden. They exposed larvae from three closely located populations to two temperatures (20 and 25°C) in the laboratory and then documented their growth and development responses at the two different temperatures. According to the two Swedish researchers, the results indicated "in general, larvae exposed to warmer temperature experienced higher survival and metamorphosed faster." They also found "differences among the populations in both trait mean values and in the plastic responses," and "among-family variation within populations was found in growth rate and time to metamorphosis, as well as in plasticity, suggesting that these traits have a capacity to evolve."

Orizaola and Laurila also report finding "strong population differentiation at a microgeographic scale in life-history characteristics and temperature-induced plasticity in [the] isolated amphibian meta-population." They report, in spite of "the near absence of molecular genetic variation within [the] meta-population, our study detected strong variation in trait means and plastic responses both among and within populations, possibly suggesting that natural selection

is shaping life-history traits of the local populations." This phenomenon may be preparing pool frogs for still further temperature increases by providing them "ample phenotypic variation" to deal with a potentially warming environment.

Skelly *et al.* (2007) critique the use of the "climate-envelope approach" to predict extinctions, citing as their primary reason for doing so the fact that this approach "implicitly assumes that species cannot evolve in response to changing climate," when in numerous cases they can do so effectively. Noting "many examples of contemporary evolution in response to climate change exist," the group of seven scientists from the United States, Canada, and Australia report, "in less than 40 years, populations of the frog *Rana sylvatica* have undergone localized evolution in thermal tolerance (Skelly and Freidenburg, 2000), temperature-specific develop-ment rate (Skelly, 2004), and thermal preference (Freidenburg and Skelly, 2004)," and "laboratory studies of insects show that thermal tolerance can change markedly after as few as 10 generations (Good, 1993)." Since "studies of microevolution in plants show substantial trait evolution in response to climate manipulations (Bone and Farres, 2001)," they state, "collectively, these findings show that genetic variation for traits related to thermal performance is common and evolutionary response to changing climate has been the typical finding in experimental and observational studies (Hendry and Kinnison, 1999; Kinnison and Hendry, 2001)."

Although evolution obviously will be slower among long-lived trees and large mammals, where long generation times are the norm, Skelly *et al.* say the case for rapid evolutionary responses among many other species "has grown much stronger (e.g., Stockwell *et al.*, 2003; Berteaux *et al.*, 2004; Hariston *et al.*, 2005; Bradshaw and Holzapfel, 2006; Schwartz *et al.*, 2006; Urban *et al.*, 2007)." They write, "on the basis of the present knowledge of genetic variation in performance traits and species' capacity for evolutionary response, it can be concluded that evolutionary change will often occur concomitantly with changes in climate as well as [with] other environmental changes (e.g., Grant and Grant, 2002; Stockwell *et al.*, 2003; Balanya *et al.*, 2006; Jump *et al.*, 2006; Pelletier *et al.*, 2007)." Frogs, as noted above, are no exception to this general rule.

Catenazzi *et al.* (2010) write, "climate change has been proposed as a driver of amphibian declines," but they note this hypothesis has been largely displaced by a competing theory built around the observation that the pathogen *Bd* has been "associated with

amphibian declines throughout the world (Berger *et al*., 1998; Briggs *et al*., 2005; Lips *et al*., 2006)" in a manner indicating an introduced and subsequently spreading epidemic disease. They studied the recent collapse in anuran species richness and abundance in the Upper Manu National Park of Southeastern Peru.

Catenazzi *et al*. surveyed frogs in the Peruvian Andes in montane forests along a steep elevation gradient (1,200–3,700 m), using visual encounter surveys to sample stream-dwelling and arboreal species and leaf-litter plots to sample terrestrial-breeding species, in order to compare species richness and abundance among the wet seasons of 1999, 2008, and 2009. The U.S. and Peruvian researchers found there had been "a dramatic decline in species richness of amphibians"—a mean decline of 38% in the area of their study over the 10-year period—with stream-breeding species being "disproportionally represented among the missing taxa in 2008 and 2009." They state this result "is consistent with observations in other Neotropical (Lips, 1998) and Australian (Laurance *et al*., 1996; Williams and Hero, 1998) sites where the species richness and abundance of frogs have declined or frogs have been extirpated," noting "declines in these other areas are unequivocally linked to the introduction of *Bd* to naïve amphibian populations (Berger *et al*., 1998; Lips *et al*., 2006)."

Their results show "the geographic and elevational distribution of *Bd* extends to southern Peru," noting this extent is consistent with Lips *et al*.'s (2008) hypothesis of *Bd* spreading southward in a wave from a *Bd* introduction site in southwestern Ecuador. Alternatively, they suggest the *Bd* introduction site could be Cusco, which "receives more visitors than any other tourist destination in Peru." And, noting "frogs originating from many streams, ponds and lakes of the Bolivian-Peruvian Altiplano are sold live in the city for human consumption," they suggest this frog trade "could facilitate the spread of *Bd* over large areas in southern Peru."

Given the above observations, plus the fact that "*Bd* occurs in a wide range of land-cover types and microclimates," Catenazzi *et al*. say "it is unclear how climate change would increase the rate of spread or the virulence of such an opportunistic pathogen in frog populations." They conclude it hasn't. Despite decades of research and a general belief that the link between *Bd* arrival and population decline is well-resolved in regions such as Australia, there is no evidence the arrival of *Bd* coincided with amphibian population decline, because the present data are not adequate to determine whether *Bd* was present prior

to initial sampling (Phillips *et al*., 2012). Phillips *et al*. (2012) conclude, "more generally, our discovery of a complete lack of evidence linking the arrival of *Bd* and the timing of population declines in north-eastern Australia points to the alarming ease with which paradigms can become established even in the absence of critical tests of those paradigms." An alternative explanation for the upturn in recorded fungal infections is not global warming, but human-mediated intensification of fungal disease dispersal, caused by transportation and modification of natural environments (Fisher *et al*., 2012).

In a nine-year study conducted in the Little Rock Creek Basin, located within the Selway-Bitterroot Wilderness just south of Hamilton, Montana (USA), McCaffery and Maxell (2010) "evaluated relation-ships among local climate variables, annual survival and fecundity, and population growth rates" in "a high-elevation population of a temperate pond-breeding frog species, the Columbia spotted frog (*Rana luteiventris*)." They monitored all life stages of the species and related the resulting demographic data to climate data collected at a nearby weather station. The two University of Montana biologists report "parameters that describe winter severity were negatively correlated with survival, transition, and breeding probabilities in this high-elevation *R. luteiventris* population," and there was "an increase in survival and breeding probability as severity of winter decreased."

"Contrary to much of what has been discussed in the literature," McCaffery and Maxell write, "these results suggest that under certain circumstances, a warming climate may be helpful to some amphibian populations, particularly those that live in harsh conditions at the edge of their thermal tolerances." As a case in point, they state their results "unambiguously demonstrate that earlier ending winters with lower snowpack in this system lead to higher survival rates, higher probabilities of breeding, and higher population viability." Thus, they conclude, "more generally, amphibians and other ectotherms inhabiting alpine or boreal habitats at or near their thermal ecological limits may benefit from the milder winters provided by a warming climate."

Additional studies show other real-world data that refute the contention global warming is driving amphibians to extinction. Berger *et al*. (2004), for example, found lower temperatures enhanced the development of chytridiomycosis in a study of eastern Australian frogs, and Seimon *et al*. (2007) determined glacial recession in the Peruvian Andes has been creating new amphibian habitats at recently

deglaciated sites. Woodhams *et al.* (2010) note "amphibian skin peptides are one important defense against chytridiomycosis," and examining "the population-level variation in this innate immune defense [is important] to understand its relationship with disease dynamics." Briggs *et al.* (2010) note some amphibians with chytridiomycosis "develop only minor infections and suffer little or no negative effects." And Zukerman (2010) reports some of the most devastated populations of Australia's barred river frogs (*Mixophyes esiteratus*), tusked-frogs (*Adelotus sp.*), and several tree frog species (*Litoria sp.*), once thought to have been wiped out by the fungus, are now showing strong signs of recovery.

All in all, the above studies suggest amphibian populations will suffer little, if any, harm from projected CO_2-induced global warming, and they may even benefit from it.

5.3 Arthropods

- Enhanced plant productivity driven by elevated levels of atmospheric CO_2 tends to support greater abundance of soil microarthropods.

Arthropods are invertebrate animals composed of a segmented body, jointed appendages, and an exoskeleton. A handful of studies have examined how these animals may be affected by Earth's rising atmospheric CO_2 concentration. One of the early emerging hypotheses is that if the productivity of the plants at the base of a food chain is enhanced by the aerial fertilization effect of extra CO_2, they could be expected to support greater animal populations at the other end, including arthropods.

Siemann (1998) studied the effects of both short- and long-term nitrogen fertilization on plant productivity and arthropod communities in an upland grass ecosystem in Minnesota. In both situations, plant productivity was enhanced; arthropods responded by increasing both their numbers and the number of their species, suggesting if atmospheric CO_2 enrichment tends to enhance plant productivity, it also will increase arthropod numbers and ecosystem species richness.

Rillig *et al.* (1999) confirmed this conclusion. In serpentine and sandstone grasslands in California, they found an approximate doubling of the air's CO_2 content significantly enhanced the masses of fungi living in the soil, resulting in large increases in the numbers of fungal-feeding microarthropods (108 and 39% increases in the sandstone and serpentine grasslands, respectively). Likewise, in a study of poplar tree cuttings in Michigan, Lussenhop *et al.* (1998) observed the fine roots of the trees in their approximately doubled CO_2 treatment supported twice as many microarthropods as the fine roots of the trees growing in ambient air. And in a multiple-microcosm study of mini-terrestrial ecosystems conducted in the United Kingdom, Jones *et al.* (1998) found a 53% increase in atmospheric CO_2 concentration produced an enhanced soil fungal population that supported 52% more soil microarthropods.

Sanders *et al.* (2004) studied effects of atmospheric CO_2 enrichment on the plant and arthropod communities of the understory of a closed-canopy sweetgum plantation (which reduces the light available to the understory between 70 and 95% during the growing season) in a study where the air's CO_2 content was increased by approximately 48%. They report total arthropod abundance did not differ between ambient and elevated CO_2 plots, nor did the abundances of detritivores, omnivores, or parasitoids. They conclude, "changes in plant community composition did not translate into differences in arthropod communities."

Sticht *et al.* (2006) investigated how elevated atmospheric CO_2 concentration (550 ppm as opposed to the ambient concentration of about 380 ppm) delivered via free-air CO_2 enrichment (FACE) technology interacted with two levels of nitrogen (N) fertilization (normal N and half-normal N) to

influence the abundance and diversity of collembolans in a field planted to winter wheat at the Federal Agricultural Research Centre in Braun-schweig, Lower Saxony, Germany, where the 45% increase in the air's CO_2 content increased aboveground wheat biomass production by approximately 14%. Invertebrate communities in general, and collembolans in particular, play an important role in maintaining soil fertility, as the authors say they "participate in organic matter decomposition and can stimulate nutrient mobilization and plant nutrient uptake (e.g. Wardle *et al.*, 2004)."

The German researchers found "CO_2 enrichment enhanced the collembolan abundance by 58% under conventional N fertilization and by 100% under restricted N supply," and "under FACE conditions the collembolan diversity was higher (28 species) compared to ambient air conditions (23 species)." Sticht *et al.* conclude, "an increase in collembolan abundance and diversity can be expected as a result of enhanced quantity and changed quality of organic matter input into the soil associated with elevated atmospheric CO_2." And since this phenomenon "can stimulate nutrient mobilization and plant nutrient uptake," as they note, it is especially encouraging that its relative strength was greatest when nitrogen was most limiting in their experiment.

Enhanced plant productivity driven by elevated levels of atmospheric CO_2 tends to support greater abundance of soil microarthropods.

5.4 Birds

- Although some changes in bird populations and their habitat areas have been documented in the literature, linking such changes to CO_2-induced global warming remains elusive. Also, when there have been changes, they often are positive, as many species have adapted and are thriving in response to rising temperatures of the modern era.

One of the great concerns associated with predictions of CO_2-induced global warming is the claim that the number of birds and their habitat areas will decline. Some estimates go so far as to suggest global warming could result in the extinction of several bird species. In the following subsections, such claims are examined through peer-reviewed studies conducted on birds in an effort to see how they have responded to what IPCC has called the unprecedented rise in atmospheric CO_2 and temperature of the late-twentieth and early twenty-first century.

Although some changes in bird populations and their habitat areas have been documented in the literature, linking such changes to CO_2-induced global warming remains elusive. Also, when there have been changes, they often are positive, as many species have adapted and are thriving in response to rising temperatures of the modern era.

5.4.1 Population Dynamics

How has modern warming impacted bird population dynamics? Several researchers have addressed this question for various bird species in many locations across the planet. This section summarizes what they have learned.

Schmidt *et al*. (2009) employed Bayesian hierarchical models to estimate the population size of trumpeter swans (*Cygnus buccinator*) based on aerial survey data collected by the U.S. Fish and Wildlife

Service throughout all known nesting habitats in the state of Alaska. These data collections were first made in 1968 and subsequently in 1975 and every five years thereafter through 2005. The results indicated "adult swan populations in Alaska increased at an average rate of 5.9% annually and cygnet production increased at 5.3% annually." The authors also found "cygnet production exhibited higher rates of increase at higher latitudes in later years," which they opine was "a response to warmer spring temperatures." The five researchers conclude, "trumpeter swan populations are increasing in Alaska, especially at northern latitudes," stating their study "represents one of the first to demonstrate a shift in breeding range of a bird possibly due to climate change." Hence, "for trumpeter swans, it appears that breeding range limits in Alaska have expanded" in response to the warming experienced there between 1968 and 2005.

White *et al*. (2011) analyzed how Great Cormorant numbers varied over the years in response to changes in sea surface temperature (SST) in the vicinity of Greenland's Disko Bay, using data obtained from the U.S. National Climate Data Center plus data for the number of breeding pairs of Great Cormorants in Disko Bay and adjacent areas they obtained from aerial and boat-based surveys described by Boertmann *et al*. (1996) and Boertmann (2006) for the period 1946–2005. According to the six scientists, population change rates of Great Cormorant colonies in the vicinity of Disko Bay "were significantly positively correlated with mean winter SST," adding, "populations increased during relatively warm years and decreased during relatively cold years," while also noting "the highest rates of population change correspond with periods of relatively high SST in recent years and during the 1960s." White *et al*. conclude, "taken together, the positive relationship between rates of population change in Cormorants and SST, the likely positive impact of Arctic warming on the preferred prey species of Cormorants, and the flexible food preferences and foraging strategies of Cormorants suggest that Cormorants are likely to benefit from a warming Arctic."

Grandgeorge *et al*. (2008) analyzed population sizes and phylogenetic and spatial structures of British and Irish seabirds based on "(1) presence or absence of the seabird species in the different counties of Britain and Ireland between 1875 to 1900 and 1968 to 1972, (2) seabird breeding censuses of Britain and Ireland from 1969 to 1970, 1985 to 1988 and 1998 to 2002, (3) at-sea abundance and

distribution surveys of seabirds in the North Sea from 1980 to 1985 and 1990 to 1995, and (4) a bio-energetics model to estimate energy expenditures for 40 seabird species." With respect to population dynamics, their work revealed total seabird numbers "increased at an average rate of 1% per annum between 1969 and 2002, with a related increase of 115% in predicted total seabird predation." Also, "between 1875 and 1972 no seabird species was lost and there was an overall expansion in breeding range of the seabird population of Britain and Ireland, with the number of counties occupied increasing from 31 to 47."

The six scientists conclude, "the seabird community of Britain and Ireland has been remarkably resilient to environmental change in the 20th century." In fact, it "prospered during the 20th century" and "significantly raised ocean temperatures in the North Sea (Beaugrand, 2004)" may even have "created more favorable environmental conditions for some seabird species," citing Thompson (2006).

Lemoine *et al*. (2007) used data from the *Breeding Bird Atlas* of Lake Constance, which borders Germany, Switzerland, and Austria, to analyze the impact of land-use and climate changes on the region's abundance of Central European birds between the periods 1980–1981 and 1990–1992, and between 1990–1992 and 2000–2002. They found "the total number of [bird] species in the Lake Constance region increased from 141 species in 1980 to 146 species in 1990 and to 154 species in 2000," and "winter temperatures increased by 2.71°C and spring temperatures increased by 2.12°C over the 23 years from the first to the last census." These and other data led them to conclude, "increases in temperature appear to have allowed increases in abundance of species whose range centers were located in southern Europe and that may have been limited by low winter or spring temperature." In addition, they report "the impact of climate change on bird populations increased in importance between 1990 and 2000 and is now more significant than any other tested factor."

Seoane and Carrascal (2008) write, "it has been hypothesized that species preferring low environmental temperatures, which inhabit cooler habitats or areas, would be negatively affected by global warming as a consequence of the widely accepted increase of temperature during the last two decades." They note "this effect is assumed to be more intense at higher latitudes and altitudes because these areas seem to be changing more rapidly." They devised a study "to assess whether population changes agree with what could be expected under

global warming (a decrease in species typical of cooler environments)," focusing on birds. Working in the Spanish portion of the Iberian Peninsula in the southwestern part of the Mediterranean Basin, the two researchers determined breeding population changes for 57 species of common passerine birds between 1996 and 2004 in areas without any apparent land-use changes. This work revealed, "one-half of the study species showed significant increasing recent trends despite the public concern that bird populations are generally decreasing," and "only one-tenth showed a significant decrease."

Seoane and Carrascal state, "the coherent pattern in population trends we found disagrees with the proposed detrimental effect of global warming on bird populations of western Europe." They are not the only ones to have reached this conclusion. They note, for example, "one-half of terrestrial passerine birds in the United Kingdom exhibited increasing recent trends in a very similar time period (1994–2004)," citing Raven *et al.* (2005), and they explain, "there is also a marked consistency between the observed increasing trends for forest and open woodland species in the Iberian Peninsula and at more northern European latitudes in the same recent years," citing Gregory *et al.* (2005). Likewise, they write, "Julliard *et al.* (2004a), working with 77 common bird species in France, found that species with large ecological breadth showed a tendency to increase their numbers throughout the analyzed period."

Seoane and Carrascal state, "bird species that inhabit dense wooded habitats show striking patterns of population increase throughout time." Noting "this is also the case with those bird species mainly distributed across central and northern Europe that reach their southern boundary limits in the north of the Iberian Peninsula," they theorize "these short- to medium-term population increases may be due to concomitant increases in productivity." In support of this notion they cite Julliard *et al.* (2004b) and the empirical observations of Myneni *et al.* (1997), Tucker *et al.* (2001), Zhou *et al.* (2001), Fang *et al.* (2003), and Slayback *et al.* (2003), whose work figured prominently in establishing the reality of the late twentieth-century warming- and CO_2-induced greening of the Earth phenomenon (see Section 4.2 on Biospheric Productivity), which has produced, in the words of the Spanish scientists, "an increase in plant growth or terrestrial net primary production in middle latitudes of the Northern Hemisphere since the 1980s, particularly in forest environments." It is clear the supposedly unprecedented warmth of the past two decades has not led to what Seoane and Carrascal call

"the proposed detrimental effect of global warming on bird populations of western Europe."

Qian *et al.* (2009) compiled a comprehensive dataset of bird species richness in China based on pertinent scientific literature published over the past three decades for 207 localities, the vast majority of which were national nature reserves with a mean area of 3270 km^2, which dataset they analyzed for their relationships to 13 environmental variables. The authors observe, "of all environmental variables examined, normalized difference vegetation index [NDVI], a measure of plant productivity, is the best variable to explain the variance in breeding bird richness." Four of the 13 variables they tested explained 45.3% of the total species richness variance, with 21.2% being accounted for by NDVI, 12.5% by elevation range, and 11.6% by annual potential evapotranspiration and mean annual temperature together. They note the two most important predictors of their study (NDVI and elevation range) "have been found to be major predictors for breeding bird richness in other regions and the whole of the globe, indicating that the finding of [their] study at a smaller scale is to a large degree consistent with those of previous studies of breeding birds at larger scales."

In a major review of plant-animal interactions in 51 terrestrial ecosystems conducted 20 years earlier, McNaughton *et al.* (1989) found the biomass of plant-eating animals is a strongly increasing function of aboveground primary production, and in a subsequent review of 22 aquatic ecosystems, Cyr and Pace (1993) found the herbivore biomass of watery habitats also increases in response to increases in vegetative productivity. Thus it is abundantly clear greater plant productivity—both terrestrial and aquatic—leads to greater populations of plants and the animals that feed upon them, which should lead to greater ecosystem biodiversity and a reduced risk of extinction. Atmospheric CO_2 enrichment increases plant productivity (see Chapter 1), which supports more animal life, which leads to greater animal bio-diversity, which is good for the planet and good for mankind.

A warmer climate has benefited birds on Australia's Heard Island, some 4,000 kilometers southwest of Perth. Over the last five decades of the twentieth century, as this sub-Antarctic island experienced a local warming of approximately 1°C, there were rapid increases in flora and fauna. The population of the King penguin, for example, "exploded from only three breeding pairs in 1947 to 25,000," and the Heard Island cormorant, listed

previously as "vulnerable," increased to 1,200 pairs. Recovering from near extinction, fur seals now number 28,000 adults and 1,000 pups (Pockely, 2001).

Penguins in Antarctica also have fared well in warmer times. In response to dramatic warming observed on the western Antarctic Peninsula over the past several decades, the penguin population has become more diverse as chinstrap and gentoo penguins have begun to take up residence among the long-inhabiting Adelie penguin population (Smith *et al.*, 1999). A study of penguin populations on the Ardley Peninsula of maritime Antarctica by Sun *et al.* (2000) found over the past 3,000 years the penguin population was lowest at 1,800–2,300 years BP, during a period of low temperature.

Huang *et al.* (2009) reported similar findings after evaluating paleo-evidence for penguin populations at Gardner Island in East Antarctica. According to the five researchers, penguins colonized the site shortly after it became ice-free 8,500 years ago. A pronounced population peak is evident in the data from about 4,700 to 2,400 BP, which corresponds closely to a substantially warmer period at this site. The authors document four other studies showing a penguin optimum roughly 3,000 to 4,000 years ago and coinciding with notably warm conditions. Together, these five studies encompass East Antarctica, the Ross Sea region, and the West Antarctic Peninsula. With all data currently available pointing to penguins having been most abundant during the warmest period of the Holocene several thousand years ago, it would seem reasonable to believe penguins will respond positively, not negatively, to any future warming.

Although global warming, regardless of its cause (natural or anthropogenic), appears to favor the population of many bird species, other human-related factors may offset such benefits and induce harm. For example, studies on the population dynamics of King penguins, *Aptenodytes patagonicus*, have been ongoing for many years. Recently, these fish-eating, top-of-the-food-chain predators have been used as indicator species for studies on the impacts of climate change in the southern hemisphere (Croxall *et al.*, 2002; Tynan 1998). In many respects, penguins have become "polar bear equivalents" of the Antarctic ecosystem. It appears something other than global warming has had a major influence on their population in recent years.

Saraux *et al.* (2011) note "in 2007, the Intergovernmental Panel on Climate Change highlighted an urgent need to assess the responses of marine ecosystems to climate change. Because they lie in a high-latitude region, the Southern Ocean ecosystems are expected to be strongly affected by global warming. Using top predators of this highly productive ocean (such as penguins) as integrative indicators may help us assess the impacts of climate change on marine ecosystems."

Following that charge from IPCC, several reports have used data collected from penguins marked with flipper bands (Barbraud and Weimerskirch 2001; Jenouvrier *et al.*, 2009) to predict impacts on the entire population from climate change scenarios modeled for the future. Flipper bands are metal markers attached to the upper part of the front flipper, where they are easily visible on land or in the water. Since penguins are birds that fly through the water, these "flippers" are actually wings and thus the sole source of a penguin's swimming power. Banding involves a single loop slipped over the upper, muscular section of one wing (equivalent to the human upper arm) and is meant to remain there for the life of the bird. These bands themselves, however, might have an influence on the data being collected on these penguins.

Research was conducted over a decade, in part to test the assumption that birds would adapt within a year at most to any negative effects of the metal flipper band (Barbraud and Weimerskirch 2001). Saraux *et al.* (2011) analyzed differences in reproduction and survival on 50 banded and 50 unbanded penguins over 10 years. The researchers evaluated annual and overall survival, arrival time at the breeding colony, laying dates, breeding success, success in chick rearing, duration of feeding trips ("foraging") and population growth.

They found the "banding of free-ranging king penguins (*Aptenodytes patagonicus*) impairs both survival and reproduction, ultimately affecting population growth rate." Over the 10-year period, banded birds were found to produce 39% fewer chicks and had a survival rate 16% lower than non-banded birds. Much of this effect appeared to be due to an increased time banded birds required to find sufficient food (both before and during the summer breeding season) and to their relatively late arrival at the breeding colony.

Saraux and colleagues write "one of our major findings is that responses of flipper-banded penguins to climate variability (that is, changes in sea surface temperature and in the Southern Oscillation index) differ from those of non-banded birds. We show that only long-term investigations may allow an evaluation of the impact of flipper bands and that every

major life-history trait can be affected, calling into question the banding schemes still going on. In addition, our understanding of the effects of climate change on marine ecosystems based on flipper-band data should be reconsidered."

Another human-related activity with a significant impact on bird populations is the construction of wind farms. Pearce-Higgins *et al.* (2009) note "the displacement of birds away from turbines can result in individuals abandoning otherwise suitable habitat," and this "has been found to occur in a number of individual wind farm studies," citing Leddy *et al.* (1999), Larsen and Madsen (2000), Kowallik and Borbach-Jaene (2001), Hotker (2006), Hotker *et al.* (2006), and Larsen and Guillemette (2007). Pearce-Higgins *et al.* report, "some poorly sited wind farms have resulted in sufficient deaths to produce a population-level effect," citing Barrios and Rodriguez (2004, 2007), Everaert and Stienen (2006), Smallwood and Thelander (2007), Sterner *et al.* (2007), and Thelander and Smallwood (2007).

Pearce-Higgins *et al.* assessed the degree of occurrence of 12 widely distributed species of breeding birds within the vicinity of wind farm infrastructure (turbines, access tracks, and overhead transmission lines) on 12 wind farms located within unenclosed upland habitats (moorland, rough grassland, and blanket bog) in the United Kingdom, including most of the existing large upland wind farms in Scotland and northern England. The five UK scientists obtained "considerable evidence for localized reduction in breeding bird density on upland wind farms." After accounting for habitat variation, they report, "seven of the twelve species studied exhibited significantly lower frequencies of occurrence close to the turbines," and there was "equivocal evidence of turbine avoidance in a further two," and "no species were more likely to occur close to the turbines." Access tracks proved much less of a nuisance than turbines, and there was no evidence for consistent avoidance of overhead transmission lines. They conclude, "levels of turbine avoidance suggest breeding bird densities may be reduced within a 500-m buffer of the turbines by 15–52%, with buzzard (*Buteo buteo*), hen harrier (*Circus cyaneus*), golden plover (*Pluvialis apricaria*), snipe (*Gallinago gallinago*), curlew (*Numenius arquata*) and wheatear (*Oenanthe oenanthe*) most affected."

Pearce-Higgins *et al.* say their findings emphasize the need for a "strategic approach" to ensure wind farm development avoids areas with high densities of potentially vulnerable species, not only in the UK but also "across other similar windy semi-natural habitats in northwest Europe, southern South America, and central North America." Efforts should be made to "avoid high densities of potentially vulnerable open country species such as waders and raptors," they write. Their findings augment those of many others who have raised serious questions about the constructing of wind farms in inappropriate locations.

5.4.2 Range Expansion

IPCC claims the increase in temperature predicted to result from the ongoing rise in the air's CO_2 content will be of such magnitude and speed that many species of plants and animals will not be able to migrate poleward in latitude or upward in elevation rapidly enough to avoid extinction as they are forced to seek cooler living conditions. There are many reasons for rejecting this contention, one of the most powerful being that increases in the air's CO_2 content generally enable plants to endure warmer weather, and as a result there is little or no need for them to shift the heat-limiting warm-temperature boundaries of their ranges as temperatures rise (see Section 3.13 and Section 4.2.3). At the cold-limiting cool-temperature boundaries of their ranges, warming provides opportunities for plants to push poleward and upward, resulting in expansions of their ranges and reductions in their risk of extinction.

This section reviews studies that suggest birds may respond in like manner, mimicking the respective shifts and non-shifts of the cold- and heat-limited boundaries of the ranges of the plants and associated herbivore life forms on which they depend for food.

Thomas and Lennon (1999) helped initiate extinction concerns about birds when they analyzed temporal trends in the spatial distributions of British birds over a 20-year period of global warming, looking for climate-induced changes in their breeding ranges. They found the northern margins of southerly species' breeding ranges shifted northward by an average of 19 km from 1970 to 1990, while the southern margins of northerly species' breeding ranges did not shift at all, in the mean. British birds thus expanded their ranges in the face of global warming, clearly a positive response that makes extinction less likely than it was before the warming.

Norment *et al.* (1999) analyzed bird surveys conducted along the Thelon River and its tributaries in the Canadian Northwest Territories from the 1920s through much of the 1990s, finding three bird species had expanded their breeding ranges southward, nine northward, and 16 were new to the area. The authors note the primarily northward range expansions may be explained by "a recent warming trend at the northern treeline during the 1970s and 1980s." Alternatively, they note the influx of new species may result from "increasing populations in more southerly areas." In either case, the birds appear to be faring quite well—even thriving—in the face of increasing temperatures in this forest-tundra landscape, which also appears to be the case in Norway (Saether *et al.*, 2000).

Research suggests seabirds of Greenland are also likely to benefit from global warming. According to Wagner and Melles (2001), a significant number of seabirds inhabited the area around Liverpool Land, on the east coast of Greenland, during the Medieval Warm Period (900–1300 AD), yet there was little or no (inferred) bird presence for a several-hundred-year period prior to this time (Dark Ages Cold Period) and another significant absence of birds thereafter during the Little Ice Age, which marked "the coldest period since the early Holocene in East Greenland." As temperatures have risen over the past 100 years, seabirds once again have expanded their range to inhabit the area.

Kinzelbach (2004) explored the range history of the serin, a bird that "was a topic of particular interest to ornithologists of the 19th and 20th century" due to "the rapid expansion of its range in historical times." The author reexamined "all the sources of records of

the serin in 16th century Europe, ... both those already known and some that have been newly discovered." The data confirmed the findings of Mayr (1926), that "north of 48°N there were no free-living populations of *Serinus serinus* in the 16th century." During that period, the serin's range was constrained, Kinzelbach reports, as it "was halted by colder periods of the Little Ice Age after 1585, only resuming a rapid expansion at the beginning of the 19th century," after which it was "able to expand its range from the Mediterranean region throughout large areas of Central Europe within a mere 200 years."

Brommer (2004) categorized birds of Finland as either northerly (34 species) or southerly (116 species) and quantified changes in their range margins and distributions from two atlases of breeding birds, one covering the period 1974–1979 and one for 1986–1989, to determine how the two groups of species responded to what he called "the period of the Earth's most rapid climate warming in the last 10,000 years," citing McCarthy *et al*. (2001). Southern species experienced a mean poleward advancement of their northern range boundaries of 18.8 km over the 12-year period, while the southern-range boundaries of the northern species remained essentially unaltered. Noting similar results had been obtained for birds in the United Kingdom (Thomas and Lennon, 1999) and other animals (primarily butterflies) elsewhere (Parmesan, 1996; Parmesan *et al*., 1999), Brommer concludes, "in general, for Northern Hemisphere species, southerly range margins of species are less responsive to climate change than the northerly margins." This demonstrates once again the ranges of birds (and possibly other animals) in a warming world likely will increase, as their northern range boundaries expand poleward and upward while their southern range boundaries remain largely unaltered, which should render them less subject to extinction than they are currently or have been in the past.

For the portion of the United States east of the Rocky Mountains, Hitch and Leberg (2007) used data from the North American Breeding Bird Survey to evaluate shifts in the northern range boundaries of 26 species of birds with southern distributions and the southern range boundaries of 29 species of birds with northern distributions between the periods 1967–1971 and 1998–2002. They found the northern margins of the southern group of birds showed significant northward shifts that averaged 2.35 km per year for all species studied, which they describe as being "consistent with the results of Thomas and Lennon (1999) from Great Britain." Also in agreement with the observations on British birds, they determined

"levels of warming do not appear to be so great [that] they are forcing birds to abandon the southernmost portions of their distributions."

Grandgeorge *et al*. (2008) analyzed population sizes and phylogenetic and spatial structures of British and Irish seabirds based on "(1) presence or absence of the seabird species in the different counties of Britain and Ireland between 1875 to 1900 and 1968 to 1972, (2) seabird breeding censuses of Britain and Ireland from 1969 to 1970, 1985 to 1988 and 1998 to 2002, (3) at-sea abundance and distribution surveys of seabirds in the North Sea from 1980 to 1985 and 1990 to 1995, and (4) a bioenergetics model to estimate energy expenditures for 40 seabird species." They found "a marked expansion in the breeding range of seabirds in Britain and Ireland between 1875 and 1972." In addition, they report total seabird numbers "increased at an average rate of 1% per annum between 1969 and 2002, with a related increase of 115% in predicted total seabird predation." Also, they state, "between 1875 and 1972 no seabird species was lost and there was an overall expansion in breeding range of the seabird population of Britain and Ireland, with the number of counties occupied increasing from 31 to 47."

The six scientists conclude, "the seabird community of Britain and Ireland has been remarkably resilient to environmental change in the 20th century." In fact, it "prospered during the 20th century," and "significantly raised ocean temperatures in the North Sea (Beaugrand, 2004)" may have "created more favorable environmental conditions for some seabird species," citing Thompson (2006).

Brommer (2008) notes a "population-level change expected under a climate-warming scenario is a poleward shift in the distribution of organisms," and he states many believe birds that "do not shift their range margin consist of species that are declining, and would therefore be of particular management concern." A few years earlier, Brommer (2004) had measured the range sizes and northern range margin locations of 116 bird species with a predominantly southern distribution in Finland, and of those species "the trend slope describing the change in their abundance for the period 1983–2005 was calculated for 53 species by Vaisanen (2006)." This, he notes, resulted in "the largest dataset available of the long-term trends in population numbers of Finnish birds that is comparable across species, because it has both been gathered and analyzed using the same procedures." Brommer (2008) determined the concomitant changes in the northern range margins of

the 53 species.

The Finnish bird specialist found "species foraging in wet habitats had experienced strong range margin shifts as compared with other feeding ecologies." However, he found "no evidence that those feeding ecological groups that showed a relatively small shift in range margin had experienced low population growth or a population decline." Therefore, in discussing "the lack of correlation between the shift in range margin of the different feeding ecologies and the change in their mean abundance," Brommer states this real-world finding "is contrary to expected under a climate-change scenario, because, all else being equal, a clear range-margin shift should indicate a good capacity to track climatic change, which should result in a more positive trend in abundance if climate change is indeed the main driver of population-level change."

Maclean *et al*. (2008) analyzed counts of seven wading bird species—the Eurasian oystercatcher, grey plover, red knot, dunlin, bar-tailed godwit, Eurasian curlew, and common redshank—made at approximately 3,500 sites in Belgium, Denmark, France, Germany, Ireland, the Netherlands, and the United Kingdom on at least an annual basis since the late 1970s. They did this in order to determine what range adjustments the waders may have made in response to regional warming, calculating the weighted geographical centroids of the bird populations for all sites with complete coverage for every year between 1981 and 2000. They found "the weighted geographical centroid of the overwintering population of the majority of species has shifted in a northeasterly direction, perpendicular to winter isotherms," with overall 20-year shifts ranging from 30 to 119 km. In addition, they report, "when the dataset for each species was split into 10 parts, according to the mean temperature of the sites, responses are much stronger at the colder extremities of species ranges." They found, "at warmer sites, there was no palpable relationship between changes in bird numbers and changes in temperature." They conclude, "range expansions rather than shifts are occurring" as the planet warms.

Maclean *et al*. note the commonly used climate-envelope approach to predicting warming-induced species migrations "essentially assumes that as climate alters, changes at one margin of a species' range are mirrored by those at the other, such that approximately the same 'climate space' is occupied regardless of actual climate," whereas the evidence suggests "that this may not be the case: climate space can also change."

Maclean *et al*. further write, "it is actually not surprising that responses to temperature appear only to be occurring at the colder extremities of species ranges," for "it has long been known that it is common for species to be limited by environmental factors at one extremity, but by biological interactions at the other," citing Connell (1983) and Begon *et al*. (2005). They conclude it is likely "the warmer extremities of the species ranges examined in this study are controlled primarily by biotic interactions, whereas the colder margins are dependent on temperature."

In a model-based study, Jensen *et al*. (2008) state "global climate change is expected to shift species ranges polewards, with a risk of range contractions and population declines of especially high-Arctic species," citing the Arctic Climate Impact Assessment (ACIA, 2005). To evaluate this claim, they constructed species distribution models for the Svalbard-nesting pink-footed goose (*Anser brachyrhynchus*), in order to "relate their occurrence to environmental and climatic variables." They used the most parsimonious of the models to "predict their distribution under a warmer climate scenario," based on "mean May temperature, the number of frost-free months and the proportion of moist and wet moss-dominated vegetation in the area," the latter being "an indicator of suitable feeding conditions."

They found global warming "will have a positive effect on the suitability of Svalbard for nesting geese in terms of range expansion into the northern and eastern parts of Svalbard which are currently unsuitable." They also note this result does not even consider whether glaciers will decrease in size and expose still more potential nest sites. Thus they conclude by stating increased temperatures could help the population of pink-footed geese, as "elongation of the frost-free season in Svalbard may relax their dependence on the acquisition of body stores before arrival (so-called 'capital' breeding, *sensu* Drent and Daan, 1980), so that geese will have more time to acquire the necessary resources upon arrival and still breed successfully," noting "both factors are likely to have a positive effect on the population growth."

Zuckerberg *et al*. (2009) "used the New York State Breeding Birds Atlas, a statewide survey of 5,332 25-km^2 blocks surveyed in 1980–1985 and 2000–2005, to test several predictions that the birds of New York State are responding to climate change." They found "all bird species (n = 129) included in this analysis showed an average northward range shift in their mean latitude of 3.58 km." Citing a number of other studies, the researchers conclude, "the repeated

pattern of a predicted northward shift in bird ranges in various geographic regions of the [Northern Hemisphere] provides compelling evidence that climate change is driving range shifts." This provides compelling evidence Earth's birds did precisely what they should have done, over the period of Zuckerberg *et al*.'s study, in order to maintain a strong presence on the planet in the face of the rising temperatures (natural or anthropogenic) of that period.

Hockey and Midgley (2009) write, "in the influential fourth assessment report of the Intergovernmental Panel on Climate Change, Rosenzweig *et al*. (2007) tested several thousand time-series data sets for changes in species behavior and geographic range consistent with climate change, reaching the conclusion that it is very likely that climate change is driving changes in natural biological systems." They note, "the use of such large data sets in meta-analyses may discourage the close inspection of observations and result in naively misattributing observed shifts to climate when other explanations may be more parsimonious."

To test this hypothesis, Hockey and Midgley "collated information about recent range changes in South African birds, specifically indigenous species that have colonized the Cape Peninsula, at the southwestern tip of Africa in the Western Cape province, since the 1940s," where they state there have been "widespread anthropogenic changes of many kinds to the landscape, including urbanization, commercial afforestation and the introduction and spread of invasive alien trees, most of which occurred before climate change accelerated in the 1970s."

The two researchers found the colonization events "concur with a 'climate change' explanation, assuming extrapolation of Northern Hemisphere results and simplistic application of theory," but "on individual inspection, all but one may be more parsimoniously explained by direct anthropogenic changes to the landscape than by the indirect effects of climate change." Also, "no *a priori* predictions relating to climate change, such as colonizers being small and/or originating in nearby arid shrub-lands, were upheld."

The South African scientists state their work suggests "observed climate changes have not yet been sufficient to trigger extensive shifts in the ranges of indigenous birds in this region, or that *a priori* assumptions are incorrect." Either way, they continue, "this study highlights the danger of naive attribution of range changes to climate change, even if those range changes accord with the predictions of climate-change models," because "misattribution could distract conservationists from addressing pressing issues involving other drivers of biodiversity change such as habitat transformation, and obscure important lessons that might be learned from the dynamics that pertain to such changes."

Tyrberg (2010) compared fossil avifaunas of the Last Interglacial (LIG), about 130,000 to 117,000 years ago from multiple sites around the world to the modern avifaunas found in those locations. During much of this time interval, the globe was about 2°C warmer than it is today, and it was up to 10°C warmer in much of the Arctic. For fossil faunas, only species that still exist were included in the comparisons, because during the cold period of the last glacial, which followed the LIG, many species went extinct due to the cold, and climate tolerance can be determined reliably only for living species.

Based on the areal distributions of fossil avifaunas in different parts of the world, regions were delineated in which many of the identified species coexisted. If it was found the same sets of species share the same common ranges today, it was concluded the avifauna, as a whole, did not respond to any significant degree to the warmer temperatures of the LIG.

For sites that were about 2°C warmer during the LIG—including four sites in Florida, one in Alaska, two in Germany, and one in New Zealand—species present during the LIG were found to be the same as those that inhabit those regions today. At a site in Wales, however, where LIG temperatures were a full 4°C warmer than today, the fossil avifauna was similar to the current avifauna of Spain and Portugal, indicating the fossil avifauna had located themselves further northward during the LIG in response to the much greater warmth of that period. And in another exception to the study's primary findings of similar faunal structures, the LIG avifauna at a site in North Africa (which is now desert, with no birds present) was similar to that of the area south of the desert today, indicating—in light of the fact that during the LIG the Sahara desert received much more rainfall than it does currently—precipitation was the overriding factor determining both the current and fossil avifauna choice of territories.

Tyrberg concludes, "as for the effect of the generally warmer climate during the LIG it seems clear that differences on the order of 2°C or less, both on land and in sea-surface temperatures, are barely, if at all, detectable in the avifaunas."

Popy *et al*. (2010) employed data from two bird atlas surveys performed on a 1 km by 1 km grid (the first in 1992–1994 and the second in 2003–2005) in

an alpine valley in the Italian Piedmont in search of evidence for an upward shift in the ranges of 75 bird species (68 of which were detected in both surveys) over this period, during which time the region's mean air temperature rose by 1.0°C. They found "the number of species whose mean elevation increased (n = 42) was higher than the number whose mean elevation decreased (n = 19), but the overall upward shift [29 m] was not significantly different from zero." In addition, they state even the 29-m increase was "smaller than would be expected from 'climatic envelope' models," as the "1.0°C increase in temperature would be equivalent to *c.* 200 m in elevation, based on an average gradient of -0.5°C per 100 m." In addition, they write, "at the European scale, no overall expansion or contraction of the distributions of the studied species was detected." Popy *et al.* conclude, "until a better understanding of the underlying mechanisms is achieved, predictions based only on 'climate envelope' models should be either validated or considered cautiously."

Using the same sampling techniques employed by Terborgh and Weske (1975) in 1969, and working at five of the nine localities studied by those earlier investigators, Forero-Medina *et al.* (2011) resampled bird communities at five elevations (690, 1310, 1570, 1970, and 2220 meters) within the Reserva Comunal El Sira on the Cerros del Sira massif in Peru some 41 years later, in 2010. They sought to determine what changes might have occurred in the elevations of the several species encountered at the two sampling times. Of the 55 species encountered in both sampling periods, 36 had moved up in elevation, 12 had moved down, and seven had not moved in either direction, resulting in an average upward shift of 49 meters for the 55 bird species over the 41-year period. They describe this change in elevation as being "significantly smaller" than the 152-meter increase one would have expected from the amount of warming experienced throughout the region between the times of the two studies.

In an attempt to determine to what extent tropical and subtropical birds from lower latitudes may have been making their way northwards in response to regional warming since the mid–1970s, Rappole *et al.* (2011) conducted a three-year field study on ranch land of the Welder Wildlife Refuge along a 30-km stretch of the Aransas River in southeastern Texas, which they say is located "at the northern end of the New World subtropics." Their findings indicate "range change is occurring at a rapid rate for tropical, subtropical, and warm desert birds in Texas." They report, "comparisons between former (1974) and current avian distributions for the region show significant breeding range extension of 40–220 km to the north, northeast or east for at least 68 species, many of which cross major biogeographic boundaries." They conclude "change in key parameters of habitat, e.g. seasonal food availability, as affected by factors related to climate change, e.g. mean annual precipitation, temporal distribution of precipitation (monthly means), or monthly means for nighttime-low temperatures during the breeding season, provide the most likely explanations for observed range extensions."

As for the single overriding "environmental factor associated with avian range shift in South Texas," Rappole *et al.* identify "change in mean annual temperature," as documented by Norwine and John (2007). They report the movement of this "large segment of the subtropical avian community into temperate habitats has not been met with a corresponding shift of temperate species as had been predicted by a number of models." Quite to the contrary, they continue, "the communities now overlap, creating, in effect, novel communities." These new communities possess a greater biodiversity than the ones that existed there prior to the arrival of the many new tropical and subtropical bird species.

The findings cited in this section make it clear that where confirmed regional warming over the time periods has been investigated, the vast majority of studies of bird range adjustments have revealed opportunistic poleward expansions of their cold-limited boundaries with little or no change in the locations of their (supposedly) heat-limited boundaries. This behavior is not a matter of massive range reductions or of bird species rushing, or even inching, toward extinction, as is often projected in model-based studies. Instead, the species are fortifying themselves against the possibility of extinction, behaving as resilient evolutionary survivors and colonizing new habitat as it becomes available, strengthening their populations against the myriad challenges associated with environmental change.

5.4.3 Adaptation, Evolution, and Phenotypic Responses

Amid concerns of species extinctions in response to rising temperatures, observational data indicate birds are effectively coping with and adapting to various challenges to their existence, real or perceived, arising from global warming. This section examines adaptive responses pertaining to reproductive success, timing of spring arrival, and trophic mismatches. In brief, the findings discussed here provide ample reason to conclude birds likely will benefit from future global warming.

5.4.3.1 Reproductive Success

Concerns have been expressed that global warming may upset certain reproductive traits in birds, leading to downward trends in the populations of many species. However, as discussed below, birds are well-equipped to respond to warming, often adapting their breeding habits so their reproductive success is frequently higher at warmer temperatures.

Brown *et al.* (1999) studied a population of individually recognizable, color-banded Mexican jays in the Chiricahua Mountains of Arizona (USA) over the period 1971–1998 for trends in egg-laying dates and monthly minimum air temperatures. Over this 29-year period, they determined the date of first nest construction occurred 10.8 days earlier, and the date of first clutch came 10.1 days earlier. These changes were associated with significant upward trends in monthly minimum temperature in the study area; in many bird species "breeding is timed so as to have young in the nest when the principal food of the nestlings is at its peak." With warmer minimum temperatures occurring earlier over their study period, they suggest this climatic trend could be producing an earlier abundance of such food, which would help explain the earlier egg-laying date.

The researchers also identified a second way in which earlier-occurring warmer night temperatures might lead to earlier breeding dates in birds: by alleviating thermal stresses on females on cold nights. Citing several studies that had revealed similar breeding trends in European birds, they suggest the "recognition of similar trends on both continents in very different environments is consistent with the interpretation that some avian populations are already responding to climate changes in the last 29 years or so." These widespread changes are positive in nature, for not only are bird ranges increasing in size as air temperatures rise, the temporal availability of food needed to sustain important life processes is advancing in synchrony with the timing of egg-laying.

Visser *et al.* (2003) examined laying dates for 24 populations of great and blue tits (*Parus major* and *Parus caeruleus*, respectively) in six European countries from 1979 to 1998, during which time several (but not all) of the locations studied exhibited increases in near-surface air temperature. Results indicated "the phenological response to large-scale changes in spring temperature varies across a species' range, even between populations situated close to each other." They also report "this variation cannot be fully explained by variation in the temperature change during the pre- and post-laying periods." Their results "show the value of replicating population studies across parts of a species' range, as the effects of climate change may differ, even within a single species, on a small geographical scale."

Halupka *et al.* (2008) documented various breeding parameters of reed warblers (long-lived passerine birds that winter in Africa but breed in the reed beds of marshlands in the Palaearctic) during 12 breeding seasons (1970–1973, 1980–1983, 1994, 2003, and 2005–2006) and compared trends in what they measured with concomitant trends in mean monthly temperatures. They found temperatures in the mean breeding season (April-August) increased significantly between 1970 and 2006, as did the mean temperature of each individual month of the breeding season, with the average temperature for the May-July period rising by 2°C. Egg-laying started three weeks earlier in 2005 and 2006 than in 1970 (as assessed by the first-egg date of the earliest pair of breeding birds), and the median first-egg date shifted forward by 18 days.

The end of egg-laying, however, did not change significantly in either direction, so there was a corresponding increase in the length of the egg-laying period, and with this longer laying period available to them, more birds were able to rear second broods. In the 1970s and 1980s, for example, the Polish researchers report, "only about 0–15% of individuals

laid second clutches," but "between 1994 and 2006 up to 35% of birds reared second broods." In addition, they report, "during seasons with warm springs, early nests were better protected by being hidden in newly emerged reeds," and "as a result, these nests suffered fewer losses from predation." They conclude, "the studied population of reed warblers benefits from climate warming."

Based on bird-ringing records spanning 41 years (1964–2004), Husek and Adamik (2008) "documented shifts in the timing of breeding and brood size in a long-distance migrant, the red-backed shrike (*Lanius collurio*) from a central European population." They compared their results with the climatic history of the region over the same period. They determined temperatures in May increased significantly over the period of their study, and "in line with this increasing May temperature" there was "a 3- to 4-day shift towards earlier breeding." This pattern, they write, "is consistent with the results of similar studies on other long-distance migrating songbirds (e.g., Dunn, 2004)." In addition, they report, there was "an increase in brood size by approximately 0.3 nestlings since 1964." They state, "given that early broods are usually larger (Lack, 1968; this study) and that they have a higher nest success (Muller *et al.*, 2005), this may have a positive effect on future population increases as the temperature continues to rise."

After observing two second clutches in a newly established population of tree swallows in the Shenandoah Valley of Virginia (USA), Monroe *et al.* (2008) monitored all late nests in the following two breeding seasons to see what they could learn about the phenomenon. This revealed, "among all females nesting in the early breeding rounds of 2006 and 2007, 5% of birds with successful first clutches later laid second clutches." The mean productivity for double-brooded females for 2006–2007 was 4.4 ± 1.3 fledglings from first clutches and 3.4 ± 0.8 from second clutches, so "double-brooded females significantly increased their total annual productivity compared to birds nesting only in the early rounds of breeding." The productivity of the double-brooded females was approximately 75 percent greater than that of the single-brooded females. Monroe *et al.* conclude, "in general, late summer and fall nesting among North American birds is underappreciated and may be increasing due to global warming," citing Koenig and Stahl (2007).

Dyrcz and Halupka (2009) examined long-term responses in the breeding performance of Great Reed Warblers living on fish ponds near Milicz in southwest Poland during various years from 1970 to 2007 (1970–1974, 1981–1984, 1997, and 2004–2007), over which period mean temperatures during the egg-laying months of the species (May–July) rose by 2.2°C, from 15.3 to 17.5°C. The two researchers found a "significant advancement in both earliest and annual median first-egg-laying dates" that "correlated with temperature increases early in the season." Latest first-egg-laying dates remained unchanged, as did several other breeding statistics, including clutch size, nest losses, and number of young per nest. Consequently—and contrary to a Bavarian population of Great Reed Warblers that also advanced its latest first-egg-laying date—the Polish bird population expanded its breeding season in response to regional warming, whereas the Bavarian birds merely shifted theirs, as documented by Schaefer *et al.* (2006).

Dyrcz and Halupka conclude, "the studied population does not benefit from climate warming (as found in Bavaria), but apparently does not suffer," reiterating "the Great Reed Warbler has adapted well ... by shifting the timing of breeding." The results of their study, they state, "do not confirm the prediction of Bairlein and Winkel (2000) that long-distance migrants would suffer due to climate change." In addition, they write, a comparison of their data with that of the Bavarian population "provides evidence that different populations of the same species can adapt in different ways to climate change," noting "this was also previously found for woodland species," citing Visser *et al.* (2002) and Sanz (2003).

Wesolowski and Cholewa (2009) investigated evidence for climate warming in Bialowieza National Park of East Poland over the period 1975–2007 to determine "whether local populations of four sedentary birds (*Sitta europaea, Poecile palustris, Cyanistes caeruleus, Parus major*) advanced their breeding phenology during that time, and how breeding phenology was affected by temperature variation during the period preceding egg laying." According to the authors, "mean yearly temperatures varied strongly across years, with a significant warming (~1°C) trend," and "in all species the onset of breeding was vary variable across years (up to 30 days), as birds started breeding earlier in springs with higher temperatures in the pre-laying period." They note the spring of 1990—when February and March were extremely warm with "mean temperatures +5°C higher than these months' averages, equivalent to the 'worst' IPCC warming scenario"—served as a natural experiment, showing "what would happen when the late winter/early spring period got substantially warmer." They found "all four species were able to

react to this challenge by advancing the onset of breeding to unusually early dates that are usually found only in the Mediterranean populations."

The two researchers write, "the ability to react even in these extreme conditions shows that the range of phenotypic plasticity in these birds is far greater than normally observed, and suggests that there is still unexpressed potential in lay date flexibility." They therefore conclude, "local birds are already prepared to cope with envisaged warming, suggesting that there is no need for new response mechanisms." In addition, they state this phenomenon is "clearly noticeable among different groups of organisms in Bialowieza National Park (e.g. timing of bud burst in trees, Wesolowski and Rowinski, 2006, 2008; development of herbs on the forest floor, Falinski 2001, Sparks *et al.*, 2009)," and they thus also conclude, "birds, trees and herbs in this primeval forest apparently 'read' environmental cues in a similar way and react to them in a comparable fashion," probably because "they have been exposed to the same vagaries of local climate over ages if not millennia, and there was plenty of time to match phenology of interacting species with one another."

Thomas *et al.* (2010) note "the timing of annual breeding is a crucial determinant of reproductive success, individual fitness, and population per-formance, particularly in insectivorous passerine birds," because "by synchronizing hatching with the narrow time window of maximal food abundance, parents can enhance their reproductive success through an increase in offspring growth rate and body condition, survival to fledging, and subsequent recruitment into the breeding population." They studied two populations of blue tits in northern Corsica (Muro and Pirio) to determine "how laying date is related to spring temperatures and vegetation phenology." These two factors were assumed to figure highly in determining the peak period of blue tit food abundance (caterpillars). They discovered "Blue Tits use a cue system that is context specific to fine-tune laying dates to match local conditions both on a spatial (habitat) scale and on a temporal (inter-annual) scale," and their "reliance on both tempera-ture and phenology when breeding late in the season, as occurs in most populations where tits have been intensively studied north of the Mediterranean region, satisfactorily explains how these populations can advance breeding in response to rising spring temperatures while maintaining a relatively large variation in the onset of breeding on a local spatial scale."

Thomas *et al.* acknowledge, "if a single environmental feature [such as temperature] were responsible for the timing of breeding, climate change could cause a severe decline in breeding success, with negative demographic consequences." However, they state they "have not detected any consistent mismatch between Blue Tit breeding dates and caterpillar peak [abundance] dates over the 14 and 21 years for which they have data for Muro and Pirio, respectively." Their findings, they conclude, "offer some hope that breeding populations will respond well to global warming."

Barnagaud *et al.* (2011) note "deciphering the effects of climatic conditions on population dynamics is of major importance in understanding how organisms are likely to be affected by climate changes." Toward that end, they "used broad scale annual censuses of adult and young Black Grouse in the French Alps between 1990 and 2007 to test whether the breeding success of the species is affected by inter-annual climatic variation and long-term climate change," based on "annual counts of Black Grouse hens and chicks carried out by the French Mountain Galliforms Observatory on 58 counting sites," where "counts were performed on the same sites and areas from one year to another, with the same operators."

They note "the Alps are currently undergoing a significant global change in climatic conditions, with warmer temperatures and drier conditions, especially in winter, that reflect particularly well such large scale processes as the NAO [North Atlantic Oscillation]," citing Beniston *et al.* (1997), Giorgi *et al.* (1997), and Beniston (2005, 2006). They determined "the [current] optimal weather conditions for the reproduction of the Black Grouse in the French Alps correspond to average winter NAO values for the last 30 years," which suggests, they write, "the species has adapted to more frequent positive NAO anomalies in the last decades, i.e., to a warmer and drier climate."

Noting "neither the numbers of hens nor the breeding indexes have declined during the last 18 years," they further state "this result is consistent with recent reports (Storch, 2007) suggesting that the alpine populations of Black Grouse which declined during most of the twentieth century (Magnani, 1987) have stabilized in the past two decades, despite the climate warming threat." They point out "this absence of decline agrees with community-level studies showing lower-than-expected effects of climate change on alpine birds (Archaux, 2004)." The seven scientists also say their results indicate "Black Grouse have until now been able to track climatic trends

towards a warmer and drier climate," and they "appear to be more threatened by declines in the availability of suitable areas and changes in habitat structure than by direct effects of climate warming on [their] reproduction." Thus, they conclude, "even a highly specialized mountain species can track rapid climate changes without decreasing its productivity, at least within the limits of current climate changes."

Weimerskirch *et al.* (2012) write, "in marine systems, wind is a major component of the environment, and climate change-induced alterations in oceanic wind regimes and strength have already occurred and are predicted to increase." With respect to what has "already occurred," they note "over the past fifty years, Southern Hemisphere westerlies have shifted poleward and increased in intensity," which could affect "the movement or distribution of wind-dependent species, such as migratory land birds or pelagic seabirds." The latter, the authors note, "rely extensively on wind to move at low costs between breeding and foraging sites," citing Weimerskirch *et al.* (2000) and Wakefield *et al.* (2009).

Weimerskirch *et al.* analyzed the possible influence of wind conditions over the Southern Ocean on the foraging ecology and life-history traits of the wandering albatross (*Diomedea exulans*), one of the most wide-ranging pelagic seabirds, employing data on the duration of their foraging trips and breeding success collected over the period 1966–2010, and foraging performance and body mass collected over the period 1989–2010, focusing on breeding birds from the Crozet Islands, which are situated in the windiest area of the Southern Ocean.

Over the period of time characterized by IPCC as having experienced unprecedented global warming, the foraging range of wandering albatrosses shifted poleward, as the wind also "strongly increased and shifted poleward," the four researchers report. As a result of this change, albatross "rates of travel and flight speeds have increased," a trend they say also has been found to have occurred in the southwestern Indian Ocean over the past 30 years by Peron *et al.* (2010). One important consequence of this change was a 22% decrease in the duration of albatross foraging trips between 1970 and 2008 (a drop from 12.4 to 9.7 days). And as a consequence of this change, they write, "breeding success has improved, and birds have increased in mass by more than one kilogram," a 10–12% increase in body weight for males and females alike.

The above-described real-world wind changes of the past half-century, in the words of Weimerskirch *et al.* (2012), "have affected positively the foraging efficiency and foraging range of wandering albatrosses, ultimately improving breeding success and reducing mortality risks, respectively." As can be estimated from their graph of the pertinent data, albatross breeding success rose from approximately 65% to 77% over the period studied.

5.4.3.2 Spring Arrival Dates

Changes in the date of spring migration arrival date of birds have been viewed by some as a fingerprint of climate change and possibly of species distress. Trends in this parameter should be evaluated with caution before making such a leap.

A case in point is the study of Mills (2005), who used data collected at Long Point Bird Observatory on the north shore of Lake Erie in Ontario, Canada over the period 1975–2000 to investigate whether there had been changes in the timing of spring and autumn migrations of 13 species of birds that might be viewed as ecological responses to global warming. He analyzed for trends in the day of first arrival in the spring, and in the days of first, second, and third quartile arrivals in the spring, as well as like departures in the autumn.

All 13 species exhibited earlier trends in the date

of first arrival in the spring. When subjected to stringent thresholds of statistical analysis, however, only one species was considered to exhibit a definite trend. Spring quartile analyses were not nearly as universal. Only nine of the 13 species trended toward an earlier arrival date, and four trended toward a later arrival date. Of the nine that trended toward an earlier arrival date, only two were statistically significant, leaving the author to conclude, "most individuals of most species cannot conclusively be said to have migrated in 2000 earlier than their 1975 ancestors." Analysis of the quartile means revealed no significant phenological change by bird sex. With respect to autumn trends, five species showed delayed migration, two showed advanced migration, and six exhibited no trend.

Mills writes, "caution should be exercised in drawing broad conclusions about changes in migration phenology" with respect to global warming. He notes, for example, using first arrival dates to characterize migration systems "can be problematic because they are data from one tail of a distribution, they comprise a mostly male population and they may not correlate well with the balance of the migration period." He also notes "changes do not appear to be universal in spring, and change in that season is (a) considerably less than that suggested by [first arrival date] analysis and (b) both less complex and less common than that exhibited during autumn migration."

For studies that show a more conclusive link between temperature and date of bird migration, rather than considering such observations to be a sign of species in distress, an alternative and perhaps more correct interpretation is that such changes are simply a manifestation of the ability of birds to adapt or evolve in response to an environmental perturbation. Model-based claims of species decline typically do not account for adaptative or evolutionary responses, but because birds are winged creatures, it would be expected that under the threat of global warming they might take flight and migrate to cooler regions of the globe as an adaptive measure. Several studies of bird migration dates suggest they may be doing so.

Gordo and Sanz (2006) analyzed a large database of about 44,000 records they assembled from observations at more than 1,300 sites throughout Spain during the period 1944–2004 in a study of the migratory behavior for five trans-Saharan bird species: *Ciconia ciconia* or white stork, *Cuculus canorus* or cuckoo, *Apus apus* or swift, *Hirundo rustica* or barn swallow, and *Luscinia megarhynchos* or nightingale. This phenomenon previously had been

proposed by the country's Instituto Nacional de Meteorologia as "a potential bioindicator of the timing of seasons," the current study of which the two Spanish researchers describe as "the most complete and thorough analysis available for the Mediterranean region."

Gordo and Sanz report "spring arrival dates have tended to advance since the mid–1970s," and "individuals arrived earlier in warmer years," noting "the earlier arrivals related to higher temperatures should be due to the advancement of the spring course in the Iberian Peninsula and consequently the presence of ecological suitable conditions for an early colonization of first breeders." They found "current arrival dates are similar or even seem to be a bit later to those occurring at the beginning of the study period." According to Gordo and Sanz, "the advance in arrival date recorded over the last few decades should be better interpreted as a trend towards re-establishing the timing of migration after an anomalous period of delayed arrivals during the 1970s–1980s," which suggests birds have been adapting to temperature changes throughout the Mediterranean region, where temperatures were likely warmer in the mid–1940s than they were throughout the 1990s and during the first years of the twenty-first century.

Studying the skylark (*Alauda arvensis*), which is migratory in Eastern and Northern Europe but resident in areas with milder winters (such as the UK), Askeyev *et al.* (2009) analyzed the dates of their spring arrival in the Volga-Kama region of the Tatarstan Republic of Russia, using "one of the longest extant records of bird migration in the world," which runs from 1811 to 2008, with sporadic missing years in the first half of the record. They report March temperatures rose about 5.2°C over their study period, but 3.7°C (~70%) of that warming occurred over the final three decades of the nearly two-century-long interval. They also found a corresponding inflection point in the rate-of-advancement of skylark spring arrival-date that was approximately 15 times greater (0.368 day per year) than it was over the study period's first 17 decades (0.024 day per year).

Plotting arrival-date as a function of temperature, they found the inflection point occurred at a mean March temperature of –3.5°C, suggesting a mean rate of advancement of spring arrival-date of 0.5 day per °C for mean March temperature increases below a negative 3.5°C, and a mean rate of advancement of arrival-date of 3.4 days per °C for mean March temperature increases above –3.5°C. That represents close to a seven-fold increase in the rate of

advancement of spring arrival-date upon exceeding this biological "tipping point" temperature.

Askeyev *et al.* conclude, "the nonlinear nature of the relationship between first arrival and temperature suggests that above a critical temperature threshold a much more rapid change in first arrival date will occur." This observation suggests regardless of whether "tipping points" occur in the realm of climatology, they do in fact occur, and in some cases already have occurred, to the benefit of certain of Earth's birds—the hotter it gets, the better they do what they need to do to deal with the evolving situation.

Van Buskirk *et al.* (2012) state, "phenological responses to climate change are well-documented in plants and animals," and "it is widely assumed that much of the shift in phenology is due to facultative changes in the activities or physiologies of individuals induced by environmental conditions, known as phenotypic plasticity." However, they write, "phenotypic plasticity is not the only mechanism that can produce population responses to climate change," noting "gradual or sudden shifts in the selection regime can be triggered by environmental change, and these in turn can alter the genetic composition of populations." They point out "rapid evolved responses to climate change are widely anticipated by evolutionary biologists (Bradshaw and Holzapfel, 2001; Davis *et al.*, 2005; Gienapp *et al.*, 2008; Hoffman and Willi, 2008; Hoffmann and Sgro, 2011), and already have been observed in a few cases (Umina *et al.*, 2005; Bradshaw and Holzapfel, 2008)."

Between June 1961 and August 2006, Van Buskirk *et al.* operated 35 mist nets for five to six days a week on a 10-ha study area on the Powdermill Nature Reserve in Pennsylvania (USA), in order to obtain the data needed to estimate the magnitude of temperature-induced phenotypic plasticity in spring arrival date of 27 species of birds in eastern North America, by recording the effects of annual variation in spring temperature on the behavior of thousands of individuals. They hypothesized that if phenotypic plasticity could not account for the totality of observed shifts in migration phenology over this period, what remained unaccounted for could be attributed, at least partly, to microevolutionary change.

The three researchers report "for 2441 individuals detected in multiple years, arrival occurred earlier during warm years, especially in species that migrate short distances," but the change in phenology predicted "under a model of pure phenotypic plasticity" fell far short of the change in arrival date

they observed, explaining only 13–25% of the climate-induced trend in phenology. Although they acknowledge their approach to the problem "probably underestimates the full scope of plasticity," Van Buskirk *et al.* say their data suggest "part of the response to environmental change [warming] has been caused by microevolution." They also conclude "the estimated evolutionary rates [0.016 haldanes] are plausible."

The three scientists write, "rapid genetic response to climate change is widely seen as a critical component of the kind of adaptation that will be required of many organisms," especially in a world that warms as suggested by the models employed by IPCC. In addition, "the contribution of plasticity will allow individuals to adjust their phenotype to short-term environmental fluctuations, which are projected to increase under most scenarios of climate change." That's good news for birds.

5.4.3.3 Trophic Mismatches

Another concern about the potential effects of global warming is that, as the world warms, mismatches may occur among various life cycle stages of plants, the insects that feed on them, and numerous species of animals, such as birds, that feed on insects and provide them as food for their young, a situation that could spell disaster for some species. This concept has been said by Visser and Both (2005) to constitute an "insufficient adjustment" to climate change. This section investigates the validity of such concerns, finding trophic mismatches are a non-problem in most instances.

Bauer *et al*. (2010) examined the effect of 47 years of warming (1961–2007) on the time of leafing-out of dominant English oak trees (*Quercus robur*) at four research sites in the Czech Republic located in full-grown, multi-aged floodplain forests that had been under no forestry management. The researchers also evaluated the time of appearance of the two most abundant species of caterpillars in the floodplain forests—the winter moth (*Operophtera brumata*) and the tortrix moth (*Tortrix viridana*)—and the first and mean laying dates of two of the ecosystem's most common birds: great tits (*Parus major*) and collared flycatchers (*Ficedula albicollis*).

According to the researchers, "mean annual temperature showed a significant increase of 0.27–0.33°C per decade, with approximately the same magnitude of change during spring at all sites." They also found, "on average (all four sites), the bud burst date for English Oak has advanced by 7.9 days and full foliage by 8.9 days, with approximately the same shifts being recorded for the peak of the beginning and end of frass for herbivorous caterpillars," the observational variable they used to characterize the caterpillars' presence. Last, they determined "the first laying date of Great Tits has advanced by between 6.2 to 8.0 days," and "the mean laying date has advanced by 6.4 to 8.0 days." Similarly, the "Collared Fly-catcher first laying date has advanced by 8.5 to 9.2 days over the past 47 years, and the mean laying date by 7.7 to 9.6 days."

Bauer *et al*. state "trends in the timing of reproduction processes of both bird species are coherent with the trends in development of English Oak and with peak herbivorous caterpillar activity." In this specific food chain, the common shifting of the different organisms' phenological stages toward the beginning of the year "does not appear to have led to mistiming in the trophic food chain."

Citing Visser *et al*. (1998, 2006) and Visser (2008), Matthysen *et al*. (2011) note "the increasing mismatch between great tit *Parus major* laying dates and their caterpillar food supply in the Netherlands has rapidly become a classic example of a lack of adaptation to climate change." However, they report, "other populations of the same bird species have subsequently been shown to advance their laying dates much more strongly" in order to match the earlier spring growth of vegetation that typically occurs during periods of extended warming, citing Cresswell and McCleery (2003) and Charmantier *et al*. (2008).

Matthysen *et al*. "studied the breeding cycle of two sympatric and closely related species, the blue tit *Cyanistes caeruleus* and the great tit *Parus major,* in a rich oak-beech forest," where they had collected data on the breeding biology of the birds from 1979 to 2007 in a 12-hectare plot provided with nest boxes inside the Peerdsbos forest near Antwerp, Belgium. Both bird species were shown to have "advanced their mean first-egg dates by 11–12 days over the last three decades," and "the time from first egg to fledging has shortened by 2–3 days, through a decrease in laying interruptions, incubation time and nestling develop-ment time." As a consequence, they write, "the average time of fledging has advanced by 15.4 and 18.6 days for blue and great tits, respectively, and variance in fledging dates has decreased by 70–75%." Most important, they note, "indirect estimates of the food peak suggest that both species have maintained synchronization with the food supply," and "analyses of within-individual variation show that most of the change can be explained by individual plasticity in laying date, fledging date and nest time." Matthysen *et al*. emphasize "synchronization of the nestling period with the food supply not only depends on first-egg dates but also on additional reproductive parameters including laying interruptions, incubation time and nestling growth rate." As a result of adjustments in these several related phenomena, they report, "both of our study species have been able to maintain synchrony with their food supply in the face of global warming."

Vatka *et al*. (2011) further investigated the possibility global warming may lead to trophic mismatches between the times when birds of temperate and boreal regions require an abundance of food to feed their new hatchlings and the times when that food is available in its greatest abundance, as in the cases of great tits, blue tits, and pied flycatchers in the Netherlands, which require a timely abundance of caterpillars to feed their young (Visser *et al*., 1998; Visser *et al*., 2006; Both *et al*., 2009). Vatka *et al*. note, "the same has not happened with great tits in England (Cresswell and McCleery, 2003) nor with great tits and collared flycatchers in the Czech Republic (Bauer *et al*., 2010)." They describe yet a third type of food supply-and-demand response to warming they recently observed and documented.

Working with data collected in northern Finland over the period 1975–2009 within coniferous, deciduous, and mixed forests of varying ages—including young stands, swamps, and clear cuttings—the three Finnish scientists studied "changes in the timing of breeding in the willow tit (*Poecile montanus*), and the timing of its caterpillar food resource in relation to warming springs," using "generalized linear mixed effect models to study the importance of synchrony between the timing of breeding in willow tits and the caterpillar food availability on the breeding success, measured as nestling survival rate and mean nestling weight." In contrast to prior no change results and poorer synchrony findings, Vatka *et al*. report they not only "found no signs of emerging asynchrony" but that synchrony actually improved during the study, and it had moderate positive effects on breeding success. The observed improvement in synchrony mirrors results from the coal tit in the Netherlands, the authors add, citing Both *et al*. (2009).

Reed *et al*. (2013) studied a wild population of great tits (*Parus major*) in the Netherlands in relation to the phenology of their food supply, noting "great tits rely on caterpillars to feed their chicks and strive to match their breeding time with the pronounced seasonal peak in caterpillar biomass, which enhances offspring survival." The researchers studied this by "using almost four decades of individual-level life-history data from a great tit population." They report warmer springs had indeed "generated a mismatch between the annual breeding time and the seasonal food peak, intensifying directional selection for earlier laying dates." However, they found inter-annual variation in population mismatch had not affected population growth, and they "demonstrated a mechanism contributing to this uncoupling, whereby fitness losses associated with mismatch are counteracted by fitness gains due to relaxed competition." The team of Dutch, French, Norwegian, and U.S. scientists states their findings imply "natural populations may be able to tolerate considerable maladaptation driven by shifting climatic conditions without undergoing immediate declines." They conclude, "our results imply that considerable directional selection might be demographically tolerable on decadal time scales without immediate population declines, effectively buying time for microevolution to restore adaptation."

Burthe *et al*. (2012) "compared phenological trends for species from four levels of a North Sea food web over 24 years [1983–2006] when sea surface temperature (SST) increased significantly," starting with primary producers (phytoplankton), primary consumers (zooplankton), and secondary consumers (sandeels), and finally focusing on five seabird predators—the common guillemot (*Uria aalge*), razor bill (*Alca torda*), European shag (*Phalacrocorax aristotelis*), black-legged kittiwake (*Rissa tridactyla*), and Atlantic puffin (*Fratercula arctica*)—all of which are seabirds that prey on current-year sandeels (*Ammodytes marinus*). The nine researchers say they found "little consistency in phenological trends between adjacent trophic levels, no significant relationships with SST, and no significant pairwise correlations between predator and prey phenologies," which they take as evidence "trophic mismatching is occurring." Yet in spite of the supposed trophic mismatches discovered over the course of their research, Burthe *et al*. report, "to date, there is no evidence that these changes are impacting on the breeding success of any of the seabird species."

Although much remains to be learned about this topic, it is clear trophic mismatches, thought to be initiated by global warming, need not produce negative responses from bird populations. Many bird species may not be affected at all, and others may even benefit from such a climate change.

5.4.3.4 Other Responses

Additional adaptive or evolutionary responses to warming, not discussed in the prior subsections, have been identified in the literature for birds, each of which suggests birds are adequately suited to withstand any of the temperature changes predicted to accompany the future rise in atmospheric CO_2.

In regard to the challenges migratory animals may face due to potential changes in climate, Dias *et al*. (2011) write, "existing phenotypic plasticity *per se* may allow, within certain limits, the persistence of species and populations (even if in suboptimal circumstances), gaining time for selection to act, or for more favorable environmental conditions to be restored," noting "there is strong evidence that recent climate changes may have already impacted migratory behavior" as it pertains to birds, citing Fiedler (2003) and Newton (2008).

Dias *et al*. evaluated individual flexibility in the migration strategies of a highly pelagic seabird, the Cory's shearwater (*Calonectris diomedea*). They deployed leg-mounted geolocators weighing approximately 3.6 grams at the end of the breeding seasons of 2006, 2007, and 2008, recovering them in the early stages of the subsequent breeding seasons, to track the migration of 57 of the birds that spent the breeding season at Selvagem Grand Island (30°02' N, 15°52' W). The five researchers report 14 birds that were tracked for more than one non-breeding season "showed a remarkable capacity to change winter destinations between years," with some shifting all the way from the South Atlantic to the North Atlantic, and from the Atlantic Ocean to the Indian Ocean. They found individual birds "also showed flexibility in stopover behavior and migratory schedule." Dias *et al*. conclude Cory's shearwaters are in a good position "to face the consequences of a changing environment," adding, "whether Cory's shearwaters are unusual in this respect, or whether future analyses will reveal that flexibility in migration strategies is a more general trait of marine migratory fauna is something that repeated tracking of individuals in coming years should clarify."

According to Forero-Medina *et al*. (2011), "the tropics contain most of the world's species at risk of extinction (Pimm and Jenkins, 2010), yet few studies evaluate the response of tropical species to climate disruption other than through modeling (Jetz *et al*., 2007; Marini *et al*., 2009; La Sorte and Jetz, 2010)." Using the same sampling techniques employed by Terborgh and Weske (1975) in 1969, and working at five of the nine localities studied by those earlier investigators, Forero-Medina *et al*. (2011) resampled bird communities at five elevations (690, 1310, 1570, 1970, and 2220 meters) within the Reserva Comunal El Sira on the Cerros del Sira massif in Peru 41 years later in 2010, seeking to determine what changes might have occurred in the elevations of the several

species encountered at the two sampling times. Of the 55 species encountered in both sampling years, the four researchers report 36 had moved up in elevation, 12 had moved down, and seven had not moved in either direction, resulting in an average upward shift of 49 meters for the 55 bird species over the 41-year period. They describe this change in elevation as "significantly smaller" than the 152-meter increase one would have expected from the amount of warming experienced throughout the region between the times of the two studies.

Forero-Medina *et al.* note more than one mountain had been involved in the initial study of Terborgh and Weske (1975), and "the same bird species exhibited different elevation ranges on different mountains, indicating considerable flexibility in the occupancy of habitat and independence of temperature (Diamond, 1970; Terborgh, 1985)." Therefore, they write, "the limited upward elevational shifts reported here are unlikely to be simple responses to increased temperature *per se*." Instead, they suggest, "birds are likely responding to gradual changes in the nature of the habitat or availability of food resources through their dependence on long-lived elements of the ecosystem (trees), and how the species' competitors respond." They note "the rate of migration of trees is less (45%) than that predicted from the temperature increase of the region," and "similar lags in the response of trees may be occurring at the Sira, accounting for the lag in response of birds."

Put another way, Forero-Medina *et al.* conclude, "instead of being directly dependent on temperature, birds may be responding to gradual changes in the nature of their habitat or availability of food resources, and presence of competitors," so "endothermy [the ability of certain animals to control their body temperature] may provide birds with some flexibility to temperature changes and allow them to move less than expected."

Van Buskirk *et al.* (2010) write, "recent climate change has caused comparatively rapid shifts in the phenology and geographic distributions of many plants and animals," but "there is debate over the degree to which populations can meet the challenges of climate change with evolutionary or phenotypic responses in life history and morphology," which for a warming climate includes a reduction in body size. They devised an experimental strategy to explore the issue further, studying the body sizes of birds captured in mist-nets and traps between June 1961 and November 2006 at the Powdermill Nature Reserve, a field station operated by the Carnegie

Museum of Natural History in Pennsylvania (USA) at a location broadly representative of bird communities in the Appalachian region of eastern North America. At this location, 35 mist nets were operated five to six days per week during spring and autumn migrations. A reduced number of nets was used during summer, and birds for winter banding were caught in wire traps when the temperature was below freezing.

The three researchers report migrating birds captured at the banding station "have steadily decreasing fat-free mass and wing chord since 1961, consistent with a response to a warmer climate" and confirming "phenotypic responses to climate change are currently underway in entire avian assemblages," where "size was negatively correlated with temperature in the previous year, and long-term trends were associated with the direction of natural selection acting on size over the winter." In addition, they note, "species undergoing the strongest selection favoring small wing chord showed the most rapid long-term declines in wing [size]," which suggests "phenotypic changes are therefore in line with the prevailing selection regime." Noting "in summer, 51 of 65 breeding species had negative slopes of mass against year, 20 of 26 wintering species had negative slopes, 60 of 83 spring migrants had negative slopes, and 66 of 75 autumn migrants had negative slopes," Van Buskirk *et al.* state their results "offer compelling evidence that climate change has already produced observable adaptive shifts in morphology, behavior, and phenology of a great many species," which suggests these birds have evolved a capacity for rapid phenotypic shifts to optimum body mass in response to climate fluctuations.

Additional support for this thesis comes from Carey (2009), who notes "organisms living today are descended from ancestors that experienced considerable climate change in the past," and thus suggests, "species that persist into future climates may be able to do so in part owing to the genetic heritage passed down from ancestors who survived climate changes in the past." She also states, "if climate change were the only new challenge facing birds, one might imagine that many species could become adapted to new conditions and survive with existing population variability and the genetic information that their ancestors used to survive past climate change."

Karell *et al.* (2011) theorize "global climate warming changes the environment of most organisms and is expected to lead to a change in selection pressures with micro-evolutionary consequences that allow the adaptation of organisms to the new environment and thereby long-term population

persistence." They further note, "microevolution in response to climate change has been demonstrated in invertebrate populations (Umina *et al.*, 2005; Balanya *et al.*, 2006)," but "these studies lack information on the mechanisms and selective factors linking particular genotypes to climate."

Karell *et al.* explored "the links between climate change and alteration of the selective regime on a highly heritable phenotypic trait, plumage coloration in the tawny owl (*Strix aluco*), a common bird of prey throughout the temperate regions of Europe." They used data from 1981 to 2008 in a 250-km^2 study area in Southern Finland dominated by mixed forests, agricultural areas, and small freshwater courses, where "plumage coloration was scored using a semi-continuous ordinal scale (range from 4 (grey) to 14 reddish-brown)) on all breeding individuals on each encounter ($N = 1116$ records of 491 individuals) using a standardized and repeatable scoring that shows coloration is independent of age and sex." In addition, they scored museum skin specimens collected between 1915 and 1980; and they extracted the data on all records of adult ringed and recaptured tawny owls in Finland to which color morph (grey or brown) had been assigned during 1961–2008. Finally, they write, "measures of temperature and snow depth from the time window that correlated best with annual tawny owl survival were selected as covariates for further modeling."

The five Finnish researchers determined "brown individuals had lower survival than grey ones as snow cover became deeper" and there was a "lower survival for brown individuals compared with grey ones in cold temperatures," as cooler conditions would be expected to promote a deeper snow cover. Thus they report as snow depth decreased over time in response to warming, "there was a time trend in survival of the color morphs from 1981–2008, in which survival of the grey morph was fairly stable across years, whereas survival of brown individuals improved dramatically towards the end of the time series." They also report this phenotypic change was present on a larger nationwide scale—the increase of the brown morph occurred "all over Finland, involving thousands of individuals," such that "the survival propensities of the morphs have equalized in recent, mild winters."

Karell *et al.* remark the phenotypic change they documented "is unlikely to be caused by genetic drift, because drift is only a major force for changing allele frequencies in small populations." Therefore, "given the strong genetic underpinning of tawny owl morphs," they say they consider the observed pheno-

typic trend in the proportion of the brown morph as "indicative for a shift in gene frequencies." Hence, they conclude, to the best of their knowledge, the results of their study constitute "the first empirical evidence of climate-driven change in selection on a heritable trait," providing a whole new perspective on the potential of Earth's fauna to withstand the challenges of global warming.

Gremillet *et al.* (2012) state little auks (*Alle alle*) are the most numerous seabirds in the North Atlantic, with an estimated population of 40 to 80 million individuals, citing Stempniewicz (2001), and they consume up to 24% of local plankton production, citing Karnovsky and Hunt (2002). The researchers also note the "little auk field metabolic rate is 70% higher than predicted by body mass, and they have very limited capacity to store fat." Consequently, they say, little auks "are predicted to be particularly sensitive to altered feeding conditions," citing Harding *et al.* (2009). More specifically, they write, the recent work of Karnovsky *et al.* (2010) "showed a very strong link between summer SST [sea surface temperature] within the foraging areas of little auks, species composition of local zooplankton communities, and dietary preferences of the birds, whereby colder water contained more larger copepods, which were also preferentially fed upon by little auks," so "birds had to feed on smaller, less profitable copepod species in warmer water." As a result of these observations, they hypothesize "higher SSTs would modify little auk diet, foraging effort, provisioning rates, breeding success and adult survival," which they presume would significantly decline in response to warming.

In an integrative study of the behavior, physiology, and fitness of colonies of little auks at three sites of significantly different temperature—Kap Hoegh, East Greenland (70°43'N, 22°38'W), Hornsund, West Spitsbergen (77°00'N, 15°22'E), and Kongsfjorden, West Spitsbergen (79°01'N, 12°25'E)—Gremillet *et al.* evaluated the effects of ocean warming on little auks across the Greenland Sea over the period 2005–2007. They noted "comparing the ecophysiology of little auks from different colonies subject to contrasting SST regimes at one moment in time" would allow them to "simulate the effect that increasing water temperatures might have on this Arctic species across the 21st century."

"During the study period," the researchers write, "little auks maintained their fitness despite contrasting ocean surface temperatures and copepod availability across the Greenland Sea." Gremillet *et al.* write, "contrary to our hypothesis, the birds

649

responded to a wide range of sea surface temperatures via plasticity of their foraging behavior, allowing them to maintain their fitness levels," indicating "they are successful at dealing with the influence of current climate change in the Arctic." In the concluding sentence of their abstract, the team of nine scientists from eight countries (Canada, Denmark, France, Ireland, Norway, Poland, South Africa, and the United States) writes, "predicted effects of climate change are significantly attenuated by such plasticity, confounding attempts to forecast future effects of climate change using envelope models."

According to Smit *et al*. (2013), "one of the main predictions of bioclimatic envelope models is that populations near the climatic extremes of species' distributions, where thermoregulatory costs are presumably high, are performing sub-optimally and are at greater risk of extinction," citing Thomas *et al*. (2004). However, Smit *et al*. suggest, "if populations are physiologically adapted (genetic variation across generations and/or plastic adjustments) to their respective climates, species may be capable of maintaining high levels of performance throughout their geographic ranges," citing Chown *et al*. (2010) and Glanville *et al*. (2012).

Smit *et al*. investigated the effects of air temperature (T_A) on body temperature (T_B) and the behavior of an arid-zone endotherm, the White-Browed Sparrow-Weaver (*Plocepasser mahali*) at two sites 100 km apart, in the southern Kalahari Desert of South Africa, over two consecutive summer seasons. The four researchers found a relatively large variation in T_B that occurred both within and between populations, suggesting "an arid-zone passerine responds differently to prevailing weather conditions in two locations over its range, and that it also responds to seasonal changes in weather conditions." This further suggests "a species' current range may not be an accurate representation of its climatic tolerance."

"Taken together with the data of Glanville *et al*. (2012)," Smit *et al*. explain, this result "suggests that the thermal physiology of endotherms is far more flexible than previously thought, and could potentially contribute to the adaptation of populations under changing climatic conditions," citing Boyles *et al*. (2011)." They conclude, "when predicting species' responses to climate change, their sensitivity (sensu Williams *et al*., 2008) should be resolved at the population, rather than species, level."

5.5 Insects

- Published research indicates rising temperatures will not likely increase, and may decrease, plant damage from leaf-eating herbivores, as rising atmospheric CO_2 boosts the production of certain defensive compounds in plants that are detrimental to animal pests.

Included among the many animal-related concerns over global warming is the worry there will be an increase in the intensity of herbivore pressure on plants. This section reviews research that has been conducted on this topic, beginning with research regarding aphids and then moths, and then regarding specific kinds of vegetation (herbaceous plants, woody plants, and other plants.

5.5.1 Aphids

We begin our survey of the effects of rising temperature and CO_2 levels on aphids with Ma *et al*. (2004), who conducted detailed experiments on the impacts of high temperature, period of exposure, and developmental stage on the survival of the aphid *Metopolophium dirhodum*, which they say "is the most abundant of the three cereal aphid species in Germany and central European countries." This protocol revealed "temperatures over 29°C for 8 hours significantly reduced survival, which decreased generally as the temperature increased." The researchers also determined "exposing aphids to 32.5°C for 4 hours or longer significantly reduced survival," and "mature aphids had a lower tolerance of high temperatures than nymphs." Ma *et al*. conclude, "global warming may play a role in the long-term changes in the population abundance of *M. dirhodum*." Specifically, "an increase in TX [daily average temperature] of 1°C and MaxT [maximum daily temperature] of 1.3°C during the main period of the aphid population increase would result in a 33% reduction in peak population size," and "an increase in TX of 2°C and MaxT of 2.6°C would result in an

early population collapse (74% reduction of population size)."

Adler *et al*. (2007) examined the effects of long-term experimental warming on an aphid-sagebrush (*Obtusicauda coweni-Artemisia tridentata*) interaction out-of-doors in the field at the Rocky Mountain Biological Laboratory, Colorado (USA), where five of ten 3-m x 10-m plots in an ungrazed montane meadow were warmed by overhead infrared heaters that provided a continuous heat flux of 22 W/m^2 to the plots ever since 1993. Working at this facility for three consecutive years (1996–1998), they determined how warming affected aphid density, and they used additional observations, manipulative experiments, and chemical analyses to explore some of the mechanisms that might mediate potential effects of warming on aphid density.

The four researchers report, "in no year did we find support for the prediction that warming increased aphid abundance or population growth." They found "warming decreased aphid density on sagebrush in one year, tended to decrease aphids in a second year, and had no effect in a third year." In the first of these years (1997), "there were over 3 times as many aphids per stalk in control compared to warmed plots," and "the proportion of stems infested was almost twice as high." Furthermore, "in enclosures that excluded predators, warming decreased aphid population growth by an amount consistent with observed field density differences," and in a separate snow-manipulation experiment in unheated plots, they found "the timing of snowmelt did not affect aphid density." Adler *et al*. conclude, "long-term studies within a natural community context may provide counterexamples to the prediction that warming will increase herbivore pressure on plants."

Much more research has been conducted on the direct and indirect response of aphids to rising atmospheric CO_2. Docherty *et al*. (1997), for example, grew beech and sycamore saplings in glasshouses maintained at atmospheric CO_2 concentrations of 350 and 600 ppm, while groups of three sap-feeding aphid species were allowed to feed on the saplings. Overall, the elevated CO_2 had few significant effects on aphid feeding and performance. There was, however, a non-significant tendency for elevated CO_2 to reduce the individual weights and population sizes of the aphids, suggesting future increases in the air's CO_2 content might reduce aphid feeding pressures on beech and sycamore saplings, and possibly other plants as well.

Whittaker (1999) reviewed the scientific literature on population responses of herbivorous insects to atmospheric CO_2 enrichment, concentrating on papers resulting from relatively long-term studies. The only herbivorous insects found to exhibit population increases in response to elevated CO_2 exposure were those classified as phloem feeders; specifically, aphids. Although this finding appeared to favor aphids over plants, additional studies came to different conclusions.

Newman *et al*. (1999) grew tall fescue plants for two weeks in open-top chambers maintained at atmospheric CO_2 concentrations of 350 and 700 ppm before inoculating them with aphids (*Rhopalosiphum padi*). After nine additional weeks of differential CO_2 exposure, the plants were harvested and their associated aphids counted. Although elevated CO_2 increased plant dry matter production by 37%, this did not result in similar increases in aphid colonization. The plants grown in air of elevated CO_2 concentration contained far fewer aphids than the plants grown in ambient air.

Percy *et al*. (2002) grew the most widely distributed tree species in all of North America—trembling aspen—in 12 30-m-diameter FACE rings in air maintained at ambient CO_2 and O_3 concentrations, ambient O_3 and elevated CO_2 (560 ppm during daylight hours), ambient CO_2 and elevated O_3 (46.4–55.5 ppb during daylight hours), and elevated CO_2 and O_3 over each growing season from 1998 through 2001. Throughout the experiment they assessed a number of the young trees' growth characteristics and the responses of the sap-feeding aphid *Chaitophorus stevensis*, which they say "infests aspen throughout its range." By itself, elevated CO_2 did not affect aphid abundance, but it increased the densities of natural enemies of the aphids, which over the long term would tend to reduce aphid numbers. Also, by itself, elevated O_3 did not affect aphid abundance, but it had a strong negative effect on natural enemies of aphids, which over the long term would tend to increase aphid numbers. When both trace gases were applied together, elevated CO_2 completely counteracted the reduction in the abundance of natural enemies of aphids caused by elevated O_3. Hence, elevated CO_2 tended to reduce the negative impact of aphids on trembling aspen in this study.

Holopainen (2002) reviewed the scientific literature addressing the joint effects of elevated concentrations of atmospheric O_3 and CO_2 on aphid-plant interactions. Compiling the results of 26 pertinent studies, Holopainen found atmospheric CO_2 enrichment increased aphid performance in six studies, decreased it in six studies, and had no significant impact on it in the remaining 14 studies. Similar

results were found for aphid-plant interactions in the presence of elevated O_3 concentrations.

Newman (2003) reviewed the scientific literature on aphid responses to concurrent increases in atmospheric CO_2 and air temperature and also investigated the subject via the aphid population model of Newman *et al*. (2003). He concluded when the air's CO_2 concentration and temperature are both elevated, "aphid population dynamics will be more similar to current ambient conditions than expected from the results of experiments studying either factor alone." The only general conclusion that can be drawn, Newman states, is "insect responses to CO_2 are unlikely to all be in the same direction." Nevertheless, "the lack of a simple common phenomenon does not deny that there is some overriding generality in the responses by the system."

Awmack *et al*. (2004) conducted a two-year study at the Aspen FACE site near Rhinelander, Wisconsin (USA) of the individual and combined effects of elevated CO_2 (+200 ppm) and O_3 (1.5 x ambient) on the performance of *Cepegillettea betulaefoliae* aphids feeding on paper birch trees, in what they call "the first investigation of the long-term effects of elevated CO_2 and O_3 atmospheres on natural insect herbivore populations." At the individual scale, they report, "elevated CO_2 and O_3 did not significantly affect [aphid] growth rates, potential fecundity (embryo number) or offspring quality." At the population scale, "elevated O_3 had a strong positive effect," but "elevated CO_2 did not significantly affect aphid populations."

In comparing their results with those of prior related studies, the three scientists report "the responses of other aphid species to elevated CO_2 or O_3 are also complex." In particular, they note "tree-feeding aphids show few significant responses to elevated CO_2 (Docherty *et al*., 1997), while crop-feeding species may respond positively (Awmack *et al*., 1997; Bezemer *et al*., 1998; Hughes and Bazzaz, 2001; Zhang *et al*., 2001; Stacey and Fellowes, 2002), negatively (Newman *et al*., 1999) or not at all (Hughes and Bazzaz, 2001), and the same species may show different responses on different host plant species (Awmack *et al*., 1997; Bezemer *et al*., 1999)." In summarizing their observations, they state "aphid individual performance did not predict population responses to CO_2 and O_3," and they conclude, "elevated CO_2 and O_3 atmospheres are unlikely to affect *C. betulaefoliae* populations in the presence of natural enemy communities."

In a study of a different aphid (*Chaitophorus stevensis*) conducted at the same FACE site, Mondor *et al*. (2004) focused on pheromones, which they note "are utilized by insects for several purposes, including alarm signaling," and which in the case of phloem-feeding aphids induces high-density groups of them on exposed leaves of trembling aspen trees to disperse and move to areas of lower predation risk. In this experiment the four treatments were: control (367 ppm CO_2, 38 ppb O_3), elevated CO_2 (537 ppm), elevated O_3 (51 ppb), and elevated CO_2 and O_3 (537 ppm CO_2, 51 ppb O_3). Within each treatment, several aspen leaves containing a single aphid colony of 25 ± 2 individuals were treated in one of two ways: (1) an aphid was prodded lightly on the thorax so as to not produce a visible pheromone droplet, or (2) an aphid was prodded more heavily on the thorax and induced to emit a visible pheromone droplet, after which, in the words of the scientists, "aphids exhibiting any dispersal reactions in response to pheromone emission as well as those exhibiting the most extreme dispersal response, walking down the petiole and off the leaf, were recorded over 5 min."

Mondor *et al*.'s observations were striking. They found the aphids they studied "have diminished escape responses in enriched carbon dioxide environments, while those in enriched ozone have augmented escape responses, to alarm pheromone." They report, "0% of adults dispersed from the leaf under elevated CO_2, while 100% dispersed under elevated O_3," indicating the effects of elevated CO_2 and elevated O_3 on aphid response to pheromone alarm signaling are diametrically opposed. Elevated O_3 (which is detrimental to vegetation) helped aphids escape predation and therefore live to do further harm to the leaves they infest, but elevated CO_2 (which is beneficial to vegetation) made it more difficult for aphids to escape predation and thereby provided an additional benefit to plant foliage. Mondor *et al*. state this phenomenon may be of broader scope than what is revealed by their specific study, noting other reports suggest "parasitoids and predators are more abundant and/or efficacious under elevated CO_2 levels (Stiling *et al*., 1999; Percy *et al*., 2002), but are negatively affected by elevated O_3 (Gate *et al*., 1995; Percy *et al*., 2002)."

Chen *et al*. (2004) grew spring wheat from seed to maturity in high-fertility well-watered pots out-of-doors in open-top chambers (OTCs) maintained at atmospheric CO_2 concentrations of 370, 550, and 750 ppm. Approximately two months after seeding, 20 apterous adult aphids (*Sitobion avenae*) from an adjacent field were placed on the wheat plants of each of 25 pots in each OTC, and 15 pots were left as controls. At subsequent five-day intervals, both

apterous and alate aphids were counted. About one month later, 10 alate morph fourth instar nymphs were introduced onto the plants of each of nine control pots, and for the next two weeks the number of offspring laid on those plants were recorded and removed daily to measure reproductive activity. At the end of the study, the wheat plants were harvested and their various growth responses determined.

The scientists found the introduced aphid populations increased after infestation, peaked during the grain-filling stage, and declined a bit as the wheat matured. On the final day of measurement, aphids in the 550 ppm CO_2 treatment were 32% more numerous than those in ambient air, and aphids in the 750 ppm treatment were 50% more numerous. Alate aphids also produced more offspring on host plants grown in elevated CO_2: 13% more in the 550 ppm treatment, and 19% more in the 750 ppm treatment.

As for the wheat plants, Chen *et al*. report "elevated CO_2 generally enhanced plant height, aboveground biomass, ear length, and number of and dry weight of grains per ear, consistent with most other studies." With respect to aboveground biomass, for example, the 550 ppm treatment displayed an increase of 36%, and the 750 ppm treatment displayed an increase of 50%, in the case of both aphid-infested and non-infested plants.

Chen *et al*. comment, "aphid infestation caused negative effects on all the plant traits measured ... but the negative effects were smaller than the positive effects of elevated CO_2 on the plant traits." They conclude, "the increased productivity occurring in plants exposed to higher levels of CO_2 more than compensate for the increased capacity of the aphids to cause damage." In this experiment, therefore, both the plant and the insect that feeds on it were benefited by the applied increases in atmospheric CO_2 concentration.

Chen *et al*. (2005) grew transgenic cotton plants for 30 days in well-watered and fertilized sand/vermiculite mixtures in pots set in controlled-environment chambers maintained at atmospheric CO_2 concentrations of 370, 700, and 1,050 ppm. A subset of aphid-infected plants was additionally supplied with predatory ladybugs, and three generations of cotton aphids (*Aphis gossypii*) were subsequently allowed to feed on some of the plants. Based on measurements made throughout this complex set of operations, Chen *et al*. found "plant height, biomass, leaf area, and carbon:nitrogen ratios were significantly higher in plants exposed to elevated CO_2 levels," and "more dry matter and fat content and less soluble protein were found in *A.*

gossypii in elevated CO_2." They also found "cotton aphid fecundity significantly increased ... through successive generations reared on plants grown under elevated CO_2"; "significantly higher mean relative growth rates were observed in lady beetle larvae under elevated CO_2"; and "the larval and pupal durations of the lady beetle were significantly shorter and [their] consumption rates increased when fed *A. gossypii* from elevated CO_2 treatments." Chen *et al*. say their study "provides the first empirical evidence that changes in prey quality mediated by elevated CO_2 can alter the prey preference of their natural enemies," and in this particular case, they found this phenomenon could "enhance the biological control of aphids by lady beetle."

According to Auad *et al*. (2012), the yellow sugarcane aphid—first called *Chaitophorus flavus*, but later changed to *Sipha flava*—"has an extensive geographic range that includes all the Americas and Hawaii," and it "is not only a serious pest of sugarcane, but it infests corn, sorghum, wheat, and several other grasses." They note "plant injury caused by this aphid is often severe and is associated with the release of an unidentified toxin followed by leaf chlorosis (Breen and Teetes, 1986; Webster, 1990)." In Brazil, where Auad *et al*. reside, the four scientists report elephant grass (*Pennisetum purpureum*)—one of the most widely used grasses for dairy cattle forage—"is being compromised by *S. flava* attack." The four Brazilian researchers investigated the "effects of elevated CO_2 alone and in combination with elevated temperature on the interactions of *S. flava* and one of its hosts," *P. purpureum*.

Auad *et al*. discovered "the combination of elevated CO_2 and high temperature significantly decreased the duration of nymphal stadia" and "the longevity and reproductive success of *S. flava*," such that "adults produced fewer nymphs in an environment with elevated CO_2 and high temperature than an environment with elevated CO_2 and lower fluctuating temperatures."

The four researchers conclude "*S. flava* populations will significantly decrease under future climatic conditions when both the concentration of atmospheric CO_2 and temperature are projected to increase."

Klaiber *et al*. (2013) "used a model system comprised of Brussels sprout (*Brassica oleraceae* var. *gemmifera*) and a specialized herbivorous insect, the cabbage aphid (*Brevicoryne brassicae*) to test for the effects of various periods of exposure to an elevated (2 x ambient) CO_2 concentration on key plant functional traits and on host plant location behavior

by the insect, assessed as plant colonization rates." With respect to plant/herbivore interactions, the four Swiss scientists say, "doubling the ambient CO_2 concentration had a marked effect on plant colonization by winged aphids particularly when plants were exposed to CO_2 for longer periods." After an exposure of only two weeks, for example, there was no difference in colonization rate, whereas after six and 10 weeks "elevated CO_2 led to a respective 15 and 26% reduction of colonization rates" by the cabbage aphid. The authors also note plant volatile emissions, which have been linked to attracting insects, were significantly reduced at the higher CO_2 concentration. Klaiber *et al.* conclude, "in agro-ecosystems, reduced crop plant colonization by an herbivorous pest insect under elevated CO_2 might be advantageous."

It appears the ongoing rise in the air's CO_2 content will likely not have a major impact on aphid-plant interactions, although the scales appear to be tipped in favor of plants over aphids. It is also possible both plants and aphids will benefit from atmospheric CO_2 enrichment, but with plants benefiting more.

5.5.2 Moths

Among the insects most responsible for herbivore pressure on plants is moths. This section reviews research on how moths are likely to fare in a warmer world with higher levels of CO_2 in the air.

Kerslake *et al*. (1998) collected five-year-old heather plants from a Scottish moor and grew them in open-top chambers maintained at atmospheric CO_2 concentrations of 350 and 600 ppm for 20 months, with and without soil nitrogen fertilization. Twice during the study, larvae of *Operophtera brumata*, a voracious winter moth whose outbreaks have caused extensive damage to heather moorland in recent years, were allowed to feed on current-year shoots for up to one month. The survivorship of larvae placed on CO_2-enriched foliage was not significantly different from that of larvae placed on foliage produced in ambient air, regardless of nitrogen treatment. In addition, feeding on CO_2-enriched foliage did not affect larval growth rate, development, or final pupal weight. Consequently, Kerslake *et al*. conclude their study "provides no evidence that increasing atmospheric CO_2 concentrations will affect the potential for outbreak of *Operophtera brumata* on this host."

Hattenschwiler and Schafellner (1999) grew seven-year-old spruce trees at atmospheric CO_2 concentrations of 280, 420, and 560 ppm in various nitrogen deposition treatments for three years, after which they performed needle quality assessments and allowed nun moth (*Lymantria monacha*) larvae to feed on current-year needles for 12 days. This moth is an especially voracious defoliator that resides in most parts of Europe and East Asia between 40 and 60° N latitude, and it is commonly regarded as the "coniferous counterpart" of its close relative the gypsy moth, which feeds primarily on deciduous trees.

The two scientists observed elevated CO_2 significantly enhanced needle starch, tannin, and phenolic concentrations, while significantly decreasing needle water and nitrogen contents. Thus, atmospheric CO_2 enrichment reduced overall needle quality from the perspective of this foliage-consuming moth, as nitrogen content is the primary factor associated with leaf quality. Increasing nitrogen deposition, on the other hand, tended to enhance needle quality, for it lowered starch, tannin, and phenolic concentrations while boosting needle nitrogen content. The positive influence of nitrogen deposition on needle quality was not large enough to completely offset the quality reduction caused by elevated CO_2.

Larvae placed on CO_2-enriched foliage consumed less needle biomass than larvae placed on low-CO_2-grown foliage, regardless of nitrogen treatment, and the larvae feeding on CO_2-enriched foliage exhibited reduced relative growth rates and attained an average biomass only two-thirds of that attained by larvae consuming foliage produced at 280 ppm CO_2. Hattenschwiler and Schafellner conclude, "altered needle quality in response to elevated CO_2 will impair the growth and development of *Lymantria monacha* larvae," which should lead to reductions in the degree of spruce tree destruction caused by this voracious defoliator.

Stiling *et al*. (2002) studied the effects of an approximate doubling of the air's CO_2 concentration on a number of characteristics of several insect herbivores feeding on plants native to a scrub-oak forest ecosystem at the Kennedy Space Center, Florida (USA) in eight ambient and eight CO_2-enriched open-top chambers. They found the "relative levels of damage by the two most common herbivore guilds, leaf-mining moths and leaf-chewers (primarily larval lepidopterans and grasshoppers), were significantly lower in elevated CO_2 than in ambient CO_2," and "the response to elevated CO_2 was the same across all plant species." Also, "more host-plant

induced mortality was found for all miners on all plants in elevated CO_2 than in ambient CO_2." These effects were so powerful that in addition to the relative densities of insect herbivores being reduced in the CO_2-enriched chambers, and "even though there were more leaves of most plant species in the elevated CO_2 chambers," the total densities of leaf miners in the high-CO_2 chambers were also lower for all plant species. It would appear that in a higher CO_2 world of the future, Earth's natural ecosystems may be able to better withstand the onslaughts of various insect pests, including moths, that have plagued them in the past. Stiling *et al*. note, is "reductions in herbivore loads in elevated CO_2 could boost plant growth beyond what might be expected based on pure plant responses to elevated CO_2."

In a follow-up study to that of Stilling *et al*., conducted at the same facilities, Rossi *et al*. (2004), focused on the abundance of a guild of lepidopteran leafminers that attack the leaves of myrtle oak, as well as various leaf chewers. They periodically examined 100 marked leaves in each of 16 open-top chambers for nine months, after which "differences in mean percent of leaves with leafminers and chewed leaves on trees from ambient and elevated chambers were assessed using paired *t*-tests." This protocol revealed "both the abundance of the guild of leafmining lepidopterans and damage caused by leaf chewing insects attacking myrtle oak were depressed in elevated CO_2." Leafminer abundance was 44% lower ($P = 0.096$) in the CO_2-enriched chambers compared to the ambient-air chambers, and the amount of leaves suffering chewing damage was 37% lower ($P = 0.072$) in the CO_2-enriched air.

Williams *et al*. (2003) bagged first instar gypsy moth larvae on branches of red maple saplings entering their fourth year of growth within open-top chambers maintained at four sets of CO_2/temperature conditions: (1) ambient temperature, ambient CO_2, (2) ambient temperature, elevated CO_2 (ambient + 300 ppm), (3) elevated temperature (ambient + 3.5°C), ambient CO_2, and (4) elevated temperature, elevated CO_2. For these conditions they measured several parameters to test their hypothesis that a CO_2-enriched atmosphere would lead to reductions in foliar nitrogen concentrations and increases in defensive phenolics that would in turn lead to increases in insect mortality.

The results indicated "larvae feeding on CO_2-enriched foliage ate a comparably poorer food source than those feeding on ambient CO_2-grown plants, irrespective of temperature." Nevertheless, they determined "CO_2-induced reductions in foliage

quality were unrelated to insect mortality, development rate and pupal weight." They concluded, "phytochemical changes resulted in no negative effects on gypsy moth performance," but neither did they help them.

Noting increases in the atmosphere's CO_2 concentration typically lead to greater decreases in the concentrations of nitrogen in the foliage of C_3 as opposed to C_4 grasses, Barbehenn *et al*. (2004) note "it has been predicted that insect herbivores will increase their feeding damage on C_3 plants to a greater extent than on C_4 plants (Lincoln *et al*., 1984, 1986; Lambers, 1993)." To test this hypothesis, they grew *Lolium multiflorum* (Italian ryegrass, a common C_3 pasture grass) and *Bouteloua curtipendula* (sideoats gramma, a native C_4 rangeland grass) in chambers maintained at either the ambient atmospheric CO_2 concentration of 370 ppm or the doubled CO_2 concentration of 740 ppm for two months, after which newly molted sixth-instar larvae of *Pseudaletia unipuncta* (a grass-specialist noctuid) and *Spodoptera frugiperda* (a generalist noctuid) were allowed to feed on the two grasses.

As expected, Barbehenn *et al*. found foliage protein concentration decreased by 20% in the C_3 grass but by only 1% in the C_4 grass when they were grown in CO_2-enriched air. They write, "to the extent that protein is the most limiting of the macronutrients examined, these changes represent a decline in the nutritional quality of the C_3 grass." However, and "contrary to our expectations," they add, "neither caterpillar species significantly increased its consumption rate to compensate for the lower concentration of protein in [the] C_3 grass." They note "this result does not support the hypothesis that C_3 plants will be subject to greater rates of herbivory relative to C_4 plants in future [high-CO_2] atmospheric conditions (Lincoln *et al*., 1984)." In addition, and "despite significant changes in the nutritional quality of *L. multiflorum* under elevated CO_2," they note "no effect on the relative growth rate of either caterpillar species on either grass species resulted," and there were "no significant differences in insect performance between CO_2 levels." They suggest "post-ingestive mechanisms could provide a sufficient means of compensation for the lower nutritional quality of C_3 plants grown under elevated CO_2."

Barbehenn *et al*. suggest "there will not be a single pattern that characterizes all grass feeders" with respect to their feeding preferences and developmental responses in a world where certain C_3 plants may experience foliar protein concentrations lower than those they exhibit today, nor will the

changes that may occur necessarily be detrimental to herbivore development or the health and vigor of their host plants. Nevertheless, subsequent studies continue to suggest moth species likely will be negatively impacted by the ongoing rise in the air's CO_2 content.

A case in point is the study of Chen *et al.* (2005), who grew well-watered and fertilized cotton plants of two varieties (one expressing *Bacillus thuringiensis* toxin genes and one a non-transgenic cultivar from the same recurrent parent) in pots placed within open-top chambers maintained at either 376 or 754 ppm CO_2 in Sanhe County, Hebei Province, China, from planting in mid-May to harvest in October. Immature bolls were periodically collected and analyzed for various chemical characteristics, and others were stored under refrigerated conditions for later feeding to larvae of the cotton bollworm. They found the elevated CO_2 treatment increased immature boll concentrations of condensed tannins by approximately 22% and 26% in transgenic and non-transgenetic cotton, respectively, and it slightly decreased the body biomass of the cotton bollworm and reduced moth fecundity. The Bt treatment was even more effective in this regard, and in the combined Bt-high-CO_2 treatment the negative cotton bollworm responses were expressed most strongly.

Bidart-Bouzat *et al.* (2005) grew three genotypes of mouse-ear cress (*Arabidopsis thaliana*) from seed in pots within controlled-environment chambers maintained at either ambient CO_2 (360 ppm) or elevated CO_2 (720 ppm). On each of half of the plants (the herbivory treatment) in each of these CO_2 treatments, they placed two second-instar larvae of the diamondback moth (*Plutella xylostella*) at bolting time and removed them at pupation, which resulted in an average of 20% of each plant's total leaf area in the herbivory treatment being removed. Then, each pupa was placed in a gelatin capsule until adult emergence and ultimate death, after which insect gender was determined and the pupa's weight recorded.

At the end of this herbivory trial, the leaves of the control and larvae-infested plants were analyzed for concentrations of individual glucosinolates—a group of plant-derived chemicals that can act as herbivore deterrents (Mauricio and Rausher, 1997)—and total glucosinolate production was determined by summation of the individual glucosinolate assays. Influences of elevated CO_2 on moth performance and its association with plant defense-related traits also were evaluated.

Overall, the researchers found herbivory by larvae of the diamondback moth did not induce any increase in the production of glucosinolates in the mouse-ear cress in the ambient CO_2 treatment. However, the three scientists report, "herbivory-induced increases in glucosinolate contents, ranging from 28% to 62% above basal levels, were found under elevated CO_2 in two out of the three genotypes studied." In addition, "elevated CO_2 decreased the overall performance of diamondback moths." And because "induced defenses can increase plant fitness by reducing subsequent herbivore attacks (Agrawal, 1999; Kessler and Baldwin, 2004)," Bidart-Bouzat *et al.* suggest "the pronounced increase in glucosinolate levels under CO_2 enrichment may pose a threat not only for insect generalists that are likely to be more influenced by rapid changes in the concentration of these chemicals, but also for other insect specialists more susceptible than diamondback moths to high glucosinolate levels (Stowe, 1998; Kliebenstein *et al.*, 2002)."

In a study of a major crop species, Wu *et al.* (2006) grew spring wheat (*Triticum aestivum* L.) from seed to maturity in pots placed in open-top chambers maintained at either 370 or 750 ppm CO_2 in Sanhe County, Hebei Province, China, after which they reared three generations of cotton bollworms (*Helicoverpa armigera* Hubner) on the milky grains of the wheat while monitoring a number of bollworm developmental characteristics. They report, "significantly lower pupal weights were observed in the first, second and third generations," and "the fecundity of *H. armigera* decreased by 10% in the first generation, 13% in the second generation and 21% in the third generation," resulting in a "potential population decrease in cotton bollworm by 9% in the second generation and 24% in the third generation." In addition, they observe, "population consumption was significantly reduced by 14% in the second generation and 24% in the third generation," and the efficiency of conversion of ingested food was reduced "by 18% in the first generation, 23% in the second generation and 30% in the third generation." They conclude, the "net damage of cotton bollworm on wheat will be less under elevated atmospheric CO_2," while "at the same time, gross wheat production is expected to increase by 63% under elevated CO_2."

Wu *et al.* (2007) write, "significant decreases in the protein, total amino acid, water and nitrogen content by 15.8%, 17.7%, 9.1% and 20.6% and increases in free fatty acid by 16.1% were observed in cotton bolls grown under elevated CO_2." When fed with these cotton bolls, the larval survival rate of *H. armigera* "decreased by 7.35% in the first generation, 9.52% in the second generation and 11.48% in the

third generation under elevated CO_2 compared with ambient CO_2." In addition, "the fecundity of *H. armigera* decreased by 7.74% in the first generation, 14.23% in the second generation and 16.85% in the third generation." They conclude, "fecundity capacity is likely to be reduced even further in the next generation."

The synergistic effects of these several phenomena, note Wu *et al.*, "resulted in a potential population decrease in cotton bollworm by 18.1% in the second generation and 52.2% in the third generation under elevated CO_2," with the result that "the potential population consumption of cotton bollworm decreased by 18.0% in the second generation and 55.6% in the third generation ... under elevated CO_2 compared with ambient CO_2." They conclude, "the potential population dynamics and potential population consumption of cotton bollworm will alleviate the harm to [cotton] plants in the future rising-CO_2 atmosphere."

Esper *et al.* (2007) reconstructed an annually resolved history of population cycles of a foliage-feeding Lepidopteran commonly known as the larch budmoth (*Zeiraphera diniana* Gn.)—or LBM for short—in the European Alps in the southern part of Switzerland. As is typical of many such insect pests, they note, "during peak activity, populations may reach very high densities over large areas," resulting in "episodes of massive defoliation and/or tree mortality" that could be of great ecological and economic significance.

The team of Swiss and U.S. researchers first developed a history of LBM outbreaks over the 1,173-year period AD 832–2004, which they describe as "the longest continuous time period over which any population cycle has ever been documented." They did so using radiodensitometric techniques to characterize the tree-ring density profiles of 180 larch (*Larix deciduas* Mill.) samples, where "LBM outbreaks were identified based upon characteristic maximum latewood density (MXD) patterns in wood samples, and verified using more traditional techniques of comparison with tree-ring chronologies from non-host species," i.e., fir and spruce. Then they developed a matching temperature history for the area by combining "a tree-ring width-based reconstruction from AD 951 to 2002 integrating 1527 pine and larch samples (Buntgen *et al.*, 2005) and a MXD-based reconstruction from AD 755 to 2004 based upon the same 180 larch samples used in the current study for LBM signal detection (Buntgen *et al.*, 2006)."

From AD 832 to 1981, there were 123 LBM outbreaks with a mean reoccurrence time of 9.3 years,

and "there was never a gap that lasted longer than two decades." From 1981 to the end of their study in 2004, however, there were no LBM outbreaks, and since there had never before (within their record) been such a long outbreak hiatus, they conclude, "the absence of mass outbreaks since the 1980s is truly exceptional."

To what do Esper *et al.* attribute this unprecedented recent development? Noting "conditions during the late twentieth century represent the warmest period of the past millennium"—as per their temperature reconstruction for the region of the Swiss Alps in which they worked—they point to "the role of extraordinary climatic conditions as the cause of outbreak failure," and they discuss what they refer to as the "probable hypothesis" of Baltensweiler (1993), who described a scenario by which local warmth may lead to reduced LBM populations.

Warmth may indeed explain the lack of LBM outbreaks, but given the results of other studies examined in this section, it should be noted atmospheric CO_2 concentrations since 1980 also have been unprecedented over the 1,173-year period of Esper *et al.*'s study. The suppression of LBM outbreaks over the past quarter-century may have been the result of some synergistic consequence of the two factors (temperature and CO_2) acting in unison, and a third possibility may involve only the increase in the air's CO_2 content.

Esper *et al.* say their findings highlight the "vulnerability of an otherwise stable ecological system in a warming environment," in what would appear to be an attempt to attach an undesirable connotation to the observed outcome. This wording seems strange indeed, for it is clear the "recent disruption of a major disturbance regime," as Esper *et al.* refer to the suppression of LBM outbreaks elsewhere in their paper, would be considered by most people to be a positive outcome, indeed something to be welcomed.

Buntgen *et al.* (2009) analyzed raw measurements of 3,151 tree-ring width (TRW) series and 150 maximum latewood density (MXD) series from 70 larch host sites and 73 spruce non-host sites spread across the European Alps and Tatra Mountains that extended back in time approximately 300 years. Focusing on the European Alps—"because periodic growth depressions caused by LBM outbreaks were not found in the TRW and MXD chronologies from the Tatra Mountains"—Buntgen *et al.* discovered "a distinct periodicity at 8–9 years from sites at elevations between 1750 and 1900 meters above sea level." In the middle of the twentieth century, for

example, they documented synchronized outbreak pulses at approximately 1936, 1945, 1954, 1963, 1972, and 1981. These outbreaks, the scientists write, "occurred independently of rising temperatures," all the way from the beginning-of-the-end of "the Little Ice Age until recent warmth." They report this long stretch of persistent and synchronized Alpine-wide defoliation—which Esper *et al*. (2007) had followed back to AD 832—finally "ceased during recent decades," when "unprecedented warming in all seasons characterized the post–1980 period."

Knepp *et al*. (2007) studied two species of oak tree—*Quercus alba* L. (white oak) and *Quercus velutina* Lam. (black oak)—and their susceptibility to *Antheraea polyphemus*, a leaf-chewing generalist lepidopteran herbivore that represents the most abundant feeding guild in the hardwood trees that grow beneath the canopy of the unmanaged loblolly pine plantation that hosts the Forest Atmosphere Carbon Transfer and Storage (FACTS–1) research site in the Piedmont region of North Carolina (USA), where the leaf-chewer can consume 2–15% of the forest's net primary production in any given year. The researchers examined host plant preference and larval performance of *A. polyphemus* when fed foliage of the two tree species that had been grown in either ambient or CO_2-enriched air (to 200 ppm above ambient) in this long-running FACE experiment. They determined "growth under elevated CO_2 reduced the food quality of oak leaves for caterpillars," and "consuming leaves of either oak species grown under elevated CO_2 slowed the rate of development of *A. polyphemus* larvae." In addition, they found feeding on foliage of *Q. velutina* that had been grown under elevated CO_2 led to reduced consumption by the larvae and greater mortality. They conclude, "reduced consumption, slower growth rates, and increased mortality of insect larvae may explain [the] lower total leaf damage observed previously in plots of this forest exposed to elevated CO_2," as documented by Hamilton *et al*. (2004) and Knepp *et al*. (2005).

Kampichler *et al*. (2008) also worked with oak trees. Noting, however, "systems studied so far have not included mature trees," they attempted to remedy this situation by determining "the abundance of dominant leaf-galls (spangle-galls induced by the cynipid wasps *Neuroterus quercusbaccarum* and *N. numismalis*) and leaf-mines (caused by the larvae of the moth *Tischeria ekebladella*) on freely colonized large oaks in a mixed forest in Switzerland, which received CO_2 enrichment [540 ppm vs. 375 ppm during daylight hours] from 2001 to 2004" via "the

Swiss Canopy Crane (SCC) and a new CO_2 enrichment technique (web-FACE)" in a forest that they say "is 80–120 years old with a canopy height of 32–38 m, consisting of seven deciduous and four coniferous species."

The German, Mexican, and Swiss researchers discovered that although elevated CO_2 reduced various leaf parameters (water content, proteins, non-structural carbohydrates, tannins, etc.) at the SCC site, "on the long term, their load with cynipid spangle-galls and leaf-mines of *T. ekebladella* was not distinguishable from that in oaks exposed to ambient CO_2 after 4 years of treatment." Consequently, although speculation has run rampant over the years about the long-term effects of atmospheric CO_2 enrichment on plant foliage and its subsequent effects on animals of various trophic levels, Kampichler *et al*. conclude in the situation they investigated, "CO_2 enrichment had no lasting effect in all three [animal] taxa, despite the substantial and consistent change in leaf chemistry of oak due to growth in elevated CO_2."

The results of the studies reviewed above indicate the ongoing rise in the air's CO_2 content will not cause greater damage to Earth's vegetation by the larvae of the many moths that inhabit the planet. If anything, it could reduce the damage they cause.

5.5.3 Other Herbivores

Besides aphids and moths, other herbivores consume vast amounts of foliage, roots, seeds, and other forms of vegetation. Because experiments involving temperatures and CO_2 content of the air often are conducted on specific types of plants, it is useful to sort the research results by the types of plants being studied. This section looks at research on herbaceous plants, woody plants, and finally other plants.

5.5.3.1 Herbaceous Plants

Insect pests have greatly vexed Earth's herbaceous plants in the past and likely will continue to do so in the future. It is possible, however, that the ongoing rise in the atmosphere's CO_2 content may impact this phenomenon, for better or for worse. Several studies have addressed this subject as it applies to herbaceous plant species, and these studies indicate such plants will be able to continue to cope with the periodic assaults of leaf-damaging herbivores as the air's CO_2 content continues to increase.

Kerslake *et al*. (1998) grew five-year-old heather (*Calluna vulgaris*) plants collected from a Scottish moor in open-top chambers maintained at atmospheric CO_2 concentrations of 350 and 600 ppm. Twice during the study, larvae of the destructive winter moth *Operophtera brumata*, outbreaks of which periodically cause extensive damage to heather moorland, were allowed to feed upon current-year shoots. Feeding on the high-CO_2-grown foliage did not affect larval growth rates, development, or final pupal weights, nor was moth survivorship sig-nificantly altered. The authors conclude their study "provides no evidence that increasing atmospheric CO_2 concentrations will affect the potential for outbreak of *Operophtera brumata* on this host."

Newman *et al*. (1999) inoculated tall fescue (*Festuca arundinacea*) plants growing in open-top chambers maintained at atmospheric CO_2 con-centrations of 350 and 700 ppm with bird cherry-oat aphids (*Rhopalosiphum padi*). After nine weeks, the plants growing in the CO_2-enriched air had experienced a 37% increase in productivity and were covered with far fewer aphids than the plants growing in ambient air.

Goverde *et al*. (1999) collected four genotypes of *Lotus corniculatus* near Paris and grew them in controlled environment chambers kept at atmospheric CO_2 concentrations of 350 and 700 ppm. Larvae of the Common Blue Butterfly (*Polyommatus icarus*) that were allowed to feed on the foliage produced in the CO_2-enriched air ate more, grew larger, and experienced shorter development times than larvae feeding on the foliage produced in the ambient-air treatment, suggesting this butterfly species likely will become increasingly robust and plentiful as the air's CO_2 content continues to rise.

Brooks and Whittaker (1999) removed grassland monoliths containing eggs of the xylem-feeding spittlebug *Neophilaenus lineatus* from the UK's Great Dun Fell in Cumbria and placed them in glasshouses maintained at atmospheric CO_2 concentrations of 350

and 600 ppm for two years. Survival of the spittlebug's nymphal states was reduced by 24% in both of the generations produced in their experiment, suggesting this particular insect likely will cause less tissue damage to the plants of this species-poor grassland in a CO_2-enriched world of the future.

Joutei *et al*. (2000) grew bean (*Phaseolus vulgaris*) plants in controlled environments kept at atmospheric CO_2 concentrations of 350 and 700 ppm, to which they introduced the destructive agricultural mite *Tetranychus urticae*. Female mites produced 34% and 49% less offspring in the CO_2-enriched chambers in their first and second generations, respectively. This CO_2-induced reduction in the reproductive success of this invasive insect, which negatively affects more than 150 crop species worldwide, bodes well for mankind's ability to grow the food needed to feed the planet's growing population in the years ahead.

Peters *et al*. (2000) fed foliage derived from FACE plots of calcareous grasslands of Switzerland (maintained at 350 and 650 ppm CO_2) to terrestrial slugs, finding they exhibited no preference toward the CO_2 treatment from which the foliage was derived. Also, in a study that targeted no specific insect pest, Castells *et al*. (2002) found a doubling of the air's CO_2 content enhanced the total phenolic con-centrations of two Mediterranean perennial grasses (*Dactylis glomerata* and *Bromus erectus*) by 15% and 87%, respectively; these compounds tend to enhance plant defensive and resistance mechanisms to attacks by both herbivores and pathogens (see Section 2.19).

Plants re-emit a substantial portion of their assimilated CO_2 back to the atmosphere as volatile organic compounds (VOCs). These substances affect both the chemical and physical properties of the air, where they generate large quantities of organic aerosols that can impact the planet's climate by forming cloud condensation nuclei that may lead to enhanced cooling during the day by reflecting a greater portion of the incoming solar radiation back to space. In addition, many VOCs protect numerous plants from a host of insect pests.

To see how these phenomena may be affected by the ongoing rise in the atmosphere's CO_2 concentra-tion and by localized areas and time periods of high ozone (O_3) pollution, Himanen *et al*. (2009) exposed groups of both normal (non-transgenic) oilseed rape (*Brassica napus* ssp. *oleifera* L.) plants and transgenic plants, containing an introduced gene that produces *Bacillus thuringiensis* (Bt) crystal endotoxin (Cry) proteins that limit herbivorous insect attacks, to air of 360 and 720 ppm CO_2, as well as O_3-free air and air

of 100 ppb O_3. These experiments were conducted in controlled-environment chambers where the plants were grown from seed for 17–18 days in 0.66-liter pots filled with a 2:1:1 mixture of fertilized compost, *Sphagnum* peat, and sand. The non-transgenic plants grown in CO_2-enriched air produced 27% more shoot biomass than those grown in ambient air, and the transgenic plants produced 25% more. In the O_3-enriched air, the non-transgenic plants produced 29% less shoot biomass than those grown in O_3-free air, and the transgenic plants produced 34% less. In addition, on a per-dry-weight basis, Himanen *et al*. say the "doubled CO_2 significantly increased terpenoid emissions from intact oilseed rape plants compared with those released from the corresponding plants grown in control CO_2," and they report there were no O_3-induced increases in VOC emissions. Thus, in addition to the fact that "production of *Bacillus thuringiensis* crystal endotoxin proteins in a crop plant limits specific herbivorous insect attack without the need for chemical treatments," the seven scientists conclude "elevated CO_2 conditions could modify herbivore-induced defenses [VOC emissions] at the vegetative stage, and enhance indirect defense in the future."

Although many studies have explored the direct effects of atmospheric CO_2 enrichment on plant growth and development, Klaiber *et al*. (2013) note the effects of elevated CO_2 on the behavioral responses of insect pests associated with major food crops have not been thoroughly investigated: "the potential effects of plant acclimation to CO_2 on host plant colonization by specialized herbivorous insects, which is a key step in the process of plant attack leading to potential yield losses, are largely unknown."

Klaiber *et al*. "used a model system comprised of Brussels sprout (*Brassica oleraceae* var. *gemmifera*) and a specialized herbivorous insect, the cabbage aphid (*Brevicoryne brassicae*) to test for the effects of various periods of exposure to an elevated (2 x ambient) CO_2 concentration on key plant functional traits and on host plant location behavior by the insect, assessed as plant colonization rates."

Plant height, leaf number, leaf area, fresh weight, and dry weight all increased in the elevated CO_2 treatments with respect to values obtained under ambient conditions, regardless of the length of CO_2 exposure. Leaf stomatal conductance also benefited at the higher CO_2 level, being reduced by nearly 50% by the end of the 10-week experiment. With respect to plant/herbivore interactions, the four Swiss scientists say "doubling the ambient CO_2 concentration had a marked effect on plant colonization by winged aphids particularly when plants were exposed to CO_2 for longer periods." After an exposure of only two weeks, for example, there was no difference in colonization rate, whereas after six and 10 weeks "elevated CO_2 led to a respective 15 and 26% reduction of colonization rates" by the cabbage aphid. The authors also note plant volatile emissions, which have been linked to attracting insects, were reduced significantly at the higher CO_2 concentration. Klaiber *et al*. conclude, "in agroecosystems, reduced crop plant colonization by an herbivorous pest insect under elevated CO_2 might be advantageous."

The majority of evidence to date suggests rising atmospheric CO_2 concentrations may reduce the frequency and severity of pest outbreaks detrimental to agriculture, without seriously impacting herbivorous organisms found in natural ecosystems that are normally viewed in a more favorable light.

5.5.3.2 Woody Plants

Insect pests have vexed Earth's trees in the past and likely will continue to do so in the future. The ongoing rise in the atmosphere's CO_2 content may affect this phenomenon, for better or for worse. The sections that follow review the results of several studies that have addressed this subject as it applies to woody plant species. These studies suggest Earth's woody plants will fare much better in a CO_2-enriched future with respect to the periodic assaults of leaf-damaging herbivores.

5.5.3.2.1 Cotton

Bt toxins produced by *Bacillus thuringiensis* supplied to plants via foliar application have been used as a means of combating crop pests for more than 50 years. The effectiveness of this pest management technique depends primarily on the amount of Bt-produced toxins ingested by susceptible insects. Consequently, Coviella and Trumble (2000) wondered whether atmospheric CO_2 enrichment might enhance the effectiveness of the technique by inducing susceptible insects to eat more treated foliage and thus be more effectively eradicated. If soil nitrogen levels are low, foliar nitrogen concentrations in CO_2-enriched air are often reduced from what they are at the current atmospheric CO_2 concentration, and, it is supposed, insects thus must eat more foliage to get the amount of nitrogen they require for proper growth and development. In eating more foliage, the insects would ingest more Bt-produced toxins, and they would be more severely affected by them.

To test this hypothesis, Coviella and Trumble grew cotton plants in 20 three-liter pots in each of six Teflon-film chambers in a temperature-controlled greenhouse; three of the chambers were maintained at an atmospheric CO_2 concentration of 370 ppm, and three were maintained at 900 ppm CO_2. In addition, half of the plants in each chamber received high levels of nitrogen (N) fertilization, while half received low levels (30 as opposed to 130 mg N/kg soil/week). After 45 days, leaves were removed from the plants and dipped in a solution containing *Bacillus thuringiensis*, after which known amounts of treated leaf material were fed to *Spodoptera exigua* larvae and their responses measured and analyzed.

These protocols revealed plants grown in the elevated CO_2 chambers did indeed have significantly lower foliar nitrogen concentrations than plants grown in the ambient CO_2 chambers under the low N fertilization regime, but this was not the case under the high N regime. Also, older larvae fed with foliage grown in elevated CO_2 with low N fertilization consumed significantly more plant material than those fed with foliage grown in ambient CO_2, but again no differences were observed in the high N treatment. In addition, and "consistent with the effect of higher Bt toxin intake due to enhanced consumption," the researchers found "insects fed on low N plants had significantly higher mortality in elevated CO_2," but again, no such effect was evident in the high N treatment. Coviella and Trumble conclude, "increasing atmospheric CO_2 is making the foliar applications more efficacious," especially in the case of soils low in nitrogen.

In addition to applying Bt toxins to plants by spraying, the ability of plants to produce them internally has been achieved by means of genetic engineering. However, there is concern foreign genes from agricultural plants may be transferred into wild relatives of transgenic crop lines and thereby upset the "balance of nature." In one of the first studies to address this concern, Coviella *et al.* (2000) grew cotton plants in the same manner as Coviella and Trumble—in 12 Teflon-film chambers in a temperature-controlled greenhouse, where six of the chambers were maintained at an atmospheric CO_2 concentration of 370 ppm and six were maintained at 900 ppm. Half the plants in each chamber were of a transgenic line containing the Bt gene for the production of the Cry1Ac toxin that is mildly toxic to *Spodoptera exigua*, and the other half were of a near isogenic line without the Bt gene. In addition, half the plants in each chamber received high levels of nitrogen (N) fertilization, while half received low levels (30 as opposed to 130 mg N/kg soil/week). Between 40 and 45 days after emergence, leaves were removed from the plants and fed to the *S. exigua*

larvae, after which a number of larval responses were measured and analyzed, along with various leaf properties.

The researchers found the low-N plants in the elevated CO_2 treatment had lower foliar N concentrations than the low-N plants in the ambient CO_2 treatment; the transgenic plants from the low-N, high CO_2 treatment produced lower levels of Bt toxin than did the transgenic plants from the low-N, ambient CO_2 treatment. The high level of N fertilization only partially compensated for this latter high-CO_2 effect. In the ambient CO_2 treatment there was also a significant increase in days to pupation for insects fed transgenic plants, but this difference was not evident in elevated CO_2. In addition, pupal weight in ambient CO_2 was significantly higher in nontransgenic plants, and, again this difference was not observed in elevated CO_2.

Coviella *et al.* say their results "support the hypothesis that the lower N content per unit of plant tissue caused by the elevated CO_2 will result in lower toxin production by transgenic plants when nitrogen supply to the plants is a limiting factor." They also note "elevated CO_2 appears to eliminate differences between transgenic and nontransgenic plants for some key insect developmental/fitness variables including length of the larval stage and pupal weight." These results, in turn, suggest that in the case of inadvertent Bt gene transference to wild relatives of transgenic crop lines, elevated levels of atmospheric CO_2 will tend to negate certain of the negative effects the wayward genes might otherwise inflict on the natural world.

Coviella *et al.*'s results suggest transgenic plants designed to produce Bt-type toxins may become less effective in carrying out the objective of their design as the air's CO_2 content continues to rise. Coupling this observation with the fact that the foliar application of *Bacillus thuringiensis* to crops should become even more effective in a higher-CO_2 world of the future, as per the findings of Coviella and Trumble, it could be argued the implantation of toxin-producing genes in plants is not the way to proceed in the face of the ongoing rise in the air's CO_2 content, which reduces the effectiveness of the genetic implantation technique at the same time it increases the effectiveness of foliar application. It is important to see what other researchers have learned about the subject.

Chen *et al.* (2005b) grew well-watered and fertilized cotton plants of two varieties (GK–12, expressing Cry1A (c) genes from *Bacillus thuringiensis*, and Simian–3, a non-transgenic cultivar from the same recurrent parent) in pots in open-top chambers maintained at either 376 or 754 ppm CO_2 in Sanhe County, Hebei Province, China, from planting in mid-May to harvest in October. Throughout this period, several immature bolls were collected and analyzed for chemical characteristics. Others were stored under refrigerated conditions for later feeding to larvae of the cotton bollworm, when various parameters related to bollworm growth and development were monitored. The scientists found the elevated CO_2 treatment increased immature boll concentrations of condensed tannins by approximately 22% and 26% in transgenic and non-transgenetic cotton, respectively. In addition, Chen *et al.* report elevated CO_2 slightly decreased the body biomass of the cotton bollworm and reduced moth fecundity. The Bt treatment was even more effective in this regard, and in the combined Bt-high-CO_2 treatment the negative cotton bollworm responses were expressed most strongly.

In a parallel study, Chen *et al.* (2005a) grew transgenic *Bacillus thuringiensis* cotton (GK–12) plants from seed for a period of 30 days in well-watered and fertilized sand/vermiculite mixtures in pots located in controlled-environment chambers maintained at atmospheric CO_2 concentrations of 370, 700, and 1,050 ppm. Three generations of cotton aphids (*Aphis gossypii*) were subsequently allowed to feed on some of the plants, and a subset of the aphid-infected plants was supplied with predatory ladybugs. Chen *et al.* report "plant height, biomass, leaf area, and carbon:nitrogen ratios were significantly higher in plants exposed to elevated CO_2 levels," and "more dry matter and fat content and less soluble protein were found in *A. gossypii* in elevated CO_2." They report "cotton aphid fecundity significantly increased ... through successive generations reared on plants grown under elevated CO_2." They also report "significantly higher mean relative growth rates were observed in lady beetle larvae under elevated CO_2," and "the larval and pupal durations of the lady beetle were significantly shorter and [their] consumption rates increased when fed *A. gossypii* from elevated CO_2 treatments." Hence, they conclude, their study "provides the first empirical evidence that changes in prey quality mediated by elevated CO_2 can alter the prey preference of their natural enemies." They found this phenomenon could "enhance the biological control of aphids by lady beetle" while enhancing control by means of negative Bt-induced effects on the aphids.

Wu *et al.* (2011) state, "secondary metabolites present in plants provide protection against invaders

because of their antimicrobial activity (Kamra *et al*., 2006)," and "elevated CO_2 leads to plants allocating more carbohydrate resources to their secondary metabolism (Agrell *et al*., 2004; Casteel *et al*., 2008)," which may thus induce them to "generate higher concentrations of defensive compounds that are toxic [to] herbivorous insects (Coviella and Trumble, 1999)." Preeminent in this group of compounds are condensed tannins, naturally occurring secondary carbon compounds produced in the leaves of virtually all families of plants that comprise up to 50% of the dry weight of their leaves. Another such compound of note is gossypol, a natural toxin present in the cotton plant that helps to protect it from insect pests such as the cotton bollworm.

Wu *et al*. studied the allocation of the carbohydrate resources of two cotton (*Gossypium hirsutum* L.) cultivars—transgenic Bt cotton (cv. GK–12) and non-transgenic Bt cotton (cv. Simian–3)—to condensed tannins and gossypol both before and after injury inflicted on the plants by the cotton bollworm (*Helicoverpa armigera* Hubner) over periods of one, three, and 12 hours in controlled-environment chambers maintained at atmospheric CO_2 concentrations of either 370 or 750 ppm.

Before any bollworm injury to the plants, the extra CO_2 led to increases of 12 and 14% in the condensed tannin concentrations in the foliage of the Bt-transgenic and non-transgenic cotton plants, respectively; increases of 10 and 10% in the gossypol concentrations of the transgenic and non-transgenic plants, respectively; and a 4% decrease in Bt toxin in the transgenic plants. After bollworm injury for periods of one, three, and 12 hours, the non-transgenic plants experienced condensed tannin increases of 14, 9, and 9%, respectively, and transgenic plants experienced increases of 16, 9, and 9%, respectively. Corresponding results for gossypol were increases of 7, 10, and 6% for the non-transgenic cultivar and 7, 7, and 6% for the transgenic cultivar. The transgenic plants also exhibited Bt toxin decreases of 3, 3, and 5%, respectively.

In discussing the implications of their findings, the four Chinese scientists state prior studies have demonstrated increases in condensed tannins and gossypol typically occur "in response to an increasing CO_2 atmosphere, especially in combination with injury caused by herbivorous insects (Druy *et al*., 1998; Roth and Lindroth, 1994)," and they suggest these increases "may compensate for the Bt toxin loss in the transgenic Bt cotton," which appears to be an outcome of their study as well. Thus we may expect cotton to become ever less susceptible to damage by the cotton bollworm as the air's CO_2 content continues to rise.

5.5.3.2.2 Maple

Williams *et al*. (2003) studied *Acer rubrum* saplings beginning their fourth year of growth in open-top chambers maintained at four atmospheric CO_2/temperature conditions: (1) ambient temperature, ambient CO_2, (2) ambient temperature, elevated CO_2 (ambient + 300 ppm), (3) elevated temperature (ambient + 3.5°C), ambient CO_2, and (4) elevated temperature, elevated CO_2. They bagged first instar gypsy moth larvae on various branches of the trees and observed their behavior.

They found "larvae feeding on CO_2-enriched foliage ate a comparably poorer food source than those feeding on ambient CO_2-grown plants, irrespective of temperature," and there was a minor reduction in leaf water content due to CO_2 enrichment. They report the "CO_2-induced reductions in foliage quality (e.g. nitrogen and water) were unrelated to insect mortality, development rate and pupal weight," and these and any other phytochemical changes that may have occurred "resulted in no negative effects on gypsy moth performance." They also found "irrespective of CO_2 concentration, on average, male larvae pupated 7.5 days earlier and female larvae 8 days earlier at elevated temperature." Noting anything that prolongs the various development stages of insects potentially exposes them to greater predation and parasitism risk, they conclude the observed temperature-induced hastening of the insects' development likely would expose them to less predation and parasitism risk, which would confer an advantage on this particular herbivore in this particular situation.

Hamilton *et al*. (2004) note many single-species investigations have suggested increases in atmospheric CO_2 will increase herbivory (Bezemer and Jones, 1998; Cannon, 1998; Coviella and Trumble, 1999; Hunter, 2001; Lincoln *et al*., 1993; Whittaker, 1999). However, because there are so many feedbacks and complex interactions among the numerous components of real-world ecosystems, they warn against putting too much faith in these predictions until relevant real-world ecosystem-level experiments have been completed.

In one such study they conducted at the Duke Forest FACE facility near Chapel Hill, North Carolina (USA), Hamilton *et al*. "measured the amount of leaf tissue damaged by insects and other herbivorous arthropods during two growing seasons in a deciduous forest understory continuously exposed to ambient (360 ppm) and elevated (560 ppm) CO_2 conditions." This forest is dominated by loblolly pine trees that account for fully 92% of the ecosystem's total woody biomass. In addition, it contains 48 species of other woody plants (trees, shrubs, and vines) that have naturally established themselves in the forest's understory. Hamilton *et al*. quantify the loss of foliage due to herbivory experienced by three deciduous tree species, one of which was *Acer rubrum*.

The results indicate "elevated CO_2 led to a trend toward reduced herbivory in [the] deciduous understory in a situation that included the full complement of naturally occurring plant and insect species." In 1999, for example, "elevated CO_2 reduced overall herbivory by more than 40%," and in 2000 they observed "the same pattern and magnitude of reduction."

With respect to changes in foliage properties that might have been expected to lead to increases in herbivory, Hamilton *et al*. report they "found no evidence for significant changes in leaf nitrogen, C/N ratio, sugar, starch or total leaf phenolics in either year of [the] study," noting these findings agree with those of "another study performed at the Duke Forest FACE site that also found no effect of elevated CO_2 on the chemical composition of leaves of understory trees (Finzi and Schlesinger, 2002)."

Hamilton *et al*. thus conclude their landmark paper by emphasizing that "despite the large number of studies that predict increased herbivory, particularly from leaf chewers, under elevated CO_2, our study found a trend toward reduced herbivory two years in a row." In addition, they note their real-world results "agree with the only other large-scale field experiment that quantified herbivory for a community exposed to elevated CO_2 (Stilling *et al*., 2003)."

Consequently, and contrary to the predictions of increased destruction of natural ecosystems by insects and other herbivorous arthropods in a CO_2-enriched world of the future, just the opposite appears to be the more likely outcome: greater plant productivity plus less foliage consumption by herbivores, "whether expressed on an absolute or a percent basis," as Hamilton *et al*. found in their study.

Knepp *et al*. (2005) quantified leaf damage by chewing insects on saplings of seven species (including *Acer rubrum*) in 2001, 2002, and 2003; five additional species (including *Acer barbatum*) were included in 2001 and 2003. They found "across the seven species that were measured in each of the three years, elevated CO_2 caused a reduction in the percentage of leaf area removed by chewing insects," such that "the percentage of leaf tissue damaged by insect herbivores was 3.8% per leaf under ambient

CO_2 and 3.3% per leaf under elevated CO_2." The greatest effects were observed in 2001, when "across 12 species the average damage per leaf under ambient CO_2 was 3.1% compared with 1.7% for plants under elevated CO_2," "indicative of a 46% decrease in the total area and total mass of leaf tissue damaged by chewing insects in the elevated CO_2 plots."

Knepp *et al*. write, "given the consistent reduction in herbivory under high CO_2 across species in 2001, it appears some universal feature of chemistry or structure that affected leaf suitability was altered by the treatment." Another possibility they discuss is "forest herbivory may decrease under elevated CO_2 because of a decline in the abundance of chewing insects," citing Stilling *et al*. (2002) to this effect and noting "slower rates of development under elevated CO_2 prolongs the time that insect herbivores are susceptible to natural enemies, which may be abundant in open-top chambers and FACE experiments but absent from greenhouse experiments." In addition, they suggest "decreased foliar quality and increased per capita consumption under elevated CO_2 may increase exposure to toxins and insect mortality," also noting "CO_2-induced changes in host plant quality directly decrease insect fecundity," citing Coviella and Trumble (1999) and Awmack and Leather (2002).

Knepp *et al*. conclude, "in contrast to the view that herbivore damage will increase under elevated CO_2 as a result of compensatory feeding on lower quality foliage, our results and those of Stilling *et al*. (2002) and Hamilton *et al*. (2004) in open experimental systems suggest that damage to trees may decrease."

But what if herbivore-induced damage increases, for whatever reason in some situations, in a future CO_2-enriched world?

The likely answer is provided by Kruger *et al*. (1998), who grew well-watered and fertilized one-year-old *Acer saccharum* saplings in glasshouses maintained at atmospheric CO_2 concentrations of either 356 or 645 ppm for 70 days, to determine the effects of elevated CO_2 on photosynthesis and growth. On the 49th day of differential CO_2 exposure, 50% of the saplings' leaf area was removed from half of the trees in order to study the impact of concomitant simulated herbivory. They found the 70-day CO_2 enrichment treatment increased the total dry weight of the non-defoliated seedlings by about 10%. When the trees were stressed by simulated herbivory, the CO_2-enriched maples produced 28% more dry weight over the final phase of the study than the maples in the ambient-air treatment.

Kruger *et al*. thus conclude, in a high-CO_2 world of the future "sugar maple might be more capable of tolerating severe defoliation events which in the past have been implicated in widespread maple declines."

5.5.3.2.3 Oak

Dury *et al.* (1998) grew four-year-old *Quercus robur* seedlings in pots in greenhouses maintained at ambient and twice-ambient atmospheric CO_2 concentrations in combination with ambient and elevated (ambient plus 3°C) air temperatures for approximately one year to study the interactive effects of elevated CO_2 and temperature on leaf nutritional quality. They found the elevated air temperature treatment significantly reduced leaf palatability, and leaf toughness increased as a consequence of temperature-induced increases in condensed tannin concentrations. In addition, the higher temperatures significantly reduced leaf nitrogen content, and elevated CO_2 caused a temporary increase in leaf phenolic concentrations and a decrease in leaf nitrogen content.

In one of the first attempts to move outside the laboratory and greenhouse and study the effects of atmospheric CO_2 enrichment on trophic food webs in a natural ecosystem, Stiling *et al.* (1999) enclosed portions of a native scrub-oak community in Florida (USA) within 3.6-m-diameter open-top chambers and fumigated them with air having CO_2 concentrations of either 350 or 700 ppm for approximately one year, to see whether elevated CO_2 would impact leaf miner densities, feeding rates, and mortality in this nutrient-poor ecosystem.

They found total leaf miner densities were 38% less on the foliage of trees growing in CO_2-enriched air than on the foliage of trees growing in ambient air. In addition, atmospheric CO_2 enrichment consistently reduced the absolute numbers of the study's six leaf miner species. However, the elevated CO_2 treatment increased the leaf area consumed by the less abundant herbivore miners by approximately 40% relative to the areas mined by the more abundant herbivores present on the foliage exposed to ambient air. In spite of this increase in feeding, the leaf miners in the CO_2-enriched chambers experienced significantly greater mortality than those in the ambient-air chambers. Although CO_2-induced reductions in leaf nitrogen content played a minor role in this phenomenon, the greatest factor contributing to increased herbivore mortality was a four-fold increase in parasitization by various wasps, which could more readily detect the more-exposed leaf miners on the CO_2-enriched foliage.

If extended to agricultural ecosystems, these findings suggest crops may experience less damage from such herbivores in a high-CO_2 world of the future, thus increasing potential harvest and economic gains. In addition, with reduced numbers of leaf miners in CO_2-enriched air, farmers could reduce their dependency on chemical pesticides to control them, thus reducing the negative impacts of these agricultural chemicals on the environment.

In another study conducted on five scrub-oak forest species at the same experimental facility, Stiling *et al.* (2002b) investigated the effects of an approximate doubling of the air's CO_2 concentration on a number of characteristics of several insect herbivores. As before, they found the "relative levels of damage by the two most common herbivore guilds, leaf-mining moths and leaf-chewers (primarily larval lepidopterans and grasshoppers), were significantly lower in elevated CO_2 than in ambient CO_2, for all five plant species," and they found "the response to elevated CO_2 was the same across all plant species." In addition, "more host-plant induced mortality was found for all miners on all plants in elevated CO_2 than in ambient CO_2." These effects were so powerful that in addition to the relative densities of insect herbivores being reduced in the CO_2-enriched chambers, and "even though there were more leaves of most plant species in the elevated CO_2 chambers," the total densities of leaf miners in the high-CO_2 chambers were lower for all plant species. In a high-CO_2 world of the future, many plants may be able to better withstand the onslaughts of various insect pests that have plagued them in the past. Another intriguing implication of this finding, as Stiling *et al.* note, is "reductions in herbivore loads in elevated CO_2 could boost plant growth beyond what might be expected based on pure plant responses to elevated CO_2."

Rossi *et al.* (2004) studied the same ecosystem, which is dominated by two species of scrub oak (*Quercus geminata* and *Q. myrtifolia*) that account for more than 90% of the ecosystem's biomass, focusing on the abundance of a guild of lepidopteran leaf-miners that attack the leaves of *Q. myrtifolia*, as well as various leaf chewers. They followed 100 marked leaves in each of 16 open-top chambers (half of them exposed to ambient air and half exposed to air containing an extra 350 ppm of CO_2) for nine months. "Differences in mean percent of leaves with leafminers and chewed leaves on trees from ambient and elevated chambers were assessed using paired *t*-tests."

The researchers report, "both the abundance of the guild of leafmining lepidopterans and damage

caused by leaf chewing insects attacking myrtle oak were depressed in elevated CO_2." They found leafminer abundance was 44% lower ($P = 0.096$) in the CO_2-enriched chambers compared to the ambient-air chambers, and the abundance of leaves suffering chewing damage was 37% lower ($P = 0.072$) in the CO_2-enriched air.

Concentrating on the same ecosystem, where atmospheric enrichment with an extra 350 ppm of CO_2 was begun in May 1996, Hall *et al*. (2005b) studied the four species that dominate the community and are present in every experimental chamber: the three oaks (*Quercus myrtifolia, Q. chapmanii*, and *Q. geminata*) plus the nitrogen-fixing legume *Galactia elliottii*. At three-month intervals from May 2001 to May 2003, undamaged leaves were removed from each of these species in all chambers and analyzed for various chemical constituents, and 200 randomly selected leaves of each species in each chamber were scored for the presence of six types of herbivore damage.

The researchers found no significant differences between the CO_2-enriched and ambient-treatment leaves of any single species in terms of condensed tannins, hydrolyzable tannins, total phenolics, or lignin. However, in all four species together there were always greater concentrations of all four leaf constituents in the CO_2-enriched leaves, with across-species mean increases of 6.8% for condensed tannins, 6.1% for hydrolyzable tannins, 5.1% for total phenolics, and 4.3% for lignin. In addition, there were large and often significant CO_2-induced decreases in all leaf damage categories among all species: chewing (-48%, P < 0.001), mines (-37%, P = 0.001), eye spot gall (-45%, P < 0.001), leaf tier (-52%, P = 0.012), leaf mite (-23%, P = 0.477), and leaf gall (-16%, P = 0.480). Hall *et al*. conclude the changes they observed in leaf chemical constituents and herbivore damage "suggest that damage to plants may decline as atmospheric CO_2 levels continue to rise."

Hall *et al*. (2005a) studied the effects of an extra 350 ppm of CO_2 on litter quality, herbivore activity, and their interactions. Over the three years of this experiment (2000, 2001, 2002), they determined "changes in litter chemistry from year to year were far larger than effects of CO_2 or insect damage, suggesting that these may have only minor effects on litter decomposition." The one exception to this finding was "condensed tannin concentrations[, which] increased under elevated CO_2 regardless of species, herbivore damage, or growing season," rising by 11% in 2000, 18% in 2001, and 41% in 2002 as a result of atmospheric CO_2 enrichment, as best we can

determine from their bar graphs. The five researchers also report, "lepidopteran larvae can exhibit slower growth rates when feeding on elevated CO_2 plants (Fajer *et al*., 1991) and become more susceptible to pathogens, parasitoids, and predators (Lindroth, 1996; Stiling *et al*., 1999)," noting further that at their field site, "which hosts the longest continuous study of the effects of elevated CO_2 on insects, herbivore populations decline[d] markedly under elevated CO_2 (Stiling *et al*., 1999, 2002a, 2003; Hall *et al*., 2005)."

Focusing their attention on two species of oak tree—*Quercus alba* L. (white oak) and *Quercus velutina* Lam. (black oak)—Knepp *et al*. (2007) examined host plant preference and larval performance of *A. polyphemus* when fed foliage of the two tree species that had been grown in either ambient or CO_2-enriched air (to 200 ppm above ambient) in a long-running FACE experiment at the Forest Atmosphere Carbon Transfer and Storage (FACTS–1) research site in the Piedmont region of North Carolina (USA). They found "growth under elevated CO_2 reduced the food quality of oak leaves for caterpillars," and "consuming leaves of either oak species grown under elevated CO_2 slowed the rate of development of *A. polyphemus* larvae." In addition, they report feeding on foliage of *Q. velutina* grown under elevated CO_2 led to reduced consumption by the larvae and greater mortality. The researchers opine, "reduced consumption, slower growth rates, and increased mortality of insect larvae may explain [the] lower total leaf damage observed previously in plots of this forest exposed to elevated CO_2," as documented by Hamilton *et al*. (2004) and Knepp *et al*. (2005).

Stiling *et al*. (2010) note in a CO_2-enriched atmosphere, "plant quality for herbivores is reduced because of decreases in plant nitrogen concentrations and increases in secondary metabolites (Poorter *et al*., 1997; Curtis and Wang, 1998; Peñuelas and Estiarte, 1998)," but "Stiling *et al*. (2009) recently showed that, over long time periods under continuously elevated CO_2, the increases in plant biomass under elevated CO_2 over compensate for reductions in foliage quality by providing a greater quantity of biomass for herbivores." Seeking to determine whether this might also be true for insectivores and detritivores, Stiling *et al*. employed pitfall trapping over the last three of 11 years of continuous CO_2 enrichment (to 350 ppm above ambient) in eight of 16 open-top chambers that enclosed portions of a scrub-oak ecosystem in Florida (USA) composed of a mix of three oak tree species (*Quercus myrtifolia, Q. geminate,* and *Q. chapmanii*) that accounted for

approximately 90% of the total aboveground ecosystem biomass, and they employed sticky traps over another six months of the study.

The three researchers report 110,618 insects and other arthropods from 25 orders were recovered from the pitfall traps, and 39,305 insects and other arthropods from 14 orders were found on the sticky traps. These data, they write, "revealed increases of insect herbivore species such as Thysanoptera (thrips), Hemiptera, and Lepidoptera, but no effects on insectivores such as spiders, parasitic wasps, and ants, or on detritivores such as Diptera (flies), Psocoptera (book lice), Blattodea (cockroaches), Collembola (spring tails), Orthoptera (crickets) and Coleoptera (beetles)."

Stiling *et al.* conclude the "increase in the number of herbivores, including raspers, suckers, and chewers, under elevated CO_2" was "likely caused by an increase in plant biomass under elevated CO_2," which for the scrub-oak ecosystem they studied amounted to 67% (Seiler *et al.*, 2009). But they additionally conclude, "increases in plant biomass and herbivore abundance brought about by elevated CO_2 do not influence insect abundance at other trophic levels such as insectivores, parasitoids and predators, or decomposers." They note their results are similar to those of two other studies (Sanders *et al.*, 2004; Hillstrom and Lindroth, 2008) that also "failed to detect effects of elevated CO_2 on most guilds." Thus, the "bottom-up effect brought about by higher plant biomass as a result of many years of elevated CO_2" in this experiment appears to enhance abundance of herbivores only.

The evidence cited above suggests herbivore damage to oak trees by various insect pests will decline as the air's CO_2 concentration continues to climb.

5.5.3.3 Other Plants

Gleadow *et al*. (1998) grew eucalyptus seedlings in glasshouses maintained at 400 and 800 ppm CO_2 for a period of six months, observing biomass increases of 98% and 134% in high and low nitrogen treatments, respectively. They also studied a sugar-based compound called prunasin, which produces cyanide in response to tissue damage caused by foraging herbivores. Although elevated CO_2 caused no significant change in leaf prunasin content, the proportion of nitrogen allocated to prunasin increased by approximately 20% in the CO_2-enriched saplings, suggestive of a potential for increased prunasin production had the saplings been under attack by herbivores.

In a study involving mechanical defoliation, Lovelock *et al*. (1999) grew seedlings of the tropical tree *Copaifera aromatica* for 50 days in pots placed within open-top chambers maintained at atmospheric CO_2 concentrations of 390 and 860 ppm. At the 14-day point of the experiment, half of the seedlings in each treatment had about 40% of their total leaf area removed. None of the defoliated trees of either CO_2 treatment fully recovered from this manipulation, but at the end of the experiment the total plant biomass of the defoliated trees in the CO_2-enriched treatment was 15% greater than that of the defoliated trees in the ambient-CO_2 treatment, attesting to the benefits of atmospheric CO_2 enrichment in helping trees deal with herbivory.

Docherty *et al*. (1997) grew beech and sycamore saplings in glasshouses maintained at atmospheric CO_2 concentrations of 350 and 600 ppm, and groups of three sap-feeding aphid species and two sap-feeding leafhopper species were allowed to feed on them. Overall, elevated CO_2 had few significant effects on the performance of the insects, although there was a non-significant tendency for elevated CO_2 to reduce the individual weights and populations of the aphids.

Hattenschwiler and Schafellner (1999) grew seven-year-old spruce (*Picea abies*) trees at atmospheric CO_2 concentrations of 280, 420, and 560 ppm and various nitrogen deposition treatments for three years, allowing nun moth larvae to feed on current-year needles for 12 days. Larvae placed on the CO_2-enriched foliage consumed less needle biomass than larvae placed on the ambiently grown foliage, regardless of nitrogen treatment. This effect was so pronounced that the larvae feeding on needles produced by the CO_2-enriched trees attained an average final biomass only two-thirds of that attained by the larvae that fed on needles produced at 280 ppm CO_2. Since the nun moth is a deadly defoliator that resides in most parts of Europe and East Asia between 40 and 60°N latitude and is commonly regarded as the coniferous counterpart of its close relative the gypsy moth, which feeds primarily on deciduous trees, the results of this study suggest the ongoing rise in the air's CO_2 content likely will lead to significant reductions in damage to spruce and other coniferous trees by this voracious insect pest.

Holton *et al*. (2003) reared parasitized and non-parasitized forest tent caterpillars (*Malacosoma disstria*) on two quaking aspen (*Populus tremuloides*) genotypes (216, which is O_3-tolerant, and 259, which is O_3-sensitive) alone and in combination at the Aspen FACE site in northern Wisconsin (USA), in plots exposed to ambient air, ambient air + 200 ppm extra CO_2, ambient air + 50% extra ozone, and ambient air + 200 ppm extra CO_2 and 50% extra O_3 during the daylight hours of one full growing season. They found "elevated CO_2 had little effect on both primary and secondary metabolites of aspen." Thus it was not surprising to learn "elevated CO_2 had few biologically significant effects on forest tent caterpillar performance." Elevated O_3, on the other hand, altered foliar composition much more than did elevated CO_2, and, as they discovered, it improved tent caterpillar

performance under ambient CO_2 conditions, but not in CO_2-enriched air. In addition, elevated O_3 decreased the larval survivorship of the parasite of the caterpillar. Without an increase in the air's CO_2 content commensurate with that projected for O_3 over the coming half-century, therefore, quaking aspen—the most widely distributed tree in North America—would be in for a world of hurt.

Mattson *et al.* (2004) note "although there have been many studies on the effects of elevated CO_2 on the interaction between plants and their insect herbivores (see Bezemer and Jones, 1998; Hunter, 2001), comparable studies on mammalian herbivores are lacking altogether, even though mammals play important roles in dynamics of many ecosystems (McNaughton and Sabuni, 1988; Pastor and Naiman, 1992)." Mattson *et al.* grew one-year-old seedlings of silver birch (*Betula pendula*) in closed-top chambers for one summer and autumn in pots containing an unfertilized commercial peat maintained at three soil nitrogen (N) levels (low = 0 kg N ha^{-1}, medium = 150 kg N ha^{-1}, high = 500 kg N ha^{-1}) and two temperature (T) levels (ambient and ambient + 3°C) in air of either 362 or 700 ppm CO_2 concentration. Feeding trials with caged Eurasian hares (*Lepus timidus*) were then carried out, and a number of chemical analyses were made of the tops of the seedlings and the basal parts of their stems.

In a second experiment, Mattson *et al.* grew paper birch (*Betula papyrifera*) from seed for two 140-day growing seasons in well-watered and fertilized pots placed within FACE rings maintained at atmospheric CO_2 concentrations of either 362 or 562 ppm, after which (in an unplanned aspect of the study) North American eastern cottontail rabbits (*Sylvilagus floridanus*) fed *ad libitum*, consuming bark tissue down to and scoring the wood, on the basal third of the seedlings, and these tissues were tested for the presence of various herbivore-deterring chemical constituents.

"As expected," they write, the results indicate "elevated CO_2 substantially increased the above-ground woody biomass growth of both paper birch (63%) and silver birch (21%)." In addition, noting "numerous studies have shown that elevated atmospheric CO_2 often, but not always, elicits increases in carbon partitioning to carbon-based secondary plant compounds," which often act as deterrents to herbivory, they say their findings "confirm this general pattern in silver and paper birch." Finally, they report high CO_2 reduced hare feeding on silver birch shoots by as much as 48% and reduced rabbit feeding on paper birch stems by about

51%, whereas neither temperature nor severe early-season defoliation (another experimental treatment) affected the trees' resistance against these mammalian herbivores.

Calling the anti-herbivory effect of elevated CO_2 "remarkably strong" and noting rabbits "over-whelmingly preferred ambient CO_2 plants," Mattson *et al.* say their data "clearly suggest that the defensive biochemistry of paper birch twigs as well as the main stem were [positively] altered as the result of elevated CO_2." As the air's CO_2 content continues to rise, at least these two species of birch trees apparently will have a significantly easier time of getting established and growing to maturity.

Sanders *et al.* (2004) studied effects of atmospheric CO_2 enrichment on the plant and arthro-pod communities of the understory of a closed-canopy sweetgum plantation (which reduces the light available to the understory between 70 and 95% during the growing season) in a FACE study where the air's CO_2 content was increased by approximately 48%. The authors report under such conditions there were large adjustments in the relative productivities of the five dominant species that account for more than 90% of the biomass and annual production of the understory vegetation. Overall, however, the total understory productivities of the two CO_2 treatments were not significantly different from each other. Also, Sanders *et al.* report, "C:N ratios for four of the five dominant plant taxa did not differ between ambient and elevated CO_2," and "there were no overall treatment or species x treatment effects" with respect to this parameter.

The three scientists further report they "found no effect of elevated CO_2 on herbivory," and "even for the one species that showed an effect of CO_2 on C:N ratio, herbivores did not compensate by foraging more." In addition, total arthropod abundance did not differ between ambient and elevated CO_2 plots, nor did the abundances of detritivores, omnivores, or parasitoids. They conclude, "changes in plant community composition did not translate into differences in arthropod communities." Sanders *et al.* state "idiosyncratic, species-specific responses to elevated CO_2 may buffer one another: the abundances of some species increase while others decrease," and, therefore, "to understand the potential effects of global [environmental] change on the complexity of multitrophic interactions that structure most com-munities, field experiments on entire communities are necessary."

Noting the "detrimental effects of ozone on plants are well known," and "carbon dioxide [CO_2]

generally affects trees in opposite ways to ozone [O_3]," Valkama *et al*. (2007) conducted a literature review they describe as "the first quantitative analysis of the interactive effects of elevated O_3 and elevated CO_2 on tree chemistry and herbivore performance," based on the results of "63 studies conducted on 22 tree species and 10 insect herbivore species and published between 1990 and 2005."

With respect to ways elevated O_3 may benefit insect herbivores that tend to damage trees, Valkama *et al*. determined "elevated O_3 significantly shortened development time of insect herbivores [when they are exposed and vulnerable to attack by various enemies] and increased their pupal mass in the overall dataset." In addition, the "relative growth rate of chewers was significantly increased by 3.5% under elevated O_3." However, "these effects were counteracted by elevated CO_2," such that "elevated O_3 in combination with CO_2 had no effect on herbivore performance," with the exception that when elevated CO_2 was added to the O_3-enriched air, it not only counteracted the O_3-induced increase in pupal biomass, but reduced it by 7% below what it was in ambient air. This analysis of the vast majority of pertinent experimental data obtained prior to 2006 suggests the ongoing rise in the air's CO_2 content likely plays an extremely important role in negating, and in some cases even more than negating, the damage otherwise capable of being done to Earth's forests by voracious insect pests.

In a study involving only changes in temperature, Andrew and Hughes (2007) "investigated how the relationship of herbivorous insects and their host plants may change under a warmer climate" by "transplanting a host plant species to locations subject to mean annual temperatures 1.2°C higher than at the species' current warmest boundary and 5.5°C higher than at its coolest edge." They "compared the structure and composition of the herbivorous insect community that colonized the transplants (i) to that of the host plant species within its natural range and (ii) to a congeneric plant species that grew naturally at the transplant latitude." In addition, they "investigated whether the herbivore community and rates of herbivory were affected by the latitudinal origin of the transplants."

According to the two Australian researchers, their study indicated "rates of herbivory did not significantly differ between the transplants and plants at sites within the natural range," and "there were no significant differences in herbivore species richness or overall rates of herbivory on the transplants originating from different latitudes." They state in the abstract of their paper, "if this result holds for other plant-herbivore systems, we might expect that under a warmer climate, broad patterns in insect community structure and rates of herbivory may remain similar to that at present, even though species composition may change substantially." Or as stated in their concluding paragraph, "if these results can be generalized to other plant hosts, we might predict that as climate zones shift poleward and mobile organisms like flying insects respond by migrating to stay within their current climatic envelope, plants will be colonized by new herbivore species within similar guilds to those currently supported," and "changes in the composition, but not necessarily the structure, of these new communities may, therefore, result."

Huttunen *et al*. (2007) grew silver birch (*Betula pendula* Roth) seedlings in pots filled with peat at three levels of nitrogen (N) fertility—no N, moderate N (130 kg N ha^{-1}), and high N (270 kg N ha^{-1})—within climate-controlled closed-top chambers from mid-June to October 2002 at the Mekrijarvi Research Station of the University of Joensuu, Finland. The chambers were maintained at atmospheric CO_2 concentrations of either 360 or 720 ppm and at either ambient air temperatures or elevated air temperatures 2°C above ambient from June to August and 4°C above ambient for the remainder of the growing season, while mimicking larval and adult leaf-feeding patterns exhibited during real-world defoliation by manually damaging the leaves of the seedlings by tearing off the apical halves of either 25% or 50% of all leaves greater than 1 cm in length on 1 July (mid-season) and again on 29 July (late-season). They then determined total plant shoot and root biomass once the plants went dormant in October.

As best as can be determined from the authors' bar graphs of their results, and averaged over all three defoliation treatments, the elevated CO_2 treatment increased the biomass of the seedlings in the moderate and high N fertility treatments much more than in the no N fertility treatment (29 and 30%, respectively, vs. 13%). The same was true of the combined elevated CO_2 and elevated temperature treatment, where the corresponding treatment-induced biomass increases were 34 and 36% vs. 20%. These results indicate the heightened temperatures tended to augment the beneficial effects of the elevated CO_2 treatment, with the greatest amplification being manifest in the no N fertility treatment (54% vs. 17 and 20% in the moderate and high N treatments, respectively). Averaged over all three N fertility treatments, the elevated CO_2 increased the plant biomass of the undefoliated seedlings by approximately 25%, that of the 25%-defoliated seedlings by

24%, and that of the 50%-defoliated seedlings by 22%. The elevated CO_2 and elevated temperature treatment increased the plant biomass of the same three categories of seedlings by approximately 31%, 30%, and 29%, respectively. The six Finnish scientists conclude "climatic change"—which they specifically define to mean elevated atmospheric temperature and CO_2—"will have a positive impact on the compensatory ability of defoliated silver birch seedlings."

One year later in a similar analysis, Huttunen *et al.* (2008) studied the leaf palatability of first-year silver birch (*Betula pendula*) seedlings to adult blue alder leaf beetles (*Agelastica alni*), periodically measuring a host of seedling parameters related to plant chemical and morphological defense properties. The seedlings were grown in climate-controlled closed-top chambers maintained at ambient and twice-ambient atmospheric CO_2 concentrations and at ambient and ambient plus 2°C air temperatures. The authors also examined the additional effects of three levels of added soil nitrogen (none, moderate, and high) plus two levels of manual defoliation (25% and 50%) on leaf palatability.

The researchers' findings were varied and complex, indicative of complicated interactions with the potential to cascade through several trophic levels and change the dynamics of forest ecosystems. "In the worst scenario," as they describe what could happen, "the consequences may include widespread damage to trees." However, they report, their study indicated the blue alder leaf beetle's "total leaf consumption was higher under the ambient climatic conditions than under elevated temperature, elevated CO_2, or the combination of elevated temperature and CO_2."

Hamilton *et al.* (2012) write, "the response of complex plant and animal communities to global change is highly variable (Tylianakis *et al.*, 2008)," but they note "recent studies have documented that loss of foliage to arthropod herbivores decreases under elevated CO_2 in woody communities (Hamilton *et al.*, 2004; Knepp *et al.*, 2005; Stiling and Cornelissen, 2007)." They also note the fitness and in some cases population size of herbivorous insects may decline in communities exposed to elevated CO_2 (Hillstrom and Lindroth, 2008; Hillstrom *et al.*, 2010)," although the "effects of elevated CO_2 on naturally occurring arthropod assemblages have not yet been widely characterized."

Working at the Duke Forest FACE facility in the Piedmont region of North Carolina (USA)—where three 30-meter-diameter plots of an expansive stand of loblolly pine had their atmospheric CO_2

concentrations boosted by approximately 200 ppm, and where three other such plots were maintained at the normal ambient CO_2 concentration—Hamilton *et al.* counted arthropods found in each of the six plots every two weeks throughout June and July 2005, in order to assign them to different feeding guilds. In addition, "stable isotope data for spiders collected in ambient and elevated CO_2 plots were analyzed to determine the extent to which herbivorous prey species moved into and out of the elevated CO_2 plots."

The seven U.S. scientists say their isotopic data "gave no indication that the treatment plots represented a 'boundary' to the movement of insects." In addition, there was no detectable effect of elevated CO_2 on the total number of individual arthropods in the two sets of treatment plots. However, "there was an increase in the numbers of individuals collected in primarily predaceous orders (Araneae and Hymenoptera; from 60% to more than 150%) under elevated CO_2 and a decrease in the numbers in primarily herbivorous orders (Lepidoptera and Coleoptera; from -30 to -45%)." Hamilton *et al.* conclude, "decreases in herbivorous arthropods and increases in predaceous arthropods may contribute to reduced herbivory under elevated CO_2 in forest systems."

Novick *et al.* (2012) write "warmer climates induced by elevated atmospheric CO_2 are expected to increase damaging bark beetle activity in pine forests," yet they say, "the effect of elevated CO_2 on resin production—the tree's primary defense against beetle attack—remains largely unknown." They note "resin physically ejects or entombs attacking beetles and, when volatile components of resin have evaporated, seals wounds in the bark," as revealed by the studies of Ruel *et al.* (1998) and Wilkens *et al.* (1998). Novick *et al.* assessed the effect of elevated CO_2 on resin production of dominant-and-unfertilized 27-year-old loblolly pine (*Pinus taeda* L.) trees growing under both ambient and elevated (ambient + 200 ppm) atmospheric CO_2 concentrations in the Duke Forest of North Carolina (USA) over the period March to October 2009.

The four researchers report the elevated CO_2 treatment increased resin flow by 140% in dominant trees growing in unfertilized subplots. This CO_2-induced resin flow enhancement "persisted throughout the growing season." Novick *et al.* conclude, "forests with low- to mid-range fertility"—which, in their words, "currently represent the majority of southern pine forests (Fox *et al.*, 2007)"—"may become increasingly protected from bark beetle

attacks in an elevated CO_2 climate." They note, "previous studies have shown that even more modest increases in resin flow (i.e., enhancements less than or equal to 100%) significantly increase the survival probability of pine trees experiencing bark beetle attack," as demonstrated by Reeve *et al.* (1995) and Strom *et al.* (2002).

Working at the aspen free-air CO_2 enrichment (Aspen FACE) site in north-central Wisconsin (USA), Nabity *et al.* (2012) investigated how herbivore damage types (leaf-chewing, gall-forming, and leaf-folding) alter component processes of photosynthesis under both ambient and elevated (ambient + 200 ppm) atmospheric CO_2 concentrations in aspen (*Populus tremuloides*, genotype 216) trees, as well as how leaf-chewing insects impact photosynthesis in birch (*Betula papyrifera*) trees. They found "growth under elevated CO_2 reduced the distance that herbivore-induced reductions in photosynthesis propagated away from the point of damage in aspen and birch." Nabity *et al.* conclude their findings suggest "at least for these species," elevated CO_2 "may reduce the impact of herbivory on photosynthesis," a very positive development.

The balance of evidence suggests Earth's non-woody plants are adequately prepared to deal with the challenges of herbivorous insects as the air's CO_2 content continues to rise.

5.5.4 Butterflies

- Global warming is creating opportunities for butterflies to expand their populations and ranges, just the opposite of alarmist projections of range contractions and butterfly species demise in response to a CO_2-induced warming of Earth.

IPCC claims butterflies are at risk of extinction due to global warming. This section reviews research studying how butterflies respond to rising air temperatures and CO_2 concentrations and comes to a very different conclusion.

5.5.4.1 Response to Temperature

Research on the impact on butterflies of temperature changes has found impacts on populations and ranges and also has revealed how butterflies adapt, evolve, and in other ways respond to changes in temperature. The following sections summarize that research.

5.5.4.1.1 Population Dynamics

In response to model-based projections in which global warming enhances the prospect for animal species demise, several researchers have conducted studies on butterflies to test the viability of this hypothesis. Fleishman *et al*. (2001), for example, used comprehensive data on butterfly distributions from six mountain ranges in the U.S. Great Basin to study how butterfly populations of that region may respond to IPCC-projected climate change. Their work revealed "few if any species of montane butterflies are likely to be extirpated from the entire Great Basin (i.e., lost from the region as a whole)." The three researchers note "during the Middle Holocene, approximately 8000–5000 years ago, temperatures in the Great Basin were several degrees warmer than today." They conclude, "we might expect that most of the montane species—including butterflies—that currently inhabit the Great Basin would be able to tolerate the magnitude of climatic warming forecast over the next several centuries."

Other scientists have focused on the response of butterflies to warming during the twentieth century, warming IPCC claims is unprecedented in the past one to two thousand years.

Davies *et al*. (2006) studied the silver-spotted skipper butterfly (*Hesperia comma*), noting during the twentieth century it "became increasingly rare in

Britain [as] a result of the widespread reduction of sparse, short-turfed calcareous grassland containing the species' sole larval host plant, sheep's fescue grass," while describing the "refuge" colonies of 1982 as but a "remnant" of what once had been. To examine whether global warming might drive the already-decimated species to extinction, the four researchers analyzed population density data and estimates of the percent of bare ground and the percent of sheep's fescue available to the butterflies, based on surveys conducted in Surrey in the chalk hills of the North Downs, south of London, in 1982 (Thomas *et al.*, 1986), 1991 (Thomas and Jones, 1993), 2000 (Thomas *et al.*, 2001; Davies *et al.*, 2005), and 2001 (R.J. Wilson, unpublished data). They also assessed egg-laying rates in different microhabitats, the effects of ambient and oviposition site temperatures on egg-laying, and the effects of sward composition on egg location. This multifaceted work revealed, "in 1982, 45 habitat patches were occupied by *H. comma*," but "in the subsequent 18-year period, the species expanded and, by 2000, a further 29 patches were colonized within the habitat network." In addition, they found "the mean egg-laying rate of *H. comma* females increased with rising ambient temperatures" and "a wider range of conditions have become available for egg-laying."

Davies *et al.* write, "climate warming has been an important driving force in the recovery of *H. comma* in Britain [as] the rise in ambient temperature experienced by the butterfly will have aided the metapopulation re-expansion in a number of ways." First, they note, "greater temperatures should increase the potential fecundity of *H. comma* females," and "if this results in larger populations, for which there is some evidence (e.g. 32 of the 45 habitat patches occupied in the Surrey network experienced site-level increases in population density between 1982 and 2000), they will be less prone to extinction," with "larger numbers of dispersing migrant individuals being available to colonize unoccupied habitat patches and establish new populations." Second, "the wider range of thermal and physical microhabitats used for egg-laying increased the potential resource density within each grassland habitat fragment," and "this may increase local population sizes." Third, "colonization rates are likely to be greater as a result of the broadening of the species realized niche, [because] as a larger proportion of the calcareous grassland within the species' distribution becomes thermally suitable, the relative size and connectivity of habitat patches within the landscape increases." Fourth, "higher temperatures may directly increase

flight (dispersal) capacity, and the greater fecundity of immigrants may improve the likelihood of successful population establishment." Davies *et al.* conclude, "the warmer summers predicted as a consequence of climate warming are likely to be beneficial to *H. comma* within Britain," and "warmer winter temperatures could also allow survival in a wider range of microhabitats."

Dennis and Sparks (2007) analyzed data on the general abundance of Lepidoptera in Britain over the period 1864–1952, based on information assembled by Beirne (1955) via his examination of "several thousand papers in entomological journals describing annual abundances of moths and butterflies." The two researchers report "abundances of British Lepidoptera were significantly positively correlated with Central England temperatures in the current year for each month from May to September and November," and "increased overall abundance in Lepidoptera coincided significantly with increased numbers of migrants," having derived the latter data from Williams (1965). In addition, they report Pollard (1988) subsequently found much the same thing for 31 butterfly species over the period 1976–1986, and Roy *et al.* (2001) extended the latter investigation to 1997 and found "strong associations between weather and population fluctuations and trends in 28 of 31 species which confirmed Pollard's (1988) findings." These observations indicate the warming-driven increase in Lepidopteran species and numbers in Britain has been an ongoing phenomenon since the end of the Little Ice Age.

Checa *et al.* (2009) studied the composition and structure of butterfly communities of the "rotting-carrion guild" of the Nymphalidae family over a period of 13 months (April 2002–April 2003) in areas surrounding the Yasuni Scientific Research Station in the Ecuadorian Amazon inside the Yasuni National Park. They obtained their data using traps baited with rotten shrimp that had been fermenting for 11–20 days. Checa *et al.* captured 9,236 individual Nymphalidae butterflies representing 208 species, including two species that had not previously been found in Ecuador, and two "new" species that had not previously been found anywhere. They discovered "a constant replacement of species throughout the year," and "these communities had the highest species richness and abundance during the months with high temperatures." They note the mean temperature of their study area "only varies over one degree during the whole year."

The four researchers comment on "temperature's central role in the biology and life history of

butterflies," noting "several key processes for butterfly survival depend on regulation of internal temperature," including mimetism and fast flight (Chai and Srygley, 1990), and fecundity and longevity, which they say have been found to be "higher at higher temperatures (Karlsson and Wiklund, 2005)." Hence, they conclude, "the tight relationship between temperature and butterfly population levels," or abundance, as well as butterfly species richness, likely will be "of major importance" for tropical butterflies in surviving potential future global warming.

5.5.4.1 2 Range Expansion

IPCC claims the increase in temperature predicted to result from the ongoing rise in the air's CO_2 content will be of such magnitude and speed that many species of plants and animals will not be able to migrate poleward in latitude or upward in elevation rapidly enough to avoid extinction, as they are forced to seek cooler living conditions. However, there are many reasons for rejecting this contention, one of the most powerful being increases in the air's CO_2 content generally enable plants to endure warmer weather, so there is little or no need for them to shift the heat-limiting warm-temperature boundaries of their ranges as temperatures rise (See Sections 3.13, 4.2.3, and 4.4, this volume). At the cold-limiting cool-temperature boundaries of their ranges, on the other hand, warming provides opportunities for plants to push poleward and upward, which results in expansions of their ranges and reductions in their risk of extinction.

This section reviews several studies examining butterfly range habitat, revealing butterflies may be mimicking the respective shifts and stability of the cold- and heat-limited boundaries of the ranges of the plants on which they depend for food.

Parmesan *et al.* (1999) examined the distributional changes of non-migratory butterfly species whose northern boundaries were in northern Europe and whose southern boundaries were in southern Europe or northern Africa, over the prior century of global warming. They found the northern range boundaries shifted northward for 65% of the 52 species examined, remained stable for 34%, and

shifted southward for 2%. As to the southern boundaries, of the 40 species examined there, 22% shifted their southern range boundary northward, for 72% it remained stable, and for 5% it shifted southward. Because "nearly all northward shifts involved extensions at the northern boundary with the southern boundary remaining stable," as the 13 researchers explain, "most species effectively expanded the size of their range when shifting northwards."

Thomas *et al.* (2001) documented an unusually rapid expansion of the ranges of two butterfly species (the silver-spotted skipper and the brown argus) along with two cricket species (the long-winged cone-head and Roesel's bush cricket). They observed the warming-induced "increased habitat breadth and dispersal tendencies have resulted in about 3- to 15-fold increases in expansion rates." In commenting on these findings, Pimm (2001) remark the geographical ranges of these insects were "expanding faster than expected" and the synergies involved in the many intricacies of the range expansion processes were "unexpected."

Crozier (2004) notes *Atalopedes campestris*, the sachem skipper butterfly, expanded its range from northern California into western Oregon in 1967, and into southwestern Washington in 1990," where she reports temperatures rose by 2–4°C over the prior half-century. In an attempt to assess the importance of this regional warming for the persistence of *A. campestris* in the recently colonized areas, Crozier "compared population dynamics at two locations (the butterfly's current range edge and just inside the range) that differ by 2–3°C." Then, to determine the role of over-winter larval survivorship, she "transplanted larvae over winter to both sites."

According to Crozier, "combined results from population and larval transplant analyses indicate that winter temperatures directly affect the persistence of *A. campestris* at its northern range edge, and that winter warming was a prerequisite for this butterfly's range expansion." Noting "populations are more likely to go extinct in colder climates," Crozier writes, "the good news about rapid climate change [of the warming type] is that new areas may be available for the introduction of endangered species." The species she studied responded to regional warming by extending its northern range boundary, thereby expanding its range.

Menendez *et al.* (2006) provided what they call "the first assessment, at a geographical scale, of how species richness has changed in response to climate change," concentrating on British butterflies. They tested "whether average species richness of resident British butterfly species has increased in recent decades, whether these changes are as great as would be expected given the amount of warming that has taken place, and whether the composition of butterfly communities is changing towards a dominance by generalist species." They determined "average species richness of the British butterfly fauna at 20 x 20 km grid resolution has increased since 1970–82, during a period when climate warming would lead us to expect increases." They also found, as expected, "southerly habitat generalists increased more than specialists," which require a specific type of habitat that is sometimes difficult for them to find, especially in the modern world where habitat destruction is commonplace. In addition, they determined observed species richness increases lagged behind those expected on the basis of climate change.

These results "confirm," according to the nine U.K. researchers, "that the average species richness of British butterflies has increased since 1970–82." Some of the range shifts responsible for the increase in species richness take more time to occur than those of other species, and the researchers state their results imply "it may be decades or centuries before the species richness and composition of biological communities adjusts to the current climate."

In another analysis from Britain, Gonzalez-Megias *et al.* (2008) investigated species turnover in 51 butterfly assemblages by examining regional extinction and colonization events that occurred between the two periods 1976–1982 and 1995–2002. The five researchers found regional colonizations exceeded extinctions: "over twice as many sites gained species as lost species," so "the average species richness of communities has increased." They also found species abundances following colonization likewise increased, because of "climate-related increases in the [land's] carrying capacity."

Comparing their results with a broader range of animal studies, Gonzalez-Megias *et al.* found "analyses of distribution changes for a wide range of other groups of animals in Britain suggest that southern representatives of most taxa are moving northwards at a rate similar to—and in some cases faster than—butterflies (Hickling *et al.*, 2006)," and they report, "as with butterflies, most of these taxonomic groups have fewer northern than southern representatives, so climate-driven colonisations are likely to exceed extinctions." They suggest "most of these taxa will also be experiencing slight community-level increases in species richness."

White and Kerr (2006) "report butterfly species' range shifts across Canada between 1900 and 1990

and develop spatially explicit tests of the degree to which observed shifts result from climate or human population density," describing the latter factor as "a reasonable proxy for land use change." In this category they included such elements as "habitat loss, pesticide use, and habitat fragmentation," all of which anthropogenic-driven factors have been tied to declines of various butterfly species. In addition, they state to their knowledge, "this is the broadest scale, longest term dataset yet assembled to quantify global change impacts on patterns of species richness." They found butterfly species richness "generally increased over the study period, a result of range expansion among the study species." They further found this increase "from the early to late part of the 20th century was positively correlated with temperature change," which had to have been the cause of the increase, for they also found species richness was "negatively correlated with human population density change."

Westwood and Blair (2010) measured the responses of 19 common butterfly species of the boreal forests of Manitoba (Canada) to temperature changes experienced there during 1971–2004, focusing on each species' date of first appearance, week of peak abundance, and length of flight period. Autumn temperatures were found to have warmed significantly, and the two Canadian researchers observed "13 of 19 species showed a significant increase in flight period extending longer into the autumn," when "flight period extensions increased by 31.5 ± 13.9 days over the study period." They also note "two species, *Junonia coenia* and *Euphydryas phaeton*, increased their northerly ranges by ~150 and 70 km, respectively."

Westwood and Blair state "warmer autumns and winters may be providing opportunities for range extensions of more southerly butterfly species held at bay by past climatic conditions." They cite other investigators who have obtained similar results, stating "northward expansions in butterfly species range correlating with northward shifts in isotherms have been documented in both Europe and North America (Karl *et al*., 1996; Parmesan, 1996; Parmesan *et al*., 1999; Hill *et al*., 1999; Hickling *et al*., 2006)," and "in Canada, the Gorgone checkerspot (*Chlosyne gorgone*, Hubner) and the Delaware skipper (*Anatryone logan*, W.H. Edwards) have recently expanded their northern ranges significantly (Kerr, 2001)."

Forister *et al*. (2010) analyzed 35 years of butterfly presence-absence data collected by a single observer at 10 sites approximately every two weeks along an elevation gradient stretching from sea level to an altitude of 2,775 meters in the Sierra Nevada Mountains of Northern California (USA). During the data-collection period both maximum and minimum temperatures rose, low-altitude habitat was negatively affected by encroaching land development, and there was no systematic variation in precipitation. The eight researchers found species richness over this period "declined at half of the sites, with the most severe reductions at the lowest elevations," where "habitat destruction [was] greatest." At intermediate elevations, they report, there were "clear upward shifts in the elevational ranges of species, consistent with the influence of global warming." And at the highest site, they found species richness increased, and "in addition to an increase in richness, abundance has also generally increased at the highest-elevation site."

Noting the Arctic is predicted to be especially susceptible to potential threats from climate change, citing Overpeck *et al*. (1996), Franzen and Ockinger (2012) studied temporal changes in the insect species richness and community composition of wild bees, butterflies, and moths over a period of 64 years at five sites in northern Sweden's Padjelanta National Park (one of the largest National Parks in Europe, located just north of the Arctic Circle, between 66°45' and 67°35'N, and 15°06' and 18°36'E). The insect data were collected during surveys conducted over the period 2006–2008 and were compared with similar data collected in 1998 and 1944, while corresponding climate data were obtained from a weather station located at 66.89°N, 18.02°E.

The two researchers determined there had been a significant increase in the daily mean temperature during the vegetation season (May–September) between 1944 and 2008, when the temperature rose at a rate of 0.015°C per year, yielding an increase of almost 1°C over the 64-year study period. With respect to insect responses, they found the total number of bumble bee, butterfly, and moth species increased from 52 in 1944 to 64 in 2008; for wild bees, which increased only from 15 to 16 species, the increase was not statistically significant. For butterflies and moths, the combined species number increase (from 37 to 48) was statistically significant. Franzen and Ockinger state, "high alpine insect species are apparently still performing relatively well," noting "both southern species, such as *Erebia ligea* and *Polyommatus icarus*, and high alpine species, such as *Boloria chariclea* and *Lasionycta staudingeri*, seem to have colonized the area," and "ranges and species richness are even increasing in

our study region, due to retreating glaciers and plant colonizations." In light of these real-world observations, they say "it is possible that warming will simply improve the performance and abundance of species in cold areas, as their mobility increases and new habitats become available," citing Ashton *et al.* (2009), Bale and Hayward (2010), and Kullman (2010).

According to Oliver *et al.* (2012), "climate warming threatens the survival of species at their warm, trailing-edge range boundaries but also provides opportunities for the ecological release of populations at the cool, leading edges of their distributions," so "as the climate warms," they continue, "leading-edge populations are expected to utilize an increased range of habitat types, leading to larger population sizes and range expansion." Oliver *et al.* tested "the hypothesis that the habitat associations of British butterflies have expanded over three decades of climate warming." They characterized "the habitat breadth of 27 southerly distributed species from 77 monitoring transects between 1977 and 2007 by considering changes in densities of butterflies across 11 habitat types."

In response to the overall climate warming that occurred between 1977 and 2007, but "contrary to expectation," as the five UK researchers report, 20 of the 27 species of butterflies they studied "showed long-term contractions in their habitat associations, despite some short-term expansions in habitat breadth in warmer-than-usual years," when the butterflies they studied spread out from their primary habitat to occupy other sites. They say these findings suggest some non-climatic driver must be responsible for most of the habitat contractions of British butterflies over the past three decades, for they note, "butterfly population declines in the past century have been primarily driven by habitat destruction and degradation, particularly in relation to agricultural intensification and abandonment," citing Asher *et al.* (2001) and Warren *et al.* (2001). They lament the likelihood these other anthropogenic-induced constraints "appear to be out-weighing the positive effects of a warming climate on habitat breadth." In the final sentence of their paper, they suggest, "only if other non-climatic drivers can be reduced or reversed will species be able to fully exploit any emerging opportunities provided by climate warming."

It appears the real world of nature is behaving just the opposite of alarmist projections of range contractions and butterfly species demise in response to a CO_2-induced warming of Earth.

5.5.4.1.3 Adaptation, Evolution, and Phenotypic Responses

Few studies have investigated adaptive or evolutionary responses of butterflies to increased temperature. But those that have done so suggest butterflies are well-equipped to manage any of the temperature changes projected by IPCC for the future.

Hughes *et al*. (2007) examined evolutionary changes in adult flight morphology in six populations of the speckled wood butterfly—*Pararge aegeria*—along a transect from its distribution core to its warming-induced northward-expanding range margin. The results were compared with the output of an individual-based spatially explicit model developed "to investigate impacts of habitat availability on the evolution of dispersal in expanding populations." The empirical data the researchers gathered in Britain "were in agreement with model output" and "showed increased dispersal ability with increasing distance from the distribution core." This included favorable changes in thorax shape, abdomen mass, and wing aspect ratio for both males and females, as well as thorax mass and wing loading for females. The researchers state, "increased dispersal ability was evident in populations from areas colonized >30 years previously."

Hughes *et al*. suggest "evolutionary increases in dispersal ability in expanding populations may help species track future climate changes and counteract impacts of habitat fragmentation by promoting colonization." However, they report, in the specific situation they investigated, "at the highest levels of habitat loss, increased dispersal was less evident during expansion and reduced dispersal was observed at equilibrium, indicating that for many species, continued habitat fragmentation is likely to outweigh any benefits from dispersal."

Another means by which butterflies can cope with higher temperatures is through the production of heat-shock proteins (HSPs). According to Karl *et al*. (2008), HSPs "are thought to play an important ecological and evolutionary role in thermal adaptation," where "the up-regulation of stress-inducible HSPs may help organisms to cope with stress thus enhancing survival (Sorensen *et al*., 2003; Dahlhoff, 2004; Dahlhoff and Rank, 2007)." Working with *Lycaena tityrus,* a widespread temperate-zone butterfly that ranges from western Europe to central Asia, Karl *et al*. tested this hypothesis by comparing expression patterns of stress-inducible HSPs across replicated populations originating from different altitudes and across different ambient temperatures. Their observations revealed "a significant interaction between altitude and rearing temperature [that] indicates that low-altitude animals showed a strongly increased HSP70 expression at the higher compared with at the lower rearing temperature." This is exactly where one would expect to see such a response in light of its obvious utility in warmer conditions.

Karl *et al*. observe "HSP70 expression increased substantially at the higher rearing temperature in low-

altitude butterflies ... [which] might represent an adaptation to occasionally occurring heat spells," suggesting this response should serve these organisms well if the dramatic warming predicted by IPCC should come to pass.

Pateman *et al.* (2012) note there are many situations in nature where one species has a close-to-exclusive relationship with another species, such as a predator-prey relationship in the animal kingdom, an animal-plant symbiotic relationship such as that between corals and the zooxanthellae they host, or the relationship between a butterfly and the plant species that acts as a host for the larval stage of the butterfly. Such interactions, according to Pateman *et al.*, are most commonly regarded as additional constraints, "because they may limit species to a narrower set of physical conditions (and, hence, narrower geographic ranges) than their fundamental climatic niches might otherwise allow." Thus if the world warms to a substantial degree, there may be a mismatch between the climatic needs of the two species, resulting in one or both of them suffering from the change in climate.

Pateman *et al.* studied the brown argus butterfly (*Aricia agestis*), which "has spread northward in Great Britain by ~79 km in 20 years, which is 2.3 times faster than the average expansion rate documented for species globally (Chen *et al.*, 2011)," endeavoring to discover what accelerated the butterfly's dramatic rate of range expansion. They analyzed the effect of climate on brown argus butterfly populations associated with different larval host plants, based on count data developed by volunteers who monitored more than 200 fixed transects in Britain, as described by Pollard and Yates (1993). Results revealed warmer summers typically result in higher brown argus larval population densities on both rockrose and Geraniaceae plants, but under cooler conditions the rockrose host plant was more favorable than Geraniaceae plants. Over the past two decades, as the frequency of warm summers increased, the five UK researchers found the brown argus butterfly adapted by expanding its larval presence onto Geraniaceae plants they had largely avoided under cooler conditions. That led to a significant expansion in the size of their range, as they had an additional plant species on which to lay their eggs and have their larvae develop successfully.

The five researchers state in the concluding sentence of the abstract of their paper, "interactions among species are often seen as constraints on species' responses to climate change, but we show that temperature-dependent changes to interspecific interactions can also facilitate change." Or as they state in the concluding sentence of the body of their paper, "we suggest that altered interactions among species do not necessarily constrain distribution changes but can facilitate expansions," thereby providing another real-world example of a previously unappreciated means by which an animal species can benefit from global warming and expand its range of territorial occupancy. And contrary to the view that generalist species will more rapidly exploit new regions made available by climate change, field assays of butterflies in recently colonized areas are composed of more specialized species, such as the UK brown argus butterfly, because of their aggressive colonization of their widely dispersed host plant (Bridle *et al.*, 2014).

5.5.4.2 Response to Elevated CO₂

Few studies have been conducted on the response of butterflies to increased levels of atmospheric CO_2, but those that have been done suggest rising CO_2 will confer a net benefit on their growth and survival.

Early work on the subject was provided by Groverde *et al*. (1999). Birdfoot Deer Vetch (*Lotus corniculatus*) is a cyanogenic plant that produces foliar cyanoglycosides to deter against herbivory by insects. The Common Blue Butterfly (*Polyommatus icarus*), however, regularly feeds on this plant—it possesses an enzyme that detoxifies these cyanide-containing defensive compounds. To study the effects of elevated CO_2 and genotype on the leaf quality of Birdfoot Deer Vetch and the larval development of the Common Blue Butterfly, Groverde *et al*. grew four genotypes of *Lotus corniculatus*, differing in cyanoglycoside and tannin concentrations, in controlled environmental chambers receiving atmospheric CO_2 concentrations of either 350 or 700 ppm.

Elevated CO_2 significantly increased leaf tannin and starch contents in a genotypically dependent and independent manner, respectively, while decreasing leaf cyanoglycoside contents, regardless of genotype. Atmospheric CO_2 enrichment did not significantly affect leaf water, sugar, protein, or nitrogen content. Thus, these CO_2-induced changes in leaf chemistry (higher starch and tannin and lower cyanoglycoside concentrations) increased its palatability, as indicated by greater leaf dry weight consumption of CO_2-enriched leaves by butterfly larvae. In addition, increased leaf consumption of CO_2-enriched leaves led to greater larval biomass and shorter larval developmental times, indicating atmospheric CO_2 enrichment affected leaf quality to positively influence larvae of the Common Blue Butterfly. Moreover, larval mortality was lower when feeding on CO_2-enriched, rather than ambiently grown, leaves. Thus, as the CO_2 content of the air rises, it is likely Birdfoot Deer Vetch plants will increase their photosynthetic rates and differentially invest their additional carbon gains in storage, structural, and defensive compounds. Atmospheric CO_2 enrichment likely will increase leaf starch and tannin contents and decrease cyanoglycoside contents, without affecting sugar, protein, water, and nitrogen contents. Col-

lectively, these chemical changes would improve the palatability of Birdfoot Deer Vetch leaves to the Common Blue Butterfly larvae.

In a follow-up study four years later, Groverde *et al*. (2004), abandoned the controlled environment chamber design of Groverde *et al*. (1999) and grew Birdfoot Deer Vetch plants from seed for three months in tubes recessed into the ground under natural conditions in a nutrient-poor calcareous grassland where an extra 232 ppm of CO_2 was supplied to them via a screen-aided CO_2 control (SACC) system (Leadley *et al*., 1997; 1999) and insect larvae were allowed to feed on the plants (half of which received extra phosphorus fertilizer) for the final month of the experiment.

The 63% increase in atmospheric CO_2 concentration enhanced the total dry weight of plants growing on the unfertilized soil by 21.5% and that of the plants growing on the phosphorus-enriched soil by 36.3%. The elevated CO_2 treatment had no effect on pupal and adult insect mass. Goverde *et al*. report there were "genotype-specific responses in the development time of *P. icarus* to elevated CO_2 conditions," with larvae originating from different mothers developing better under either elevated CO_2 or ambient CO_2, and for still others the CO_2 concentration had no effect on development. Condensed tannins in the foliage of plants growing on the nutrient-poor calcareous soil were increased by 23.7% in the CO_2-enriched air.

The results of this study and its predecessor suggest the ongoing rise in the air's CO_2 content likely will be positive for *L. corniculatus* plants, while ranging from positive to nil for the insect herbivore *P. icarus* that feeds on them. In addition, the authors suggest rising levels of CO_2 might be "a selective factor, affecting both plant and herbivore populations and their interaction," and, therefore, "genotype-specific responses must be considered because this will affect the outcome of elevated CO_2 for plant-herbivore interactions." It is currently unclear what the range of those potential outcomes might be. Finally, since the presence of condensed tannins in foliage eaten by ruminants tends to decrease their emissions of methane, it might be expected the CO_2-induced increases in the concentrations of these substances in the leaves of *L. corniculatus* may help reduce the atmospheric concentration of this powerful greenhouse gas in a CO_2-enriched world of the future.

Groverde *et al*. (2002) raised larvae of the satyrid butterfly (*Coenonympha pamphilus*) in seminatural, undisturbed calcareous grassland plots exposed to

atmospheric CO_2 concentrations of 370 and 600 ppm for five growing seasons. Elevated atmospheric CO_2 concentration was shown to increase foliar concentrations of total nonstructural carbohydrates and condensed tannins in the grassland plants. In what is often considered a negative impact, however, it decreased foliar nitrogen concentrations. Nevertheless, this phenomenon had no discernible negative impact on butterfly growth and performance characteristics. Larval developmental time, for example, was not affected by elevated CO_2, nor was adult dry mass. The elevated CO_2 increased lipid concentrations in adult male butterflies by nearly 14%, and marginally increased the number of eggs in female butterflies.

As atmospheric CO_2 concentrations increase, larvae of the satyrid butterfly likely will not be negatively affected by feeding on grassland plants that may exhibit reduced foliar nitrogen concentrations. Increases in the air's CO_2 concentration may increase the fitness of this butterfly species. Adult males exposed to elevated CO_2, for example, exhibited greater body concentrations of lipids, compounds used as energy resources in these and other butterflies. In addition, elevated CO_2 increased egg numbers in females, which also suggests an increase in fitness. Thus, this species—and perhaps others—likely will respond positively to future increases in the air's CO_2 concentration.

5.5.5 Other Insects

5.5.5.1 Response to Temperature

It is important to determine what effect global warming might have on the delicate balance between various plants and the insects that feed on them. Several researchers have done just that for several insect species. This section examines what has been reported for other types of insects not previously discussed in this chapter.

In some cases, researchers have found higher temperatures do indeed inhibit insect growth and survival. For some insect species, humankind might consider this a good thing.

Zhang *et al*. (2009), for example, note "the Oriental migratory locust (*Locusta migratoria manilensis*) has been one of the most damaging agricultural pests throughout Chinese history." Based on the decadal locust abundance data of Ma (1958) for the AD 950s–1950s, the decadal Yangtze Delta flood and drought frequency data of Jiang *et al*. (2005) for the AD 1000s–1950s, and the decadal mean temperature records of Yang *et al*. (2002) for the AD 950s–1950s, Zhang *et al*. employed wavelet analysis "to shed new light on the causal relationships between locust abundance, floods, droughts and temperature in ancient China."

The international team of Chinese, French, German, and Norwegian researchers say coolings of 160- to 170-year intervals dominated climatic variability in China over the past millennium, and these cooling periods promoted locust plagues by enhancing temperature-associated drought/flood events. The six scientists say their results suggest "global warming might not only imply reduced locust plague[s], but also reduced risk of droughts and floods for entire China." They note these findings "challenge the popular view that global warming necessarily accelerates natural and biological disasters such as drought/flood events and outbreaks of pest insects," the view long championed by the assessment reports of the Intergovernmental Panel on Climate Change. In direct contrast to that view, Zhang *et al*. say their results are an example of "benign effects of global warming on the regional risk of natural disasters."

Reineke and Hauck (2012) note "the grape leafhopper *Empoasca vitis* is regarded as a major insect pest in many European grapevine growing areas, with an increasing importance realized in recent years, maybe as a result of climatic change."

Reineke and Hauck studied in the laboratory the

development of larval instars of two leafhopper species, *E. vitis* and *E. rosae,* on grapevine leaves under different temperature regimes. The two German researchers report the shortest larval developmental time they observed occurred at night temperatures of 13–15°C and day temperatures of 23–25°C, which they say "was in agreement with predicted optimal temperatures for both species." In addition, "at the temperature regime of 20°C night and 30°C day temperature, either no egg hatch was observed or early development of first-instar larvae was not successful for both species." Reineke and Hauck conclude, "these results suggest that warm (18°C) nights and moderately warm (28°C) days are representing the upper thermal threshold for development of both *E. vitis* and *E. rosae* embryonic stages on grapevine leaves, questioning current assumptions of an increasing importance of *E. vitis* as a grapevine pest under future climate change."

Bertelsmeier *et al.* (2013) write, "climate change and invasive species are two of the most serious threats of biodiversity," noting "a general concern is that these threats interact, and that a globally warming climate could favor invasive species," with the result that "many native species are displaced, leading to local extinctions of fauna and flora." They note "several studies suggest that climate change could exacerbate the threat posed by invasive species, especially poikilotherms [animals having a body temperature that varies with the temperature of their surroundings], by removing thermal barriers and allowing them to establish at higher latitudes."

The three French researchers focused their attention on ants, because "ants are among the worst invasive species (Rabitsch 2011; Holway *et al.* 2002; Lach and Hooper-Bui 2010)," and "they are small, numerous and colonial" and can therefore "rapidly colonize a new habitat." They studied the big-headed ant, *Pheidole megacephala*, considered one of the world's 100 worst invasive species. They used ecological niche models to estimate the species' potential suitable habitat in 2020, 2050, and 2080 with an ensemble forecast obtained from five modeling techniques, including three global circulation models and two CO_2 emission scenarios, by means of which they generated world maps with suitable climatic conditions and assessed changes, both qualitatively and quantitatively.

"Surprisingly," Bertelsmeier *et al.* write, their results suggest "the invasion of big-headed ants is not only unlikely to benefit from climate change, but may even suffer from it," as their projections showed "a global decrease in the invasive potential of big-headed ants as early as 2020 and becoming even stronger by 2080, reaching a global loss of 19.4% of area with favorable climate." They note this finding is just the opposite of classical views of global climate change, wherein the ranges of many invading species are believed to increase in response to warming, especially those that are currently limited by climate. *P. megacephala* "will experience very little shifts in potential habitat," the French scientists conclude, as their niche envelope, presenting favorable climatic conditions, "will mostly shrink."

The analysis of Bertelsmeier *et al.* suggests, as they clearly state, "the worst invasive species of today may not be the worst invasive species of tomorrow," if Earth begins to warm again. After the planet's nearly two-decade climate-change hiatus, it's anyone's guess as to when that might happen.

Other insect species have benefited from a little global warming, as illustrated by recent temperature-induced expansions of their ranges.

Hickling *et al.* (2005), for example, analyzed changes in the northern and southern range boundaries of 37 non-migratory British Odonata (dragonfly and damselfly) species—four of which have northern ranges, 24 of which have southern ranges, and nine of which are ubiquitous—between the two ten-year periods 1960–1970 and 1985–1995. Their work revealed all but two of the 37 species increased their ranges between the two ten-year periods. They report their "findings that species are shifting northwards faster at their northern range margin than at their southern range margin, are consistent with the results of Parmesan *et al.* (1999)," adding, "this could suggest that species at their southern range margins are less constrained by climate than by other factors."

Poniatowski and Fartmann (2011) state the majority of central European orthopterans (an order of insects that includes grasshoppers, crickets, and locusts) "are flightless and have low dispersal ability," citing Reinhardt *et al.* (2005). However, they note, "since the 1980s—the beginning of the strong global temperature increase—some short-winged (brachypterous) species have been able to expand their ranges rapidly," as reported by Thomas *et al.* (2001), Simmons and Thomas (2004), Gardiner (2009), and Wissmann *et al.* (2009). In those cases, the scientists write, "long-winged (macropterous) individuals of the predominantly short-winged (flightless) species are assumed to have been responsible for the range shifts," citing the findings and conclusions of Simmons and Thomas (2004), Gardiner (2009), and Hochkirch and Damerau (2009).

Poniatowski and Fartmann studied the migration behavior of *Metrioptera roeselii*, a medium-sized bush-cricket, 13–26 mm in total length, which is currently expanding its range northwards in large parts of Europe (Kleukers *et al*., 2004; Gardiner, 2009; Wissmann *et al*., 2009)." This species is wing-dimorphic, but they note "the short-winged (brachypterous) morph dominates."

Based on their analyses of the relationships between bush-cricket densities and several meso-climate/weather parameters, the two German researchers found cricket abundances were positively correlated with warm and dry weather conditions during the hatching times of the nymphs, leading them to conclude, "the development of long-winged individuals is determined by density stress (crowding), as has been shown for locusts (Uvarov, 1966)." They further note, "similar results have also been reported for other bush-crickets," citing Ando and Hartley (1982), Sanger (1984), and Higaki and Ando (2003). Poniatowski and Fartmann conclude, "the rapid northward range expansion of *M. roeselii* is indirectly driven by climate change," explaining, "favorable (warm/dry) weather conditions lead to high densities at high latitudes (cf. Bale *et al*., 2002) and in turn result in many macropters," the "potential dispersers" that get the species where it needs to go in order to survive in a world of evolving warmth.

Instead of experiencing range expansions in response to rising temperatures, other insect species have invoked adapted mechanisms allowing them to maintain their populations and habitat area.

Sparks *et al*. (2010) note "honeybees are an essential component of modern agriculture," and "large acreages of pollinator-dependent crops, such as apples, almonds, blueberries and cranberries, require managed pollinators, mainly the honeybee, to ensure maximized production." They report several modern studies suggest synchronization of pollinator activity and flowering may be changed by rapid global warming, leading to deficient pollination when it is most needed and resulting in reduced crop productivity. Noting little work has focused on this imagined problem, the six Polish scientists decided to investigate the dates of honeybees' first cleansing flights, which occur in the early spring of each year after overwintering and "are undertaken by worker bees excreting faeces accumulated in their recta while restricted in the hive for the winter during cold weather."

Sparks *et al*. analyzed annual records of the first observed cleansing flights of honeybees from 80–130 hives for each of the 25 years of the 1985–2009

period in the vicinity of Poznan, Poland. They found a significant relationship between the date of the first cleansing flight and the January to March mean temperature, as well as the previous June to September mean temperature. In the two-variable model of this phenomenon they developed, "the regression coefficients suggested a 1°C increase in previous June to September mean temperature was associated with a 9.11 ± 2.36 day advance, and a 1°C increase in January to March temperature was associated with a 3.41 ± 1.00 day advance, in first cleansing flight date."

Thus they discovered "first cleansing flight dates in [their] study advanced by over 1 month during the 25 years that observations were kept," and this advancement was "similar to changes reported in first appearance dates of other insects (e.g. Roy and Sparks, 2000; Sparks *et al*., 2005; Harrington *et al*., 2007), including other hymenopterans like wasps (Tryjanowski *et al*., 2010)." This demonstrates, as has been observed by still others, "cleansing behavior is related to late winter/spring temperature (e.g. Kronenberg and Heller, 1982; Seeley, 1985)," and provides more evidence of honeybees "continued synchrony with the plant species that rely heavily on this major pollinator," as the plants' flowering dates fluctuate with the ups and downs of spring temperatures and their longer-term trends.

Bartomeus *et al*. (2011) preface their analysis by noting "the phenology of many ecological processes is modulated by temperature, making them potentially sensitive to climate change," and because of this fact, "mutualistic interactions may be especially vulnerable because of the potential for phenological mismatching if the species involved do not respond similarly to changes in temperature." Bartomeus *et al*. explored this situation with real-world data by presenting "an analysis of climate-associated shifts in the phenology of wild bees, the most important pollinators world-wide, and [comparing] these shifts to published studies of bee-pollinated plants over the same time period." They "used long-term data to compare phenological shifts for 10 bee species to shifts in 106 native plant species that are visited by these same bee species," which typically "have annual cycles that include an obligatory larval or adult diapause before spring emergence." The plant data for this comparison were provided by Primack *et al*. (2004) and Miller-Rushing *et al*. (2006) for Massachusetts (AD 1885–2003), by Bradley *et al*. (1999) for Wisconsin (1936–1999), by Cook *et al*. (2008) for New York (1931–2008), and by Abu-Asab *et al*. (2001) for Washington, DC (1970–1999, a time interval

bracketing the period of greatest temperature increase), and the bee data were developed by Bartomeus *et al*.

The results indicate "over the past 130 years, the phenology of 10 bee species from northeastern North America has advanced by a mean of 10.4 ± 1.3 days," and "most of this advance has taken place since 1970, paralleling global temperature increases." The scientists note "when the best available data are used to estimate analogous rates of advance for plants, these rates are not distinguishable from those of the bees." Bartomeus *et al*. conclude, among the generalist bee species they studied, "bee emergence is keeping pace with shifts in host-plant flowering." This finding suggests historical global warming—which IPCC contends has been unprecedented over the past millennium or two—has not detrimentally interfered with the longstanding mutually beneficial relationship between the emergence of adult wild bees and the flowering of the plants they visit.

Balanya *et al*. (2006) determined the magnitude and direction of shifts over time [13 to 46 years, mean = 24.1 years] in chromosome inversion frequencies and in ambient temperature for 26 populations of the cosmopolitan fly species *Drosophila subobscura* on three continents, to determine whether "ambient temperatures have warmed at these sites and also whether genotypes characteristic of low latitudes have increased in frequency." The authors report warming occurred at 22 of the 26 sites they investigated, and "chromosome frequencies shifted toward a more low-latitude pattern in 21 of the 22 sites that warmed over the sample interval," indicating "inversion frequencies have changed in step with climate on three continents." As a result, "genotype frequencies and climate at a given site have become more equatorial over the sample intervals," with the observed shifts being "equivalent to moving the historical sample site ~1° of latitude closer to the equator."

The authors describe the genetic shift they uncovered as "exceptionally rapid," being "detectable even for samples separated by fewer than two decades." In addition, they say, "the ability of *D. subobscura* (Rodriguez-Trelles *et al*., 1998; Orengo and Prevosti, 1996; Sole *et al*., 2002)—and probably other species with short generation times (Bradshaw and Holzapfel, 2001; Umina *et al*., 2005; Levitan and Etges, 2005; Kinnison and Hendry, 2001)—to respond genetically and rapidly to imposed environmental shifts may partially buffer their persistence in a globally warming world (Bradshaw and Holzapfel, 2006)."

Zivanovic and Mestres (2011) collected *Drosophila subobscura* flies from a swampy area on the bank of the Danube river near the town of Apatin, approximately 200 km northwest of Belgrade, Serbia, and analyzed inversion polymorphisms in them, comparing their results (from 2008 and 2009) with results obtained from flies collected at the same site in June 1994, because, as they put it, "genes located within inversions are associated with a variety of traits including those involved in climate adaptation," citing Hoffmann and Rieseberg (2008). The scientists found a significant increase in the frequency of certain chromosomal arrangements characteristic of southern latitudes, which they describe as "warm adapted," and a significant decrease in the frequency of such arrangements characteristic of northern latitudes, which they describe as "cold adapted."

The two researchers say their observations suggest they have detected "the effect of selection on chromosomal polymorphism composition," and, therefore, "some form of natural selection appears to be acting as a reaction to the increase in temperature associated with [the] many heat waves that have markedly affected the Balkan Peninsula," especially over the past decade and a half. They also note their results "agree with those from southwestern and central European populations (Rodriguez-Trelles and Rodriguez, 1998; Sole *et al*., 2002; Balanya *et al*., 2004, 2006, 2009)." In addition, they note similar things have been observed in *D. melanogaster* in Australia, citing Anderson *et al*. (2005) and Umina *et al*. (2005), and in *D. robusta* in North America, citing Levitan and Etges (2005). They report, "the climate change of recent decades has led to heritable genetic changes in animal species as diverse as birds, squirrels and mosquitoes (Bradshaw and Holzapfel, 2006)," revealing many forms of animal life may be well equipped to evolve with sufficient rapidity to survive the challenges of rapid global warming.

Nyamukondiwa and Terblanche (2010) write, "acclimation, acclimatization or hardening responses all describe different forms of phenotypic plasticity (i.e. the ability of an organism to respond to environmental stimuli with a change in phenotype)," as described by West-Eberhard (2003) and Whitman (2009). In addition, they state, "phenotypic plasticity may alter the performance of an organism through compensatory modifications of physiological function and tolerance as a result of changes in environmental conditions," suggesting this multifaceted phenomenon likely will play a major role in determining future geographic distributions of insects in a warming world.

The two South African scientists explored the phenomenon as it operates in two species of fruit fly (*Ceratitis rosa* and *C. capitata*). Using a full-factorial design, as they describe it, they investigated one-week-long acclimation responses of each species' critical minimum and maximum temperature (CT_{min} and CT_{max}) to exposure to temperatures of 20, 25, and 30°C, as well as their interactions with short-term sub-lethal temperature exposures to the same conditions as arrived at via different rates of warming. They report, "generally, increasing the acclimation temperature significantly increased CT_{max}, whereas decreasing the acclimation temperature significantly lowered CT_{min}." In addition, "slower ramping rates significantly increase CT_{max} in both *C. rosa* and *C. capitata*." This suggests "more time during heating (i.e. a slower heating rate) provides the flies with an opportunity to develop some heat protection, and therefore suggests that *C. capitata*, and possibly also *C. rosa*, might have short-term phenotypic plasticity of high temperature tolerance." They describe this as being "similar to the rapid heat hardening or the heat shock responses in *Drosophila* (Loeschcke and Hoffmann, 2006; Johnson *et al.*, 2009) and other insect species (Huang *et al.*, 2007)."

Nyamukondiwa and Terblanche conclude fruit flies "are capable of adjusting their thermal tolerance within a single generation at both weekly and hourly time scales," noting "high temperature acclimation improves high temperature tolerance, in keeping with much of the literature on thermal acclimation (Whitman, 2009)." They also state "both *C. rosa* and *C. capitata* have the capacity to adjust their thermal tolerance over short timescales in the wild," further stating this phenomenon will "probably allow both species to track changes in ambient temperature and survive sudden extremes of temperature that might otherwise be potentially lethal," citing Chown and Nicolson (2004).

This phenomenon is not restricted to flies. The two researchers indicate, for example, in several insect species "survival of lethal temperatures or critical thermal limits to activity can be significantly improved by prior exposure to sub-lethal temperatures," citing Lee *et al.* (1987), Kelty and Lee (2001), Shreve *et al.* (2004), and Powell and Bale (2006). This phenomenon is a major mechanism used by insects to cope with temperature variation at both daily (Kelty and Lee, 2001; Kelty, 2007; Overgaard and Sorensen, 2008) and seasonal (Powell and Bale, 2006; Hoffmann *et al.*, 2005; Terblanche *et al.*, 2006) time scales.

Harada *et al.* (2011) write "in temperate areas, insects are adapted physiologically or behaviourally to either [1] tolerate seasonally fluctuating changes in temperature through diapause or to [2] avoid adverse conditions through migration," with the most predictable time cue for seasonal adaptation by insects being photoperiod (Tauber *et al.*, 1986). Thus, "it is assumed that the critical photoperiod of insects is becoming gradually shortened as a result of global warming," and if populations are adapting to the consequent longer growing seasons and later onsets of winter, it would be expected that the number of yearly broods produced "should increase, that photoperiodic responses of diapause induction and wing-form determination will continue to diminish ... and that overwintering adults will cease to migrate between water courses and overwintering land sites far from water, and will begin overwintering nearer summer habitats."

In an effort to determine whether such adjustments have been occurring in the life cycle of nymphs of the water strider *Aquarius paludum* in the Kochi prefecture of Japan over the past two decades, Harada *et al.* measured a number of pertinent parameters that had been assessed by Harada and Numata (1993) two decades earlier, over the period 1989–1991. They found *A. paludum* nymphs were trivoltine (i.e., produced three broods yearly) in 1991, but more recently the generation number appears to have increased to four or more. They also found overwintering adults of both sexes had no mature flight muscles in October and November 2008, which "contrasts with previous observations," and "the 2008 population also shows a low flight propensity in response to shorter day lengths."

The Japanese scientists from Kochi University thus opine, "the absence of mature flight muscles in the autumn, and the lower flight propensity under shorter days, may comprise evidence of a cessation of dispersal between the freshwater summer habitats and overwintering sites on land far from the bodies of water." And they observe, "the increase in daily-minimum temperature during the winter in the Kochi-Nankoku area over the last 15 years may allow adults of *A. paludum* to overwinter without dispersal nearer to their summer habitat," which could lead to the proportion of adults overwintering close to the water bodies increasing from the current estimate of 60 to 70% to between 90 and 100% within ten years. Thus, they conclude, *A. paludum* populations in the Kochi-Nankoku region "are continuing to show adaptive change, apparently in relation to global warming."

Brakefield and de Jong (2011) note "a variety of processes can enable organisms, including insects, to

respond successfully to climate change (Stenseth *et al*., 2002; Bradshaw and Holzapfel, 2006; Parmesan, 2006)," including "habitat tracking, phenotypic plasticity and genetic adaptation." Evidence for the first of these mechanisms, in their words, "is becoming commonplace," as is the case with many species of butterflies that are "clearly responding with northern extensions in their range limits (Parmesan and Yohe, 2003; Hickling *et al*., 2006)," as well as with moths and other insects that "are moving up altitudinal gradients (Chen *et al*., 2009)." On the other hand, they write, "the extent to which changes in phenotypic plasticity are (or will be) involved in the numerous reports of changes in phenology (Brakefield, 1987; Roy and Sparks, 2000; Amano *et al*., 2010) is not clear." And they remark, "there are as yet few reports of genetic changes within populations linked to climate change," although "the pitcher plant mosquito, *Wyeomyia smithii*, showed a genetic response to climate change, which involved changes in sensitivity to photoperiod (Bradshaw *et al*., 2006)," which "could be detected over a period as short as five years."

Hoping to contribute to the search for genetic responses to climate change, Brakefield and de Jong report on the most recent data describing changes in a cline in the frequency of melanism morphs of the two-spot ladybird beetle, *Adalia bipunctata* L., along a transect that extends inland from the seacoast in the Netherlands.

At the time of the beetle's first survey in 1980, the two researchers report, "the frequency of melanics increased over some 40 km from 10% near the coast to nearly 60% inland." Additional surveys in 1991 and 1995 "demonstrated some progressive change in cline shape," and new samples from 1998 and 2004 confirmed these dynamics, so "over a period of about fifty generations of the beetle, the cline had decayed rapidly to yield rather uniform frequencies of melanic morphs at around 20% along the whole transect by 2004." They remark, "climate data and evidence for thermal melanism in this species support our contention that these dynamics reflect a dramatic example of a rapid genetic response within populations to climate change and local selection." Brakefield and de Jong conclude by stating their study "adds to potential examples of how some organisms are likely to be responding to climate change through direct genetic responses within populations."

It appears rising temperatures will be beneficial for some insect species, but perhaps not for others. Nevertheless, it does not appear there will be a widespread extinction of insect species, as most will adapt as they likely have done as temperatures have waxed and waned in the past.

5.5.5.2 Response to Elevated CO_2

As the air's CO_2 content continues to rise, it is important to determine what effect this might have on the delicate balance between various plants and the insects that feed on them. This section reviews the results of studies that have reported on insects not previously discussed at any length, where it is seen the ongoing rise in the air's CO_2 content likely plays an important role in negating the damage being done to Earth's vegetation by voracious insect pests.

Docherty *et al*. (1997), in addition to studying aphids, studied two sap-feeding leafhopper species that were allowed to feed on saplings of beech and sycamore grown in glasshouses maintained at atmospheric CO_2 concentrations of 350 and 600 ppm. As far as they could determine, there were no significant effects of the extra CO_2 on either the feeding or performance characteristics of either leafhopper species.

In a literature review of more than 30 studies published two years later, Whittaker (1999) found chewing insects (leaf chewers and leaf miners) showed either no change or reductions in abundance in response to atmospheric CO_2 enrichment. They note, however, population reductions in this feeding guild often were accompanied by increased herbivory in response to CO_2-induced reductions in leaf nitrogen content.

Contemporaneously, Brooks and Whittaker (1999) removed grassland monoliths from the Great Dun Fell of Cumbria, UK—which contained eggs of a destructive xylem-feeding spittlebug (*Neophilaenus lineatus*)—and grew them in glasshouses maintained for two years at atmospheric CO_2 concentrations of 350 and 600 ppm. During the course of their

experiment, two generations of the xylem-feeding insect were produced; in each case, elevated CO_2 reduced the survival of nymphal stages by an average of 24%. Brooks and Whittaker suggest this reduction in survival rate may have been caused by CO_2-induced reductions in stomatal conductance and transpirational water loss, which may have reduced xylem nutrient-water availability.

Stiling *et al*. (1999) report the results of what may have been the first attempt to study the effects of elevated CO_2 on trophic webs in a natural ecosystem; specifically, a nutrient-poor scrub-oak community in Florida (USA), where 16 open-top chambers of 3.6-m diameter were fumigated with air of either 350 or 700 ppm CO_2 for approximately one year. At the end of this period, total leaf miner densities were 38% less on the CO_2-enriched foliage than on the foliage of the ambiently grown plants. Moreover, atmospheric CO_2 enrichment consistently reduced the numbers of all six species of leaf miners studied. In a compensatory development, exposure to elevated CO_2 increased the amount of leaf area consumed by the less-abundant leaf miners by approximately 40%. Nevertheless, leaf miners in the CO_2-enriched chambers experienced significantly greater mortality than those in the control chambers. Although CO_2-induced reductions in leaf nitrogen content were determined to have played a minor role in the mortality increase, the greatest factor contributing to this phenomenon was a fourfold increase in parasitization by various wasps that could more readily detect the more-exposed leaf miners on the CO_2-enriched foliage.

Three years later, Stiling *et al*. (2002) reported even more dramatic effects of elevated CO_2 on leaf chewers. The relative levels of damage by these insects (primarily larval lepidopterans and grasshoppers) were significantly lower in the elevated CO_2 chambers than in the ambient CO_2 chambers for all five of the plant species that accounted for more than 98% of the total plant biomass of the ecosystem. In addition, the response to elevated CO_2 was the same across all plant species. Also, they report more host-plant-induced mortality was found for all miners on all plants in elevated CO_2 than in ambient CO_2. These effects were so powerful that in addition to the relative densities of insect herbivores being reduced in the CO_2-enriched chambers, and even though there were more leaves on most plant species in the elevated CO_2 chambers, the total densities of leaf miners in the high-CO_2 chambers were also lower for all plant species. Stiling *et al*. note, "reductions in herbivore loads in elevated CO_2 could boost plant growth beyond what might be expected based on pure plant responses to elevated CO_2," a beneficial effect.

In a natural ecosystem in Wisconsin (USA) comprised predominantly of trembling aspen (*Populus tremuloides* Michx.), Percy *et al*. (2002) studied the effects of increases in CO_2 alone (to 560 ppm during daylight hours), O_3 alone (to 46.4–55.5 ppb during daylight hours), and CO_2 and O_3 together on the forest tent caterpillar (*Malacosoma disstria*), a common leaf-chewing lepidopteran found in North American hardwood forests. By itself, elevated CO_2 reduced caterpillar performance by reducing female pupal mass, and elevated O_3 alone improved caterpillar performance by increasing female pupal mass. When both gases were applied together, the elevated CO_2 completely counteracted the enhancement of female pupal mass caused by elevated O_3. Hence, either alone or in combination with undesirable increases in the air's O_3 concentration, elevated CO_2 tended to reduce the performance of the forest tent caterpillar. This finding is particularly satisfying because, in the words of Percy *et al*., "historically, the forest tent caterpillar has defoliated more deciduous forest than any other insect in North America" and because "outbreaks can reduce timber yield up to 90% in one year, and increase tree vulnerability to disease and environmental stress."

Also working at the Aspen FACE site in northern Wisconsin, USA, Kopper and Lindroth (2003) studied the effects of elevated CO_2 (560 ppm) and elevated O_3 (1.5 x ambient) on trembling aspen (*Populus tremuloides* Michaux) trees, while the aspen blotch leafminer (*Phyllonorycter tremuloidiella* Braun) was allowed to naturally colonize the trees. Although there were some minor alterations in foliar chemistry in the CO_2- and O_3-enriched treatments, they produced "little to no change in larval performance," although both elevated CO_2 and O_3 "reduced colonization rates by nearly half."

Holton *et al*. (2003) reared both parasitized and non-parasitized forest tent caterpillars (*Malacosoma disstria*) on two quaking aspen (*Populus tremuloides*) genotypes (216, which is O_3-tolerant, and 259, which is O_3-sensitive) alone and in combination, also at the Aspen FACE site in northern Wisconsin, where trees were exposed to ambient air, ambient air + 200 ppm extra CO_2, ambient air + 50% extra ozone, and ambient air + 200 ppm extra CO_2 and 50% extra O_3 during the daylight hours of one full growing season. They found "elevated CO_2 had little effect on both primary and secondary metabolites of aspen." Thus, "elevated CO_2 had few biologically significant effects on forest tent caterpillar performance." Elevated O_3, on the other hand, altered foliar composition much

more than did elevated CO_2; and, as they discovered, it improved tent caterpillar performance under ambient CO_2 conditions, but not in CO_2-enriched air. In addition, elevated O_3 decreased the larval survivorship of the parasite of the caterpillar.

These findings suggest the ongoing rise in the air's CO_2 content likely will be very important to the future well-being of quaking aspen trees, especially when atmospheric O_3 concentrations are increasing concurrently. Elevated levels of atmospheric CO_2 are known to significantly increase the productivity of aspen trees, making them more robust (Percy *et al.* (2002). Moreover, the extra CO_2 of this study totally thwarted the positive impact of the extra O_3 on caterpillar performance, thus eliminating a major negative consequence for the trees. As the authors note, "aspen growth is significantly increased under high CO_2, but decreased under high O_3," and "that difference is likely to be exacerbated by the impacts of CO_2 and O_3 on herbivorous insects and parasitoids as documented in this study." Without an increase in the air's CO_2 content commensurate with that projected for O_3 over the coming half-century, therefore, quaking aspen—the most widely distributed tree in North America—would suffer.

Johns *et al.* (2003) performed, in their words, "a factorial experiment to examine the effects of elevated CO_2 and increased temperature on both the leaf-chewing adults and leaf-mining larvae of two closely related beetle species, *Octotoma championi* Baly and *Octotoma scabripennis* Guerin-Meneville (Coleoptera: Chrysomelidae), feeding on the host plant *Lantana camara* L. (Verbenaceae)." The study was conducted in environment-controlled growth chambers maintained at atmospheric CO_2 concentrations of 360 or 700 ppm and at low (22°C/18°C) or high (25°C/21°C) day/night temperatures, where well-watered and fertilized plants were grown from cuttings for just over 13 months. Under the high temperature treatment, plants grown at ambient CO_2 suffered wilting and premature leaf loss, despite daily watering, but this effect was ameliorated at elevated CO_2. They also report "the wilting of plants in the ambient CO_2/high temperature treatment reduced the emergence success of the beetles," and "consumption rates of free-living beetles were not affected by either CO_2 or temperature," whereas "in short-term trials using excised foliage, beetles given no choice between ambient and elevated CO_2-grown foliage consumed more from ambient plants."

The authors state "this study indicates that under future conditions of higher temperatures, amelioration of water stress in host plants growing in elevated CO_2 may benefit some endophagous insects by reducing premature leaf loss," and they note "under some circumstances, this benefit may outweigh the deleterious effects of lower leaf nitrogen," which is typically described as posing a major problem for insects in a high-CO_2 world of the future. In addition, Johns *et al.* say their results indicate "foliage consumption under elevated CO_2 by mobile, adult insects on whole plants may not be significantly increased, as was previously indicated by short-term experiments using excised foliage."

According to Heagle (2003), the Western flower thrip (*Frankliniella occidentalis*) "is one of the most important and difficult to control plant pests," as "it feeds on numerous plant species and spreads the tomato spotted wilt virus, which also affects numerous plant species." In an effort to learn how this pest might respond to increasing concentrations of atmospheric CO_2, Heagle grew well-watered and fertilized white clover (*Trifolium repens*) plants from virus-free stolons in 1-liter pots filled with Metro Mix 220 and placed between two rows of thrip-invested plants growing in 15-liter pots, after which they were grown for either 27 or 35 additional days in continuous-stirred tank reactor chambers (CSTRs) maintained at either ambient or elevated atmospheric CO_2 concentrations (396 or 745 ppm) and located within a non-filtered-air greenhouse. The USDA researcher reports, "at elevated CO_2, clover shoot weight and laminae weight were ˜50% greater, and laminar area was ˜20% greater than at ambient CO_2." In addition, he notes the "thrips population size was not significantly affected by CO_2, but laminar area scarred by thrips feeding was ˜90% greater at elevated than at ambient CO_2." Nevertheless, because of the CO_2-induced increase in clover growth, "undamaged leaf area was approximately 15% greater at elevated than at ambient CO_2."

Barbehenn *et al.* (2004a) note "it has been hypothesized that herbivores will disproportionately increase their feeding damage on C_3 plants to compensate for the larger changes in C_3 plants in elevated CO_2 (Lincoln *et al.*, 1984, 1986; Lambers, 1993)." This is assumed because increases in the air's CO_2 content typically lead to greater decreases in the concentrations of nitrogen and, therefore, protein in the foliage of C_3 as compared to C_4 grasses (Wand *et al.*, 1999). In a test of this hypothesis, Barbehenn *et al.* grew *Lolium multiflorum* Lam. (Italian ryegrass, a common C_3 pasture grass) and *Bouteloua curtipendula* (Michx.) Torr. (sideoats gramma, a native C_4 rangeland grass) in chambers maintained at either the ambient atmospheric CO_2 concentration of 370 ppm

or the doubled CO_2 concentration of 740 ppm for two months, after which grasshopper (*Melanoplus sanguinipes*) nymphs that had been reared to the fourth instar stage were allowed to feed on the grasses' foliage.

As expected, foliage protein concentration decreased much more in the C_3 grass than in the C_4 grass (22% vs. 7%) when the grasses were grown in CO_2-enriched air. However, and "contrary to the hypothesis that insect herbivores will increase their feeding rates disproportionately in C_3 plants under elevated atmospheric CO_2," Barbehenn *et al*. report "*M. sanguinipes* did not significantly increase its consumption rate when feeding on the C_3 grass grown under elevated CO_2," suggesting this observation implies "post-ingestive mechanisms enable these grasshoppers to compensate for variable nutritional quality in their host plants" and noting some of these post-ingestive responses may include "changes in gut size, food residence time, digestive enzyme levels, and nutrient metabolism (Simpson and Simpson, 1990; Bernays and Simpson, 1990; Hinks *et al*., 1991; Zanotto *et al*., 1993; Yang and Joern, 1994a,b)." Their data indicate, if anything, *M. sanguinipes* growth rates were increased, perhaps by as much as 12%, when they fed on the C_3 foliage that had been produced in the CO_2-enriched, as compared to the ambient-treatment, air.

As was also found by Barbehenn *et al*. (2004b), the CO_2-induced decrease in leaf protein concentration observed in this study did not induce an increase in foliage consumption in the C_3 plant studied, nor did it reduce the growth rate of the herbivore studied. The authors state "although compensatory feeding was commonly observed in early studies [of this subject], the absence of compensatory feeding on C_3 plants grown under elevated CO_2 has since been observed frequently among herbivorous insects (Bezemer and Jones, 1998)."

Noting the "detrimental effects of ozone on plants are well known," and "carbon dioxide [CO_2] generally affects trees in opposite ways to ozone [O_3]," Valkama *et al*. (2007) conducted a literature review they describe as "the first quantitative analysis of the interactive effects of elevated O_3 and elevated CO_2 on tree chemistry and herbivore performance," based on the results of "63 studies conducted on 22 tree species and 10 insect herbivore species and published between 1990 and 2005." With respect to ways by which elevated O_3 may benefit insect herbivores that tend to damage trees, Valkama *et al*. determined "elevated O_3 significantly shortened

development time of insect herbivores [when they are exposed and vulnerable to attack by various enemies] and increased their pupal mass in the overall dataset." In addition, they found the "relative growth rate of chewers was significantly increased by 3.5% under elevated O_3." However, they discovered "these effects were counteracted by elevated CO_2," such that "elevated O_3 in combination with CO_2 had no effect on herbivore performance." When elevated CO_2 was added to the O_3-enriched air, it not only counteracted the O_3-induced increase in pupal biomass, but reduced it by 7% below what it was in ambient air.

Stiling and Cornelissen (2007) "report the results of the longest-known field study (9 years) to examine the effects of elevated carbon dioxide on leaf miner densities in a scrub-oak community at Kennedy Space Center, Florida [USA]." They then describe the results of various meta-analyses they employed to determine "the effects of elevated CO_2 on both plants (n = 59 studies) and herbivores (n = 75 studies)," where ambient CO_2 concentrations ranged between 350 and 420 ppm and elevated concentrations ranged between 550 and 1,000 ppm. With respect to the first subject of their review, Stiling and Cornelissen report "the densities of all leaf miner species (6) on all host species (3) were lower in every year in elevated CO_2 than they were in ambient CO_2." With respect to the second subject, they write, "elevated CO_2 significantly decreased herbivore abundance (-21.6%), increased relative consumption rates (+16.5%), development time (+3.87%) and total consumption (+9.2%), and significantly decreased relative growth rate (-8.3%), conversion efficiency (-19.9%) and pupal weight (-5.03%)." They also note "host plants growing under enriched CO_2 environments exhibited significantly larger biomass (+38.4%), increased C/N ratio (+26.57%), and decreased nitrogen concentration (-16.4%), as well as increased concentrations of tannins (+29.9%)." Thus with plant biomass increasing and herbivorous pest abundance decreasing (by +38.4% and -21.6%, respectively, in response to an approximate doubling of the atmosphere's CO_2 concentration), it appears plants will fare increasingly well as the air's CO_2 content continues to climb.

Kampichler *et al*. (2008) write, "since CO_2 enrichment alters the composition of live plant tissues, the ongoing global increase of atmospheric CO_2 concentration is expected to affect plant-animal interactions," but "systems studied so far have not included mature trees." They set out to determine "the abundance of dominant leaf-galls (spangle-galls induced by the cynipid wasps *Neuroterus*

quercusbaccarum and *N. numismalis*) and leaf-mines (caused by the larvae of the moth *Tischeria ekebladella*) on freely colonized large oaks in a mixed forest in Switzerland, which received CO_2 enrichment [540 ppm vs. 375 ppm during daylight hours] from 2001 to 2004" by means of "the Swiss Canopy Crane (SCC) and a new CO_2 enrichment technique (web-FACE)" in a forest they describe as "80–120 years old with a canopy height of 32–38 m, consisting of seven deciduous and four coniferous species."

The German, Mexican and Swiss researchers report elevated CO_2 reduced various leaf parameters (water content, proteins, non-structural carbohydrates, tannins, etc.) at the SCC site, but "on the long term, their load with cynipid spangle-galls and leaf-mines of *T. ekebladella* was not distinguishable from that in oaks exposed to ambient CO_2 after 4 years of treatment." Kampichler *et al*. conclude, "CO_2 enrichment had no lasting effect in all three [animal] taxa, despite the substantial and consistent change in leaf chemistry of oak due to growth in elevated CO_2."

Rao *et al*. (2009) determined what foliage-mediated effects atmospheric CO_2 enrichment might have on another pernicious insect pest. They explain castor "is an important non-edible oilseed crop grown in many parts of the arid and semi-arid regions of India," and the castor semilooper (*Achaea janata*) and tobacco caterpillar (*Spodoptera litura*) "occur during early and late stages of growth of castor, respectively," when castor oil yields can be reduced "by 30–50% by the semilooper alone" and the tobacco caterpillar "can cause yield losses of 25–40%."

Rao *et al*. allowed larvae of both species to feed on castor foliage grown in present-day air (presumed to contain 350 ppm CO_2) and in air enriched with CO_2 to concentrations of 550 and 700 ppm. Their results indicate, "compared to the larvae fed on ambient CO_2 foliage, the larvae fed on 700 and 550 ppm CO_2 foliage exhibited greater consumption." However, the efficiency of conversion of both ingested and digested food into larval biomass "decreased in the case of larvae grown on 700 and 550 ppm CO_2 foliage," so they "grew slower and took longer time (two days more than ambient) to pupation," which would allow significantly more time (~13 percent) for them to be preyed upon by higher orders of creatures, many of which are considered to be much less of a threat to crop production than are insect larvae.

In the case of castor beans, then, it would appear in addition to the productivity enhancement likely to be provided by the stimulation of photosynthesis driven by atmospheric CO_2 enrichment—an approximate 34 percent increase in response to a

300 ppm increase in the air's CO_2 content (Grimmer and Komor, 1999; Grimmer *et al*., 1999)—a substantial increase in atmospheric CO_2 likely also would curtail yield losses currently caused by the castor semilooper and tobacco caterpillar.

Hillstrom *et al*. (2010) write, "natural forest systems constitute a major portion of the world's land area, and are subject to the potentially negative effects of both global climate change and invasion by exotic insects." They report, "a suite of invasive weevils has become established in the northern hardwood forests of North America," noting it is "unknown" how these insects will respond to continued increases in the air's CO_2 content.

Hillstrom *et al*. collected 200 mating pairs of *Polydrusus sericeus* weevils—which they describe as "the second most abundant invasive weevil species in northern hardwood forests"—from birch trees growing on the perimeter of the Aspen Face facility in Oneida County, Wisconsin (USA). They fed them leaves taken from the birch, aspen, and maple trees growing within either the facility's ambient-air rings or its CO_2-enriched rings (maintained at a target concentration of 560 ppm) under controlled laboratory conditions throughout the summer of 2007, while closely monitoring parameters affecting weevil longevity and fecundity.

According to the five researchers, all from the University of Wisconsin's Department of Entomology, the results indicate feeding the weevils with foliage produced on trees in the CO_2-enriched plots had no effect on male longevity, but it reduced female longevity by 19 percent. They also note, "*Polydrusus sericeus* egg production rate declined by 23% and total egg production declined by 29% for females fed foliage produced under elevated CO_2 compared with ambient CO_2."

Hillstrom *et al*. conclude, "concentrations of elevated CO_2 above 500 ppm have the potential to decrease *P. sericeus* populations by reducing female longevity and fecundity," which should be particularly beneficial for the northern hardwood forests of North America that are currently growing under atmospheric CO_2 concentrations of 390 ppm and rising.

The vast majority of pertinent experimental data suggest in the neverending battle between insect herbivores and the plants on whose foliage they feast, the ongoing rise in the air's CO_2 content likely plays an extremely important role in negating, and in some cases even more than negating, the damage otherwise capable of being done to Earth's vegetation by voracious insect pests.

5.6 Mammals

- The warming-induced extinctions of mammals that have been predicted to occur are highly unlikely to be realized in nature, and warming in fact opens new territories for mammal range expansions. In addition, rising atmospheric CO_2 concentrations may produce changes in the palatability of the trunk and branch tissues of certain trees that may protect them from being killed by hares and rabbits.

It has been projected global warming will lead to a mass demise, if not extinction, of species across Earth because they will not be able to migrate rapidly enough to keep up with the shifting climatic zones to which they are currently accustomed, or they will literally "run out of places to run," as in the case of mountain-top dwellers. As logical as that hypothesis might sound, more complex studies, such as the ones reviewed here, indicate it is wrong. Earth's plants and animals are not the simpletons the models often characterize them to be; they possess a wide array of strategies for coping with environmental change and re-colonizing former territories after having once been forced out of them.

Norment *et al.* (1999) summarized and compared the results of many surveys of mammal populations observed along the Thelon River and its tributaries in the Canadian Northwest Territories from the 1920s through much of the 1990s. Red squirrel, moose, porcupine, river otter, and beaver were found to have established themselves in the studied area in recent years, significantly increasing its biodiversity. Norment *et al.* suggest the primarily northward range expansions that produced these results may be explained by "a recent warming trend at the northern treeline during the 1970s and 1980s." Alternatively, they note the influx of new species also may be due to "increasing populations in more southerly areas." In either case, these several mammal species appear to be faring quite well, and perhaps thriving, in the face of increasing temperatures in this forest-tundra landscape.

Pockely (2001) report the results of a survey of the plants and animals on Australia's Heard Island, located some 4,000 kilometers southwest of Perth. Over the past 50 years this sub-Antarctic island has experienced a local warming of approximately 1°C that has resulted in a modest retreat of its glaciers; for the first time in a decade, scientists are documenting what this warming and melting has done to the ecology of the island. Pockley reports on the "rapid increases in flora and fauna" that have accompanied the warming, quoting Dana Bergstrom, an ecologist at the University of Queensland in Brisbane, as saying areas that previously were poorly vegetated are now "lush with large expanses of plants." He also notes populations of fur seals have expanded rapidly. He cites Eric Woehler of Australia's environment department as informing him fur seals have emerged from "near extinction" to a population of 28,000 adults and 1,000 pups.

Between these far-flung chilly regions (where warming would be expected to enhance the abilities of land mammals to survive and reproduce), Lawler (1998) examined biogeographic relationships of mammals typically found on mountaintops in the Great Basin of western North America, with the objective of determining their future well-being in the face of predicted climate-driven changes in their environment. Contrary to the conclusions of earlier, more simplistic studies that predicted dramatic global warming-induced reductions in the numbers of

mammals in this region, Lawlor concludes "virtually no extinctions can be expected from a projected 3°C rise in temperature." The results of this study, as well as those of Grayson (2000) and Grayson and Madson (2000), stand in stark contrast to model-based extinction predictions.

Working with the entire population of about 325 red squirrels (*Tamiasciurus hudsonicus*) near Kluane Lake, Yukon (Canada), Reale *et al.* (2003) ear-tagged and monitored the reproductive activity of all females each year from 1989 to 2001, while identifying and similarly dealing with most of their young from birth to adulthood, and weather data were collected at a monitoring station located 50 km from their study site. In addition, noting "spruce cones stored in the autumn of a given year are an important source of food for reproductive females in the spring of the following year," they counted the number of cones on the top three meters of about 300 trees every August.

The four Canadian researchers report spring temperature rose by nearly 2°C over the course of their study, but there was "no particular trend for precipitation." They found the mean number of spruce cones available over a female's lifetime rose more than 35% over the 10 years of their observations, "a large increase in the abundance of food experienced by female squirrels." They also report the squirrels responded to these environmental changes by advancing breeding by 18 days over the 10-year study period, representing an advancement of six days per squirrel generation. Quoting Reale *et al.*, "this dramatic advancement in breeding comprised a plastic response to increased food abundance as well as a microevolutionary response to selection." Or as they write in the concluding sentence of their paper, "the combination of phenotypic changes within generations and microevolutionary changes among generations resulted in large phenotypic responses to rapid changes in environmental conditions experienced by this population of squirrels over the past ten years."

Mattson *et al.* (2004) grew one-year-old seedlings of silver birch trees in closed-top chambers for one summer and autumn in pots containing an unfertilized commercial peat maintained at three soil nitrogen levels and two temperature regimes in air of either 362 or 700 ppm CO_2. Feeding trials with caged Eurasian hares were carried out and a number of chemical analyses made of the tops of the seedlings and the basal parts of their stems. In a second experiment, they grew paper birch trees from seed for two 140-day growing seasons in well-watered and fertilized pots placed within FACE rings maintained at atmospheric CO_2 concentrations of either 362 or 562 ppm, after which (in an unplanned aspect of the study) North American eastern cottontail rabbits fed *ad libitum*, consuming bark tissue down to and scoring the wood, on the basal third of the seedlings, and these tissues were tested for the presence of various herbivore-deterring chemical constituents.

"As expected," the authors state, "elevated CO_2 substantially increased the above-ground woody biomass growth of both paper birch (63%) and silver birch (21%)." In addition, noting "numerous studies have shown that elevated atmospheric CO_2 often, but not always, elicits increases in carbon partitioning to carbon-based secondary plant compounds," which tend to act as deterrents to herbivory, they say their findings "confirm this general pattern in silver and paper birch." Finally, they report high CO_2 reduced hare feeding on silver birch shoots by as much as 48%, and it reduced rabbit feeding on paper birch stems by about 51%, while neither temperature nor severe early-season defoliation (another experimental treatment) affected tree resistance against these mammalian herbivores.

Calling the anti-herbivory effect of elevated CO_2 "remarkably strong," and noting rabbits "overwhelmingly preferred ambient CO_2 plants," Mattson *et al.* say their data "clearly suggest that the defensive biochemistry of paper birch twigs as well as the main stem were [positively] altered as the result of elevated CO_2."

Millar and Westfall (2010) studied American pikas, small generalist herbivores that are relatives of rabbits and hares, inhabit patchily distributed rocky slopes of western North American mountains, and are good at tolerating cold. Pikas are widely believed to have a physiological sensitivity to warming, which when "coupled with the geometry of decreasing area at increasing elevation on mountain peaks," in the words of the two scientists, "has raised concern for the future persistence of pikas in the face of climate change." They note the species "has been petitioned under California [USA] state and federal laws for endangered species listing."

In a study designed to investigate the validity of the basis for that classification, Millar and Westfall developed a rapid assessment method for determining pika occurrence and used it "to assess geomorphic affinities of pika habitat, analyze climatic relationships of sites, and evaluate refugium environments for pikas under warming climates." The researchers gathered data over two field seasons in the Sierra Nevada Mountains of California, the southwestern Great Basin of California and Nevada,

and the central Great Basin of Nevada, as well as a small area in the central Oregon Cascades.

The two U.S. Forest Service researchers report, "whereas concern exists for diminishing range of pikas relative to early surveys, the distribution and extent in our study, pertinent to four subspecies and the Pacific southwest lineage of pikas, resemble the diversity range conditions described in early 20th-century pika records (e.g., Grinnell and Storer, 1924)." The lowest site at which they detected the current presence of pikas, at an elevation of 1,827 meters, "is below the historic lowest elevation of 2350 m recorded for the subspecies by Grinnell and Storer (1924) in Yosemite National Park; below the low elevation range limit for the White Mountains populations given by Howell (1924) at 2440 m; and below the lowest elevation described for the southern Sierra Nevada populations of 2134 m (Sumner and Dixon, 1953)." In addition, they write, "a similar situation occurred for another lagomorph of concern, pygmy rabbit (*Brachylagus idahoensis*), where a rapid assessment method revealed much wider distribution than had been implied from historic population databases or resurvey efforts (Himes and Drohan, 2007)."

Millar and Westfall thus conclude "pika populations in the Sierra Nevada and southwestern Great Basin are thriving, persist in a wide range of thermal environments, and show little evidence of extirpation or decline." Moreover, the documentation of a similar phenomenon operating among pygmy rabbits suggests still other animals also may be better able to cope with various aspects of climate change than we have been led to believe.

In a study of moose, Lowe *et al*. (2010) write, "intuitively, we would expect that a large northern ungulate with low tolerance for high temperatures would gradually be pushed out of the southern reaches of its range as the climate continues to warm and temperature conditions become increasingly unfavorable," because "persistent temperatures above the upper critical limit will suppress foraging time and consequently cause mass loss during the summer, and that this reduced condition could affect overwinter survival and productivity," citing Schwartz and Renecker (1998).

The authors "tested the hypothesis that climate limits the southern distribution of moose (*Alces alces*) by documenting space use and behavior of 36 females at the margin of the species' range in Ontario, Canada." They did this in 2006, 2007, and 2008 through the use of "global positioning system (GPS) telemetry to study their habitat use and movement," in an attempt "to document behavioral mechanisms indicative of adaptive responses to warm temperatures." This work was conducted during periods of the year when ambient temperatures frequently exceeded known critical thresholds (-5°C in winter and 14°C in summer) that had been demonstrated by Dussault *et al*. (2004) to induce heat stress in moose.

Lowe *et al*. "detected no differences in habitat use relative to thermoregulation thresholds," which they deemed to be particularly important during the summer, when they report the temperatures of all habitat classes greatly exceeded—by an average of 6°C, and by as much as 19°C in the first week of August 2006—the 14°C threshold for a large extent of the day and partially during the night. As a result, the three Canadian researchers conclude "moose in their southern range either ameliorate heat stress at a finer resolution than we measured or are more resilient to temperature than previously thought."

In a contemporaneous study, Garroway *et al*. (2010) write, "many species have responded to contemporary climate change through shifts in their geographic ranges," and "this could lead to increased sympatry [i.e., partially overlapping ranges] between recently diverged species, likely increasing the potential for hybridization." They further note this phenomenon "can be positive if it increases genetic variability and creates new gene combinations that increase the potential to adapt."

To test this hypothesis, between 2002 and 2004 Garroway *et al*. conducted more than 1,600 successful live-trappings of southern (*Glaucomys volans*) and northern (*Glaucomys sabrinus*) flying squirrels throughout portions of Ontario (Canada) and Pennsylvania (USA). From the hairs of these squirrels they extracted nuclear and mitochondrial DNA.

It already had been determined by Bowman *et al*. (2005) that *G. volans* had expanded its range from the south beginning in the mid–1990s in concert with a series of warm winters; the nine Canadian and U.S. researchers' new findings indicate "the expansion of *G. volans* north into the *G. sabrinus* range in Ontario has resulted in the formation of a new hybrid zone." In addition, their analyses suggest "the hybridization was recent, coinciding with the recent increase in sympatry." They state, to their knowledge "this is the first report of hybrid zone formation following a range expansion induced by contemporary climate change." These findings indicate yet another way in which living organisms can both physically (by shifting their ranges) and genetically (by hybridization) successfully confront the challenges global

warming may present.

Coulson *et al*. (2011) write "environmental change has been observed to generate simultaneous responses in population dynamics, life history, gene frequencies, and morphology in a number of species." But they wonder, "how common are such eco-evolutionary responses to environmental change likely to be?" asking, "are they inevitable [and] do they require a specific type of change?"

The team of six researchers used theory and data obtained from a study of wolves in Yellowstone Park, which is located mostly in the U.S. state of Wyoming but also reaches into smaller parts of Montana and Idaho. They "used survival and reproductive success data, body weights, and genotype at the K locus (*CBD103*, a β-defensin gene that has two alleles and determines coat color), which were collected from 280 radio-collared wolves living in the park between 1998 and 2009." They note "body weight and genotype at the K locus vary across U.S. wolf populations" and both traits influence fitness, citing the studies of Schmitz and Kolenosky (1985), Anderson *et al*. (2009), and MacNulty *et al*. (2009).

The four researchers say their results "do reveal that, for Yellowstone wolves, (i) environmental change will inevitably generate eco-evolutionary responses; (ii) change in the mean environment will have more profound population consequences than changes in the environmental variance; and (iii) environmental change affecting different functions can generate contrasting eco-evolutionary dynamics," which suggests "accurate prediction of the consequences of environmental change will probably prove elusive."

The general principles Coulson *et al*. found to apply to Yellowstone wolves should clearly apply to all other animals as well, suggesting the "climate envelope" approach used to predict shifts in the ranges of Earth's many animal species—and sometimes their extinction—in response to IPCC-predicted global warming fails to accurately describe the way real animals respond to climate change in the real world.

Hof *et al*. (2012) note "it is supposed that the large expected climate change at high northern latitudes ... makes species in (sub)arctic regions particularly susceptible (Virkkala *et al*., 2008; Sala *et al*., 2000; Jetz *et al*., 2007), especially the European part of the (sub)arctic, since this region is the most geographically complex with the most infrastructure and great cultural, social, and political heterogeneity (Nilsson *et al*., 2010)." Hof *et al*. "assessed potential changes in the geographic distribution of all terrestrial mammal species currently present in (sub)arctic Europe," along with additional species that might possibly colonize the region from the south. They used "species distribution modeling, incorporating projections of future climate and vegetation, in order to provide a better insight into the magnitude of the risk mammal species are facing, and the potential community level changes they have to endure due to climate change."

"Contrary to expectation," the three Swedish researchers report their modeling of species distributions suggests "predicted climate change up to 2080 will favor most mammals presently inhabiting (sub)arctic Europe," and "no species is predicted to go extinct." Hof *et al*. conclude, "for most (sub)arctic mammals it is not climate change per se that will threaten them, but possible constraints on their dispersal ability and changes in community composition."

Canale *et al*. (2012) say, "understanding whether, and to what extent, females can flexibly adjust their energetic investment to reproduction according to unpredicted food shortages is essential to predict whether organisms could compensate climate changes by plastic phenotype adjustments," citing Bronson (2009), Moreno and Moller (2011), and Wingfield *et al*. (2011). The three researchers "experimentally tested the consequences of chronic-moderate and short-acute food shortages on the reproductive output of a small seasonally breeding primate, the grey mouse lemur (*Microcebus murinus*) under thermoneutral conditions," where "two food treatments were respectively designed to simulate the energetic constraints imposed by a lean year (40% caloric restriction over eight months) or by a sudden, severe climatic event occurring shortly before reproduction (80% caloric restriction over a month)." During this time they "assessed the resilience of the early stages of reproduction (mating success, fertility, and gestation to these contrasted food treatments, and on the later stages (lactation and offspring growth) in response to the chronic food shortage only."

They found "food deprived mouse lemurs managed to maintain constant ... reproductive parameters, including oestrus timing, estrogenization level at oestrus, mating success, litter size, and litter mass as well as their overall number of surviving offspring at weaning," although "offspring growth was delayed in food restricted mothers." The three researchers say their results suggest "heterothermic, fattening-prone mammals display important reproductive resilience to energetic bottlenecks," and "more generally, species living in variable and

unpredictable habitats may have evolved a flexible reproductive physiology that helps buffer environmental fluctuations."

Tveraa *et al*. (2013) write, "for caribou in Greenland earlier springs have been suggested to result in a lower reproductive success," based on the assumption "*Rangifer* (caribou/reindeer) might be unable to adjust their timing of reproduction to the earlier surge of high quality food," and this potential failure could "cause a mismatch between optimal forage conditions and the timing of reproduction." Therefore, they state, "concerns have been raised regarding the future viability of *Rangifer* in Arctic and sub-Arctic tundra ecosystems."

Tveraa *et al*. "analyzed a 10-year dataset of satellite derived measures of vegetation green-up, population densities, calf body masses and female reproductive success in 19 reindeer (*Rangifer tarandus*) populations in Northern Norway." The four Norwegian researchers report "an early onset of spring and high peak plant productivity had positive effects on calf autumn body masses and female reproductive success," and "the quantity of food available, as determined by the onset of vegetation green-up and plant productivity over the summer, were the main drivers of body mass growth and reproductive success." Hence, they found no evidence for a negative effect of the speed of spring green-up, nor did they detect "a negative mismatch between early springs and subsequent recruitment." Tveraa *et al*. conclude the "effects of global warming on plant productivity and onset of spring are likely to positively affect sub-Arctic reindeer."

The studies presented above show the warming-induced extinctions of mammals that have been predicted to occur are highly unlikely to be realized in nature, and warming in fact opens new territories for mammal range expansions. In addition, rising atmospheric CO_2 concentrations may produce changes in the palatability of the trunk and branch tissues of certain trees that may protect them from being killed by hares and rabbits.

5.7 Parasites and Other Diseases

One of the perceived great tragedies of CO_2-induced global warming is that rising temperatures will increase the development, transmission, and survival rates of parasites and other diseases in general, leading to biological interactions that will raise the prevalence of disease among animals in the future. This section examines that claim.

In a provocative paper analyzing the intricacies of this complex issue, Hall *et al*. (2006) begin by asking, "Will an increasingly warmer world necessarily become a sicker world?" They pose this question because "increased temperatures can accelerate the fitness of parasites, reduce recruitment bottlenecks for parasites during winter, and weaken hosts," and "warmer temperatures may allow vectors of parasites to expand their range," which would enable them to "introduce diseases to novel habitats," which is frequently claimed about mosquitoes and malaria (see Section 7.2, this volume). They continue, "these doom-and-gloom scenarios do not necessarily apply to all taxa or all situations," and "warming does not necessarily increase the fitness of all parasites."

The four biologists and their statistician coauthor note the "virulence of parasites may not change, may decrease, or may respond unimodally to increasing temperatures (Stacey *et al*., 2003; Thomas and Blanford, 2003)." They also observe, "vital rates increase with temperature until some optimum is reached," and "once temperature exceeds this optimum, vital rates decline gradually with increasing temperature for some taxa, but rapidly for others," such that "in some host-parasite systems, a parasite's optimum occurs at cooler temperatures than the optimum of its host," citing Carruthers *et al*. (1992), Blanford and Thomas (1999), and Blanford *et al*. (2003) on fungus-grasshopper associations. In such cases, "a host can use warmer temperatures to help

defeat its parasites through behavioral modification of its thermal environment."

The situation sometimes can be even more complex than this: "warmer temperatures can also lead to shifts in temperature optima (Huey and Hertz, 1984; Huey and Kingsolver, 1989, 1993)," and "the exact evolutionary trajectory of host-parasite systems in a warmer world may depend sensitively upon underlying genetic correlation structures and inter-actions between host genotypes, parasite genotypes, and the environment (Blanford *et al.*, 2003; Thomas and Blanford, 2003; Stacey *et al.*, 2003; Mitchell *et al.*, 2004)." Consequently, they conclude, "longer-term response of the physiology of host-parasite systems to global warming becomes difficult to predict."

The researchers also note "other species can profoundly shape the outcome of parasitism in host populations," and "predators provide an important example" because predators "can actually inhibit epidemics by selectively culling sick hosts and/or by maintaining host densities below levels required for parasites to persist (Hudson *et al.*, 1992; Packer *et al.*, 2003, Lafferty, 2004; Ostfeld and Holt, 2004; Duffey *et al.*, 2005; Hall *et al.*, 2005)." Therefore, Hall *et al.* conclude, "global warming does not necessarily mean that disease prevalence will increase in all systems."

Morgan and Wall (2009) echo many of the salient points raised in the Hall *et al.* paper and further elucidate the complex nature of this topic. With respect to the relationship between temperature and parasitic development, the two authors note, "just as development rates of many parasites of veterinary importance increase with temperature, so [too] do their mortality rates [increase]." They reiterate, "temperature will also affect mortality indirectly through the action of predators, parasitoids, pathogens and competitors, whose development and abundance are also potentially temperature sensitive," so "the net effect of climate change could be complex and far from easily predicted."

The two UK researchers suggest "several biological mechanisms (including increased parasite mortality and more rapid acquisition of immunity), in tandem with changes in husbandry practices (including reproduction, housing, nutrition, breed selection, grazing patterns and other management interventions), might act to mitigate increased parasite development rates, preventing dramatic rises in overall levels of diseases." Because "optimum mitigation strategies will be highly system specific and depend on detailed understanding of interactions between climate, parasite abundance, host availability and the cues for and economics of farmer intervention," they conclude "there is a need for research that considers likely effects of climate change and mitigation strategies in terms of the whole host-parasite system, including anthropogenic responses, and not just in terms of parasite population dynamics." One year later, two such papers were published, both attempting to account for the response of human behavior on parasite abundance and disease incidence.

Focusing on cutaneous myiasis (blowfly strike) in sheep, Wall and Ellse (2011) employed a stochastic simulation model "to examine the changes in the seasonal incidence of ovine cutaneous myiasis on farms in the United Kingdom and the likely effects of changes in husbandry and control strategies" in the face of projected changes in climate. The authors note "the ability of this model to successfully account for observed patterns of strike has been confirmed previously by comparison of predicted with observed strike incidence patterns observed on 370 farms in England and Wales," citing Wall *et al.* (2002).

The two UK researchers report, "the simulations show that the range of elevated temperatures predicted by current climate change scenarios result in an elongated blowfly season with earlier spring emergence and a higher cumulative incidence of strike," and "overall, higher temperatures increased strike incidence disproportionately in ewes in early summer, but had relatively less direct effect on the pattern of lamb strike incidence," noting "a 3°C increase in average temperature approximately doubles the cumulative incidence of strike in lambs but results in four times more strikes in ewes." However, as the researchers conclude in the abstract of their paper, "the simulations suggest that integrated changes in husbandry practices are likely to be able to manage expected increases in strike, given the range of climate changes currently predicted." They explain in the body of the paper, "modest changes in husbandry practices should be able to manage expected increases in strike, under the range of climate changes currently predicted," demonstrating "consideration of the likely impact of climate change must take into account animal management practices as well as parasite biology (Morgan and Wall, 2009)."

Working with two additional co-authors on the same host and parasite, Wall *et al.* (2011) came to a similar conclusion, reporting, "the models suggest that simple changes in some husbandry practices, such as shearing or trap use, could have an important effect in reducing early season ewe strike incidences," and "practical measures exist which, with modest

changes in husbandry practices, should be able to manage expected increases in strike." The key message of this latter work is the authors' conclusion that "simple extrapolations of the known effects of temperature on ectoparasite development," in an attempt to "predict changes in disease incidence in a warmer climate," is simply "too simplistic." They emphasize "attempts to predict the likely impact of climate change on disease incidence must take into account changes in farmer behavior and animal management practices as well as parasite biology."

Baffoe *et al.* (2012) write, "with the prospect of warmer temperatures as a consequence of ongoing climate change, it is important to investigate how such increases will affect parasitoids and their top-down suppression of herbivory in agroecosystems." They studied a parasitoid that afflicts a common beetle that feeds on several short-rotation species of commercially coppiced willow trees in northern and central Europe, a trophic cascade described in more detail by Peacock *et al.* (1999), Bjorkman *et al.* (2003), and Dalin (2011). Baffoe *et al.* conducted laboratory experiments in which they "studied how the performance and biocontrol efficiency of the willow 'bodyguard' *Perilitus brevicollis* Haliday (Hymenoptera: Braconidae) were affected at different constant temperatures (10, 15, 20, 25°C) when parasitizing a pest insect, the blue willow beetle (*Phratora vulgatissima* L., Coleoptera: Chrysomelidae)." They did this by focusing on "the parasitoid's thermal threshold for development, development rate, adult body size, survival rate and the herbivore's consumption rate."

The four Swedish scientists report parasitism had no impact on herbivory at 10°C, but "parasitoid performance (survival and development rate) generally increased with increasing temperature up to 20°C." In addition, "the feeding capacity of the studied parasitized herbivores is reduced more at high than low temperatures." Thus, "these data suggest that *P. brevicollis* should become a better biocontrol agent if temperatures increase," a transformation that should have substantial positive consequences for willow trees in northern and central Europe, as well as for the enterprise of their commercial harvesting.

Bentley and Burgner (2011) examined the host/parasite relationship between juvenile sockeye salmon (*Oncorhynchus nerka*) and the tapeworm *Triaenophorus crassus* in an Alaskan watershed that had experienced a 1.9°C increase in summer water temperature over the prior 46 years. At the beginning of their experiment, Bentley and Burgner hypothesized the warming of the region "would have

resulted in a corresponding increase in fish metabolism, and thus potential consumption rates, that would increase infestation rates of the tapeworm *Triaenophorus crassus*." To test their hypothesis, they compared infestation rate data for *T. crassus* collected between 1948 and 1960 with similar data obtained in 2008 and 2009 from the Wood River system of Bristol Bay, Alaska.

The two U.S. researchers from the University of Washington's School of Aquatic and Fishery Sciences report, "comparing the average summer air temperature to the parasite prevalence of juvenile sockeye salmon, we found no significant relationship over the fifteen years of collected data." Moreover, "evaluating the influence of average summer air temperature on the parasite infestation rates of juvenile sockeye salmon, we again found no significant relationship for either parasite abundance or parasite intensity." They note, "when we compared the 13 years of historic parasite prevalence to equivalent data collected in 2008 and 2009, we did not find a statistically significant positive long-term trend in the data," and "the parasite abundance of examined sockeye salmon smolts also did not exhibit a statistically significant long-term trend using the eight years of historic data and the two years of contemporary data." Finally, "evaluating the relationship between time and parasite intensity produced similar results as the other five comparisons, with there not being a statistically significant positive relationship."

Bentley and Burgner conclude their data demonstrate "the complex effects of warming have not summed to generate a measurable change in the infestation rates of juvenile sockeye salmon in the Wood River system." Given the many factors involved in host/parasite interrelationships, together with their great complexities, it is quite possible global warming will never significantly impact parasite infestation rates in the animals they attack.

Shifting from parasites to infectious diseases, Kampen and Werner (2010) write, "with few exceptions, vector-borne diseases have long been considered of minor importance in central and northern Europe." However, they note, "since the advent of bluetongue disease (BTD) in 2006, and the 2007 chikungunya fever outbreak in Italy, this attitude has changed." Focusing on BTD, a non-contagious insect-borne viral disease of ruminants (mainly sheep, but also affecting antelope, buffalo, cattle, deer, dromedaries, and goats) caused by the bluetongue virus (BTV), Kampen and Werner describe what is known about the outbreak of this

serious animal disease in central Europe.

The two German researchers report "BTD was the first 'exotic' disease to arrive," but "it did not slowly spread northwards but jumped in through a still unknown entry point." It all started, as they describe it, "with about 2000 affected ruminant farming facilities in 2006 in the central western part of Europe," where the BTV–8 virus—which they say "had never been observed in Europe before," and for which DNA sequencing data suggested sub-Saharan Africa as its most likely point of origin—"managed to overwinter and spread in all directions in 2007, producing almost 60,000 outbreaks (farms affected) in ten European countries up to early 2008." And now, they say, the BTV–1 virus strain "appears to be approaching from the south, with some 4900 outbreaks in France in 2008," reiterating, "nobody had expected a novel and independent virus introduction into central Europe together with indigenous biting midges able to transmit BTV."

As for possible routes of introduction of the virus, they mention BTV-positive ruminants imported either legally or illegally, virus-carrying midges transported by wind over hundreds of kilometers, accidental importation by ship or aircraft, contaminated vaccines, and trade with the products of infected animals.

Kampen and Werner conclude, "it is due to continuing globalization rather than to climate change that even central and northern Europe are at risk of new pathogens as well as vectors of disease entering and establishing."

Conte *et al.* (2009) note, "the midge *Culicoides imicola* is the principal vector of bluetongue virus (BTV) that causes an infectious disease of domestic and wild ruminants," and "over the last ten years, BTV has invaded Mediterranean countries and much of Northern Europe," inducing several scientists to contend the BTV vector had expanded its range northward "because of rising temperatures," as suggested by Mellor (2004), Purse *et al.* (2005), and Mellor *et al.* (2008). However, Goffredo *et al.* (2003) made a careful examination of *Culicoides* population data in Italy prior to 2000 and determined "trapping conditions of previous collections would have had very little chance of catching *C. imicola*" or detecting its presence, suggesting there was insufficient evidence for a warming-induced northward expansion of the BTV vector because it already may already been present there but undetected.

In response to even earlier fears of a potential BTV invasion, a national surveillance program for *C. imicola* had been established in Italy in 2000, where

70,000 light-trap collections were made at about 3,800 sites. Using the first year of data obtained from this program, Conte *et al.* defined the spatial distributions of three *C. imicola* infection zones: zone I (endemicity), zone II (transition), and zone III (absence). Using data from 2002–2007, they quantified how *C. imicola* populations evolved through time in these three zones, working under the logical assumption that "a species that is undergoing geographical range expansion should have a population that remains stable over time in zone I and increases in zones II and III."

The three researchers say their results indicate there was "no detectable range expansion of *C. imicola* population in Italy over the past six years." They report "a weak, but significant reduction was observed in the transition zone." Conte *et al.* therefore conclude their data "support the hypothesis that the spread of BTV in Italy is not because of the geographical expansion of its main vector, but to a modification of the interaction between the virus, the vector and the environment, as may also have been the case in northern Europe." They say their results show "precautions should be taken when inferring range progression for species requiring highly targeted forms of sampling and for which a constant probability of detection over time should be established." This research demonstrates it is easy to blame global warming for the poleward expansion of a vector-spread disease, but quite another thing to prove that claim.

5.8 Polar Bears

- Polar bears have survived historic changes in climate that have exceeded those of the twentieth century or are forecast by computer models to occur in the future. In addition, some populations of polar bears appear to be stable despite rising temperatures and summer sea ice declines. The biggest threat they face is not from global warming, but commercial hunting by humans, which has historically taken a huge toll on polar bear populations.

In its contribution to IPCC's *Fourth Assessment Report*, Working Group II claimed global warming is "inducing declining survival rates, smaller size, and cannibalism among polar bears" (IPCC, 2007-II). It predicted a bleak future for the species if atmospheric CO_2 concentrations continue to rise. However, polar bears have survived historic changes in climate that have exceeded those of the twentieth century or are forecast by computer models to occur in the future. In addition, some populations of polar bears appear to be stable despite rising temperatures and summer sea ice declines. The biggest threat they face is not from global warming, but commercial hunting by humans, which has historically taken a huge toll on polar bear populations.

Polar bears evolved from brown bears (*Ursus arctos*). While it was formerly thought this speciation event occurred sometime in the past 400,000 years and probably no more than 200,000 years ago (Arnason *et al.*, 1995; Davis *et al.*, 2008; Harington, 2008), that picture has now changed. The oldest polar bear fossil ever found (dated to 110,000–130,000 years old) was reported in 2008 (Ingolfsson *et al.*, 2008) and a complete mitochondrial DNA (mtDNA) sequence of it was generated two years later (Lindqvist *et al.*, 2010). This discovery spawned a suite of papers on polar bear genetics that fail to agree when polar bears arose as a distinct species: Edwards *et al.* (2011) suggest a possible range of 400,000 to two million years ago; Hailer *et al.* (2012), suggest a date of about 600,000 years ago; and Miller *et al.* (2012), suggest this event occurred four to five million years ago.

Although there is some disagreement about the onset of this species, it is clear that because the oldest polar bear fossil is at least 110,000–130,000 years old, polar bears have survived at least one glacial-interglacial cycle and perhaps as many as 10 or more.. Focusing on the last major interglacial (MIS 5e, the Eemian, which lasted from ca. 130,000–115,000

years ago), there not only appears to have been less winter Arctic ice than today (including no ice in the Bering Sea), but late summer ice was reduced to a remnant off northern Greenland and Ellesmere Island (Polyak *et al.*, 2010). During the current interglacial, or Holocene, there were at least two warm periods (the Early Holocene Climatic Optimum and the Medieval Warm Period) when sea ice was less extensive than it is now (Atkinson, 2009; Dyke and England, 2003; Dyke *et al.*, 1996; Kaufman *et al.*, 2004; Polyak *et al.*, 2010; Steffensen *et al.*, 2008).

Polar bears obviously survived large-scale and often sudden climate changes in the historic past, such as those described above. This does not mean their populations remained constant throughout this period; their numbers likely rose in some periods and declined in others. But past changes in climate have not led to their extinction, which leads to the question: Why would temperature changes predicted to be of the same scale or less than those that occurred in the past be projected to cause a near-future extinction of polar bears?

In order to ascertain whether there are indeed risks to polar bears from model-predicted increases in global temperature and associated sea ice decline, researchers have examined various aspects of polar bear population dynamics and life history traits as they relate to temperature changes that have taken place over the past 30 years. Several of their findings are presented in the subsections below, where it is seen that polar bears are well-equipped to adapt with the challenges they may face as a result of any CO_2-induced global warming.

5.8.1 Population

The world's polar bear populations live in the wild only in the Northern Hemisphere on land and sea ice in the area surrounding the North Pole. Polar bears tend to stay in, or return to, local areas (Taylor and Lee, 1995; Bethke *et al.,* 1996; Taylor *et al.,* 2001), although some migration is known to occur (Messier *et al.,* 2001; Amstrup *et al.,* 2004). Their range expands and contracts with the accretion and contraction of sea ice with the seasons, with bears moving south during the winter as sea ice advances (Amstrup *et al.,* 2000). In some areas (e.g., Hudson Bay, Foxe Basin, Baffin Bay, and James Bay) polar bears move from sea ice to land for several months during the summer open-water season (Ferguson *et al.,* 1997; Lunn *et al.,* 1997; Taylor *et al.,* 2001, 2005).

The total polar bear population is unknown, since its numbers in the Arctic Basin, East Greenland, Chukchi Sea, and the Kara Sea have never been counted (Aars *et al.,* 2006; Obbard *et al.,* 2010). The official estimate has been given as 20,000–25,000 since 2005 (Aars *et al.,* 2006; Obbard *et al.,* 2010), despite claims of declining numbers. The total has remained stable despite the fact that the former estimate for the Chukchi Sea was reduced from 2,000 to zero between 2005 and 2009.

There is even less certainty regarding the number of polar bears in the 1950s and 1960s, with most estimates around 5,000 to 10,000. Virtually all scientists agree polar bear populations have grown since the 1970s. For example, Derocher (2009) has stated, "after the signing of the International Agreement on Polar Bears in the 1970s, harvests were controlled and the numbers increased. There is no argument from anyone on this point." Ramsay and

Stirling (1988) wrote, "if a population was reduced in the past and the causal agent was no longer in effect, then the population would be expected to recover to its approximate pre-decline level."

Even though polar bear populations grew during the second half of the twentieth century, a time when IPCC claims there was a rapid increase in global temperatures and loss of sea ice, Derocher and others say this population growth is evidence of the effects of hunting bans and quotas and does not contradict their claim that warming temperatures and melting sea ice have hurt polar bear populations. They point, with apparent merit, to negative demographic impacts on polar bear populations identified in the Southern Beaufort Sea and in Western Hudson Bay, and possible adverse nutritional impacts in the Northern Beaufort Sea and Southern Hudson Bay, due to changes in local sea ice conditions.

But this observation falls short of providing evidence global warming threatens polar bears with extinction. If anthropogenic global warming were a real threat to polar bears, its effects should be observable throughout the Current Warm Period, not just the last few years, and the warming would have to affect more than only a small number of sub-populations, as appears to have been the case (see discussion below). The modified argument—that global warming only in recent years is negatively affecting only some subpopulations of polar bears but not others—is not what is being reported in daily newspapers or even what IPCC claims. The real-world long-term trends in polar bear populations contradict what would be expected if the theory of anthropogenic global warming were true.

The polar bear population is divided into 19 subpopulations for management purposes (see Figure 5.8.1.1). In 2005, according to the IUCN Polar Bear Specialist Group, five subpopulations were declining, five were stable, two were increasing, and on seven there was insufficient data on which to base a decision (Aars *et al.*, 2006). Significantly, four of the five subpopulations listed as declining were at risk due to hunting, not reduced sea ice (Aars *et al.,* 2006). This is hardly a picture of a species in steep decline, or even in decline at all. It certainly does not provide an empirical basis for predictions of imminent extinction.

More recently, this view has changed somewhat (Obbard *et al.,* 2010). Seven subpopulations are now considered data-deficient (no trend given, including one that was rated as increasing in 2005), seven are listed as declining (including one subpopulation considered to have 'data deficient' status and
Figure 5.8.1.1. Polar bear subpopulations, as defined by the IUCN Polar Bear Specialist Group. Modified from map provided by the PBSG (2009). GB, Gulf of Boothia; KB, Kane Basin; LS, Lancaster Sound; MC, M'Clintock Channel; NB, Norwegian Bay; VM, Viscount Melville; NB, Northern Beaufort; SB, Southern Beaufort; WHB, Western Hudson Bay.

another—the Chukchi—that has never been surveyed but is determined to have a "reduced" status and declining trend based on sea ice reductions and suspected poaching), three are considered stable, and one is considered to be increasing. Suspected overhunting and/or poaching are considered the primary reason five of the seven declining populations are at risk, based on modeled projections over the next 10 years. For another, declines in body condition, modeled over the next 10 years, are the basis for it being given a "declining" trend (Southern Beaufort).

Only one of the seven declining populations (Western Hudson Bay) has documented a statistically significant decline in population numbers. Obbard *et al.* state, "our status report currently indicates that two subpopulations (WH [Western Hudson Bay] and SB [Southern Beaufort]) have likely declined due to climate change. It is thought that there may also be some impacts of climate change in other populations (CS [Chukchi Sea], SH [Southern Hudson Bay]), however data are not conclusive or available." New research in the Chukchi by Rode *et al.* (2014) suggests bears there are in good condition and reproducing very well, indicating projected negative

effects due to declining summer sea ice have not materialized.

In addition, whereas the decline in Western Hudson Bay polar bear numbers (about 22%) is stated to have occurred between 1987 and 2004 (Regehr *et al.,* 2007a), Obbard *et al.* (2010) acknowledge this population had been stable prior to 1998 (Stirling *et al.,* 1999). This means the statistically significant decline really occurred between 1998 and 2004 (seven years), during which there was no apparent trend in sea ice breakup dates (Regehr *et al.,* 2007a), although both 1998 and 2003 were relatively early breakup years (occurring about June 14 both years, according to the new method used by Cherry *et al.,* 2013). If the population was still on a declining trend after 2004, there should be fewer polar bears in Western Hudson Bay now than in 2004.

No data have yet been made available from mark-recapture studies undertaken between 2005 and 2011, but an aerial survey, similar to those conducted in the Barents Sea and Baffin Bay, was conducted by the Nunavut Government in 2011 (Stapleton *et al.,* 2012a). Stapleton and colleagues' estimate of the current population number is about 1,000 (95% confidence interval, range of 715–1398). Although the two methods (mark-recapture and aerial survey) cannot be directly compared, the authors say the aerial survey was "consistent with the 2004 capture-based estimate but inconsistent with projections suggesting continued decreases in abundance." So while Obbard *et al.* (2010) say "data from this subpopulation [WHB] provide the best indications of how polar bears respond to the negative effects of climate warming," it appears the population has not continued to decline as predicted.

Similar aerial surveys have been done to the north, in Foxe Basin by Stapleton *et al*. (2012b). In that study, the authors undertook a helicopter survey throughout the territory of Foxe Basin polar bears in the summers of 2009 and 2010, concluding "our abundance estimates were highly consistent between years and survey methods, (~2,580 bears (95% CI: about 2,100–3,200), and were comparable to an estimate from the early 1990s. Our results suggest that Nunavut's management regime has enabled polar bear abundance in FB to remain relatively stable."

Hunting historically has been the greatest threat to polar bear populations. The arrival of snowmobiles, helicopters, and high-powered rifles led to "harvest" levels that were not sustainable (Taylor *et al.,* 2002; Taylor *et al.,* 2006; Taylor *et al.,* 2008). Hunting was largely unregulated until passage of the 1974 International Agreement for the Conservation of Polar Bears and Their Habitat. Greenland didn't institute a quota for polar bear hunting until 2006 (Polar Bear Technical Committee, 2006). Annual kills for most populations now have been substantially reduced, but it will take at least 20 years for populations to recover.

The range of polar bears is affected by changes in climate but not in a linear fashion with temperature or the extent or thickness of sea ice. Sea ice extent and thickness are only indirectly related to polar bear populations. Only two subpopulations—the Western Hudson Bay (WH) and Southern Beaufort Sea (SB) populations—may have declined (Ferguson *et al.,* 2005; Regehr *et al.,* 2006, 2007a,b; Rode *et al.,* 2007; Hunter *et al.,* 2007); one of these (WH) is disputed (Dyck *et al.,* 2007), and the other (SB) is not a statistically significant decline.

Taylor and Dowsley (2008) summarized recent population surveys as follows: Of six polar bear populations recently evaluated during the climate warming period, two populations appear to have been reduced (WH, SB), two populations appear to have remained constant (SH, NB), one population appears to have increased (DS), and one was abundant but the information was not sufficient to estimate a trend (BS). Seven other populations (VM, LS, NW, BB, KB, MC, GB) surveyed during the period of climate warming had vital rates sufficient to sustain substantial rates of harvest (*i.e.*, hunting) at the time they were studied. Information from a Foxe Basin (FB) population survey was sufficient to document the population had remained abundant although it had been harvested at a relatively high rate and the survival and recruitment estimates necessary to determine trend were not available. The biological information on the remaining four populations (CS, LS, KS, EG) and the few bears that may inhabit the Arctic Basin is insufficient to suggest anything about current numbers or trend.

Taylor and Dowsley say "the increase to current high numbers of polar bears in the Davis Strait has occurred during the current warming period, and has occurred with declining sea ice conditions that are sometimes less than 40% coverage at winter maximum (Stirling and Parkinson, 2006). Clearly the DS bears do manage to hunt successfully in unconsolidated pack ice." They comment, as do Dyck *et al.* (2007), that polar bears have been observed to successfully hunt seals in tidal flats along shores during ice-free periods. "Considered together," Taylor and Dowsley conclude, "these demographic data do not suggest that polar bears as a species are headed for extinction in the next three generations (45 years)

or the foreseeable future. The demographic data do support increased monitoring, and augmenting periodic population surveys with ecological and behavioral studies." They also observe, "to date, no population has been expatriated due to climate change effects, so the effect of decreased densities, alternative food sources, or behavioral adaptation to less ice on population persistence is not known."

Stirling and Derocher (2012) contend "polar bears will largely disappear from the southern portions of their range by mid-century." Western Hudson Bay is clearly included in this subset of all polar bear territory, as it lies below the Arctic Circle. But what other portions of the range lie below this point? Southern Hudson Bay, the Bering Sea, most of the Chukchi Sea, and most of Davis Strait also lie below the Arctic Circle; their population status already has been discussed. However, Southern Hudson Bay (SH), which extends to about 52°N, should presumably show more pronounced effects from global warming than even Western Hudson Bay to the north.

Obbard *et al.* (2010) say in their summary, "recent analysis of coastal survey data (Stirling *et al.* 2004) suggests polar bear numbers in SH have remained unchanged in recent years" and they consider this population to be one of three "stable" polar bear subpopulations. In a more comprehensive study of Southern Hudson Bay bears, Obbard *et al.* (2007) state, "reductions in survival of juvenile, subadult and senescent polar bears were demonstrated for the WH population (Regehr *et al.*, 2007), but were only weakly supported by our data." Obbard *et al.* (2007) also note, "abundance in the Southern Hudson Bay population was unchanged between two intensive capture-recapture periods, which were separated by almost 20 years (1984–86 *vs.* 2003–05. This was so despite the evidence for a decline of 22% in abundance for the neighboring Western Hudson Bay population over roughly the same period (*i.e.*, 1987–2004; Regehr *et al.*, 2007)." They conclude, "it appears that changes in environmental factors such as sea ice distribution and duration … have not yet resulted in unambiguous changes in survival or to a consequent reduction in population size in the SH population to this date." This is in spite of the fact that Obbard *et al.* (2006), in a dedicated study of Southern Hudson Bay polar bears, found body condition (fatness) was "significantly poorer for bears captured from 2000 to 2005 than for bears captured from 1984 to 1986," and concluded, "the significance of a trend toward poorer body condition over time is unknown." Nonetheless, in 2009 the province of

Ontario listed Southern Hudson Bay polar bears as a "threatened" species (Obbard *et al.*, 2010).

The deep water over the Arctic Basin is often assumed to be of such low productivity (e.g., Amstrup *et al.*, 2007; Fischbach *et al.*, 2007; Obbard *et al.*, 2010) that it is largely unsuitable for polar bears except as a transit corridor. This assumption is contradicted by measurements of significant amounts of phytoplankton and ice algae (e.g., Gosselin *et al.*, 1997; Stirling, 1997) as well as reports at the North Pole of "small fish" (estimated as 5–8cm, presumably young polar cod, *Boreogadus saida*) thrown up by icebreakers, and algal growth visible on the underside of broken ice chunks (Todd *et al.*, 1992). Polar cod and their prey are the food of ringed seals and are known to live under ice of all types, including multiyear and first-year drifting sea ice regardless of the ocean depth (Lønne and Gulliksen, 1989). The cracks ("leads") that continuously develop in moving multiyear ice allow thinner first-year ice to form, creating habitat for seals and thus potential food for polar bears (Stirling, 1997). Although the Arctic Basin is undoubtedly less productive than continental shelf areas, it may be more productive than has been assumed.

Ovsyanikov (2010) summarizes preliminary results of two distinct pieces of polar bear research conducted by Russian biologists from 2005–2008: on Wrangel Island in the Chukchi Sea and in the central Arctic Basin. Although the Wrangel Island work was a continuation of population monitoring that has been ongoing since 1990, the Arctic Basin surveys conducted in 2005 and 2007 were the first of this kind.

The late-summer Arctic Basin surveys were split between two years, each taking a different route: the 2005 expedition surveyed northward from Wrangel Island (in the far eastern Russian Arctic), on both sides of the 180° meridian up to 79°15' N, and the 2007 trip surveyed north from Franz Joseph Land (in the far western Russian Arctic, at about 81°N, 60°E), to the North Pole and back. Observations were taken 24 hours/day from the ship bridge for the duration of the trips, and sightings of both bears and ringed seals were recorded.

In 2005, 18 bears were seen north of Wrangel, 12 of these above 75°N, which marks the edge of the continental shelf at this location. Ten of the bears seen were in four family groups, and three of these families were observed north of the continental shelf. All were in good physical condition. A female and her single cub-of-the-year were observed feeding on a ringed seal at 78°50.20' N, 177°27.40' W, where

water depth under the ice was 1,500 m. In addition, seven tracks of lone bears were recorded north of the continental shelf. A total of 48 ringed seals were observed from Wrangel Island to 79°15' N, more than half of these between 78°–79° N.

In 2007, the survey ship worked the other side of the Arctic Basin, north of Franz Joseph Land, where the continental shelf ends at around 82°–83° N (Weber, 1983). Seven polar bears were sighted beyond 81° N, all of them in good condition and all recorded on fields of substantial ice. One female was observed and photographed at the North Pole on 1–2 August 2007. A total of 61 tracks of single bears were also recorded, with a concentration around 82° N. Eleven ringed seals also were observed, five between 82° and 83° N, three between 83° and 87° N, and three between 89° and 90° N (including one at the North Pole). A lower proportion of the observations of seals and bears were noted beyond the continental shelf north of Franz Joseph Land than were sighted north of Wrangel Island but a few seals and at least one bear were recorded close to, or at, the North Pole.

Ovsyanikov suggests ringed seals living at the periphery of the Arctic Ocean move into the central Arctic Basin as the pack ice recedes in late summer and polar bears that choose to stay on the pack ice (rather than moving onto land) move along with the seals and the ice into the central Arctic beyond the continental shelves. Previous reports also have documented the presence of both ringed seals (Todd *et al.*, 1992) and polar bears in the central Arctic Basin (Van Meurs and Splettstoesser, 2003), and in 1992–1993, a female tracked via satellite by Durner and Amstrup (1995) migrated from Prudhoe Bay in the southern Beaufort to northern Greenland via the central Arctic Basin (going as far north as 88°).

Ovsyanikov's Arctic Basin survey confirms ringed seals and polar bears do not require ice that is positioned over shallow, continental shelf waters, although higher densities of both species undoubtedly exist in such areas (e.g., Derocher *et al.*, 2004). Ovsyanikov's study, although limited, is the first systematic look at polar bears and ringed seal abundance within the Arctic Basin. Further surveys may reveal the Arctic Basin is a more important habitat for polar bears than has been assumed, especially given the new finds of significant blooms of phytoplankton under thick annual ice (Arrigo *et al.,* 2011), discussed previously.

Years prior to the discovery reported by Arrigo and colleagues in 2011, Amstrup (2003) said, "Despite apparent preferences for the more productive waters near shorelines and polynyas (areas of persistent open water), polar bears occur throughout the polar basin including latitudes >88°N (Stefansson 1921; Papanin 1939; Durner and Amstrup 1995)." Amstrup also notes "the frequency of recent observations deep in the polar basin, however, mandates recognition that a separate stock could occur there." Although polar bear research in the remote and formidable Arctic Basin has so far been marginal, evidence to date suggests a significant population of polar bears live their entire lives in the Arctic Basin, although their official contribution to the global population estimate is still zero (Obbard *et al.,* 2010).

Polar bears are adapted to extremes of both warming and cooling that can and do occur. Under hostile climate conditions, polar bears will move out of affected areas and return when conditions improve and when the sea ice is neither too thick nor too ephemeral. If local sea ice changes continue for whatever reason, some subpopulations may be expatriated or decline to low numbers. However, polar bears as a species are not in danger of extinction and have not reached worrying levels of population decline.

5.8.2 Life History

5.8.2.1 Choice of Den Location by Females

In the fall, pregnant polar bear females make maternity dens in drifted snow, either on land or drifting pack ice, where they hibernate over the winter (Mauritzen *et al.*, 2001). The tiny cubs are born during hibernation (from mid-November to January) and are nursed within the den for at least two months. Mothers and cubs emerge around March-April. Individual females appear to have preferences for den location: females that den on land and those that den on ice are known in most subpopulations studied, except western Hudson Bay and around Svalbard in the Barents Sea, where all females appear to den on land (Mauritzen *et al.*, 2001; Ferguson *et al.*, 2000; Fischbach *et al.*, 2007; Lentfer, 1975; Zeyl *et al.*, 2010). According to Amstrup (2003), although it was once believed there were several high-density "core" areas for denning, "over much of their range, we now

know, polar bears den in a more diffuse pattern where individual dens are scattered over broad reaches of habitat at low density." And as Zeyl *et al.* (2010) have stated, "long-term fidelity of denning areas and faithfulness to denning substrate (*i.e.*, land vs. ice) has been observed."

Do females switch their den locations from one year to the next? If so, what is the level of loyalty ("fidelity") to either the area (the particular place on land) or the substrate (land vs. ice)? As all Svalbard-area females appear to den on land, the issue addressed in the paper by Zeyl *et al.* was whether mothers switched from one denning area to another within the Svalbard region, and whether related individuals (especially mothers and daughters) tended to den in the same area.

The authors used data collected from a technique called "mark-recapture," along with results from analysis of mitochondrial DNA (mtDNA, the kind inherited from mothers) to investigate the amount of loyalty individual female polar bears had to five denning areas around Svalbard. They also used these data to address whether any loyalty to a specific area was transmitted from mothers to daughters to such an extent that it would result in genetic clustering of mtDNA haplotypes in different den areas.

The results of the study indicate female polar bears have a moderate degree of loyalty to their chosen den areas (3/13 females switched areas from one year to the next) and daughters had a tendency to den in the same areas as their mothers (only 2/8 did not). There was not, however, the kind of genetic clustering expected if such loyalty had been ongoing over a long period of time. Although the distances between successive mark-recapture locations for Svalbard females were similar to distances reported for land-denning females in western Hudson Bay (23.7 km vs. 34 km, respectively), these were much lower than documented for females in the Beaufort Seas (308 km), where a significant proportion of bears den on sea ice (Amstrup and Gardner, 1994), the authors note. Zeyl and colleagues also note the level of denning site loyalty demonstrated by female polar bears on Svalbard is markedly lower than recorded for brown bears, their closest living relatives (who of course always den on land).

Zeyl and colleagues suggest female polar bears may switch the precise location of their dens from one year to the next depending on prevailing snow or sea ice conditions. In a similar study, Fischbach *et al.* (2007) documented some females who switched between pack ice dens and land dens (*i.e.*, a switch of substrate type). Zeyl *et al.* suggest there is more

flexibility than previously assumed in den site choice among polar bear females.

The demonstrated willingness of polar bear females to switch den locations from one year to the next, despite a general tendency towards den site loyalty, almost certainly gives them the flexibility they need as a species to persist in the face of sea ice conditions that vary from year to year. The ability of polar bear females to shift from one den site location to another or one substrate to another is just one aspect of the kind of plasticity needed to survive in this habitat.

Amstrup and Gardner (1994) stated, "contrary to previous hypotheses (Stirling and Andriashek, 1992), substantial polar bear denning occurs in the Beaufort Sea region of northern Alaska and adjacent Canada. Bears that den on pack ice are subject to risks not encountered by bears that den on land. Unstable, moving ice caused early abandonment of dens and, apparently, loss of cubs. However, the persistence of pack-ice denning indicated that those risks are not overwhelming."

As one Russian polar bear researcher commented years ago regarding bears in the eastern Russian Arctic (Kochnev, 2006), "our investigations on Wrangel Island have shown the polar bear is a very plastic animal: it can rapidly change its way of life, spatial distribution and behavior according to new ecological conditions." Zeyl and colleagues (2010) seem to agree, stating, "females are likely able to change denning locations if unsuitable ice conditions prevent them from reaching their preferred denning areas. We consider this plasticity an important attribute of polar bears when facing climate change."

Working in the same Southern Beaufort region as Fischbach *et al.* (2007), Schliebe *et al.* (2008) found in 2000–2005 an average of 3.7% of polar bears spent time on land between mid-September and the end of October; the rest were on the pack ice. They state, "across all years and survey dates between mid-September and the end of October, an average of 4 ± 2 bears/100 km (57 ± 28 bears total) were observed. Thus, a maximum of 8.0% and an average of 3.7% of the estimated 1,526 bears in the SBS population (Regehr *et al.*, 2006) were observed on land." This means there were, on average, only 56 bears on land in the fall each year (out of 1,526 bears), suggesting most pregnant females in the Southern Beaufort made their dens in the pack ice and never came to land in fall. Schliebe *et al.* conclude, "overall, we did not detect an increasing trend in polar bear densities along the Beaufort Sea coast of Alaska during the six years of this study," indicating bears were not being

forced on land due to declining summer ice coverage.

These studies make it apparent an unknown number of polar bear females den in the offshore pack ice and many Southern Beaufort bears never set foot on land. Amstrup (2003), in his discussion of pack-ice denning in the Beaufort Sea, says this about offshore denning: "despite the absence of conclusive reports, sea-ice denning probably occurs at some level in other areas." Amstrup suggests these areas include the Arctic Basin, given "the recent recognition of a possible polar basin stock of polar bears." In addition, he suggests the "linear coastline of central Arctic Russia may be more similar to the Beaufort Sea than other areas, and hence may be another area where sea-ice denning is common."

Given the known and predicted use of offshore ice for denning, it is rather astonishing that the report supplied in support of the listing of the polar bear as a threatened species in the United States (Bergen *et al.*, 2007) modeled only future changes to terrestrial denning habitat. Since those models did not address offshore sea ice denning habitat at all, it means those studies ignored a huge amount of polar bear habitat that is likely critical to their resilience to changing sea ice conditions.

5.8.2.2 Mortality Due to Den Collapse

In a list of suggested risks to polar bears in a warmer world, Derocher *et al.* (2004) state, "An additional concern specific to female polar bears in dens with altricial cubs is the possibility that rain might become more frequent in late winter and cause the snow cover over dens to collapse and suffocate the occupants." Stirling and Derocher (2012) provide more up-to-date and detailed information on this concern. Their paper summarizes all of the known anecdotal reports of rain on snow events that led to the collapse of polar bear maternity dens and/or ringed seal birthing lairs. They state "such rain on snow events are predicted to increase as the climate warms in the Arctic."

Stirling and Derocher describe four incidents: one case of a maternity den collapse (involving a six-year-old, probably first-time mother and two cubs three to four weeks old) in the southern Beaufort in 1989, apparently caused by warm weather followed by heavy snow in late January, reported originally by Clarkson and Irish (1991); a rain event in early March 1990 in western Hudson Bay that was not associated with den collapses and which led to "no evidence of dead bears the following summer"; rain and warm

weather in early April 1979 in southeastern Baffin Island that resulted in "increased predation mortality of ringed seal pups" by polar bears and Arctic foxes; a warm period, also in southeastern Baffin Island, in late April 1990, that was reported to have generated a tripling of polar bear predation success on newborn ringed seal pups because ringed seal birthing lairs were easier to break or had melted and collapsed.

These details indicate each of the den collapse incidents occurred in 1990 or before, not in more recent years as might be expected if such events were associated with warmer temperatures. It appears there has not been a single documented event of this kind since 1990, despite increasing temperatures and "progressive unidirectional changes to sea ice distribution" (Stirling and Derocher, 2012). Instead, it appears warm spells in winter and rain in the spring occur rarely in the Arctic, even in a warming world, and do not pose a significant risk to polar bears or their ringed seal prey. Anecdotal reports such as these are not evidence and do not contribute to our understanding of how polar bears respond to unidirectional climate change.

5.8.3 Nutrition and Reproductive Success

Researchers have expressed concern over the relationships between temperature and sea ice breakup and the nutrition and physical condition of polar bears and reproductive success. Closer scrutiny of these claims suggests they lack empirical bases.

5.8.3.1 Nutritional Stress and Declines in Body Condition

According to Stirling and Derocher (2012), "the most comprehensive long-term research on polar bear demography, body condition, subpopulation size, abundance, and reproductive success has been conducted on the Western Hudson Bay sub-population." For bears in this subpopulation, they found "statistically significant relationships have been documented between progressively earlier dates of sea ice breakup (which shortens the feeding time for polar bears at the most important time of the year just before coming ashore, and lengthens the fasting period)," and declines in the following parameters: mean body condition during the fall ice-free period; mean weights of suspected pregnant females prior to denning in fall; and survival of juvenile, subadult, and old (senescent) adult bears.

These claimed correlations between these life history parameters and "progressively earlier dates of sea ice breakup" in Western Hudson are based on published sea ice data only up to 1998. As their figure caption notes, data after that time (1999 to 2007) is attributed to "N.J. Lunn and I. Stirling, unpublished data." In contrast, the figure they include showing global sea ice declines, based on Stroeve *et al.* (2007), is updated to 2011 with publicly available data provided by the U.S. National Snow and Ice Data Center. Moreover, although Stirling and Derocher say "the mean mass of adult females declined (by about 20%) between 1980 and 2007" (mass being a "proxy" for body condition, which they say is tied closely to litter size, age at weaning, and cub survival), the data used to reach this conclusion are for 1980 to 2004 only: the data from 2006 to 2007 are not available in the peer-reviewed literature. This means the data on which these claims are made are strikingly out of date and/or unavailable, and the conclusions may no longer be valid.

Stirling and Derocher's claim of "progressive unidirectional changes to sea ice distribution" may be accurate for global sea ice coverage but not for ice on Hudson Bay. In a recent paper on breakup in Western Hudson Bay, Cherry *et al.* (2013) show between 1991 and 2009, there was considerable variability in breakup dates. Polar bears left the ice later in 2009 than in 1992, indicating breakup dates have not been progressively earlier since 1992. Only nine of 19 breakup dates in this period fell in June (with none falling in the first half of the month), suggesting there was little or no impact on the critical November–June feeding period. And although some bears apparently chose a favorite location to come ashore even if there was enough ice to spend more time hunting, many bears were flexible enough in their choice of where and when they left the ice to adapt to yearly variability in conditions. Overall, it appears variability may be the most prominent feature of sea ice breakup dates for Western Hudson Bay and most

polar bear females can and do take these variations in stride.

Polar bears in the Southern Beaufort region have also been reasonably well-studied. This subpopulation is shared between the United States and Canada and comprises most of the north coast of Alaska and about an equal length of the western Canadian Arctic coastline. It is characterized by a dynamic mix of annual and multiyear sea ice. Bears in the Southern Beaufort routinely den on the sea ice rather than on land and reach their maximum weights in the fall, rather than in summer, as do bears in Western Hudson Bay—probably because they spend little, if any, time on land during the summer.

Durner and Amstrup (1996) note, "polar bears in western Hudson Bay differ from other populations because the sea ice substrate required for hunting melts completely by late summer (Ramsay and Stirling, 1988), and all members of the population fast or consume only low-energy food (Derocher *et al*., 1992). On the other hand, polar bears inhabiting certain areas of the Canadian Arctic archipelago (e.g., Viscount Melville Sound) may be food deprived because of stable sea ice conditions during winter and low seal densities (Messier *et al*., 1994). Because polar bears in Alaska [*i.e.*, the Southern Beaufort] follow seasonal changes in dynamic pack ice (Amstrup and DeMaster, 1988), they may not face the food scarcity that characterizes the Hudson Bay population during summer and the northern Canadian population during the winter."

In other words, even before there were declines in sea ice coverage purportedly caused by global warming, polar bear biologists saw marked differences among subpopulations in patterns of body condition changes from season to season. In light of that understanding, do reports that blame global warming for declines in polar bear size and body condition (and associated declines in cub production and/or survival) stand up to scrutiny?

Rode *et al.* (2010) studied polar bears in the Southern Beaufort between 1982 and 2006. They used a subjective definition of sea ice conditions, called "optimal ice habitat," which is not a quality measured by satellites but "resource selection function (RSF) models" that use data from satellite-collared polar bears (1985–1995) to show where the bears that researchers captured on land or near shore moved throughout the year. Using this method, a decline in area (km^2-months) of "optimal ice habitat" (ice neither too thin nor too thick) could mean sea ice got thicker, got thinner, or disappeared—it is not possible to tell which. Rode *et al.* (2010) conclude,

"the decline over time in the availability of sea ice corresponded with declining trends in most measures of bear sizes and condition." But because their "decline over time in availability" is not a straight-forward decline in sea ice extent or timing of the ice-free period, but a decline in "optimal ice habitat," it is unlikely this parameter is really useful in addressing whether reduced levels of summer sea ice in the Southern Beaufort are the proximate cause of negative impacts on polar bears.

In direct contraction of a statement made by Obbard *et al.* (2010), discussed in more detail near the end of this section, Rode *et al.* (2010) say, "declines in the size of bears in this population have occurred during a time period when the number of bears in the region also appears to be lower than previously thought (Regehr *et al.,* 2006), and the trend in numbers appears to be downward (Regehr *et al.,* 2010). Though the mechanism associated with population-level change is not clear, nutritional limitations in the population are apparent as a result of the observed declines in bear skull sizes and body lengths. … Thus, nutritional factors may also have played a role in the observed population-level changes." Although nutritional stress has indeed been documented for this area, there has not been a statistically significant decline in the population, a point reiterated by Regehr *et al*. (2007): "changes in the sea ice have not yet been associated with changes in the size of the SB polar bear population (Regehr *et al.,* 2006)." Obbard *et al.* (2010) concur.

Even more surprising is recent research on polar bears in the neighboring Chukchi Sea subpopulation (shared between the United States and Russia), which has shown either no negative effects or marked improvement despite at least twice as much summer sea ice loss as in the Southern Beaufort. Rode *et al.* (2014) captured, measured, and released polar bears on the sea ice between mid-March and early May, 2008–2011; others did similar work in 1986–1994. Rode *et al.* compared data collected on body condition, litter size, and juvenile survival ("reproductive indices") in the Chukchi Sea between the two periods (1986–1994 and 2008–2011). They also compared body condition and reproduction in the Chukchi and neighboring Southern Beaufort for the period 2008–2011. They evaluated these metrics in relation to sea ice loss and prey availability; for Chukchi bears in 2008–2011 only, they also determined diet composition from analysis of fat samples ("fatty acid signatures") and fasting behavior from analysis of blood samples ("levels of blood urea nitrogen and creatinine").

The authors found "in 2008–2011, CS [Chukchi] bears were either larger and in better condition, or similar in size and condition, to CS bears in 1986–1994." They also found "no difference in the number of yearlings per female, yearling litter size, or the annual percentage of females with yearlings between periods in the CS. … Overall, CS bears in 2008–2011 were larger and in better condition than SB [Southern Beaufort] bears during the same period." The number of yearlings per female in spring was also higher in the Chukchi Sea than in the Southern Beaufort.

Most surprisingly, Chukchi bears were larger and heavier than virtually all other subpopulations studied. Rode *et al.* (2014) found "spring COY litter sizes are among the highest reported for 18 of 19 polar bear populations. … [S]pring litter sizes of CS yearlings from the study were also higher than other populations." The authors note, "the larger body mass of adult females in the CS corresponded not only with larger litter sizes, but also with heavier yearlings (Fig.5 [in original document]) which have a greater chance of survival." Rode *et al.* state, "body size, condition, and reproductive indices of CS polar bears did not decline over time between 1986–1994 and 2008–2011 despite a 44-day increase in the number of reduced-ice days. Furthermore, CS bears were larger, in better condition, and appeared to have higher recruitment compared to the adjacent SB population during 2008–2011. These differences were biologically significant."

In the Chukchi subpopulation, the authors conclude, "body condition was maintained or improved when sea ice declined" and "continued high biological productivity in the Chukchi and northern Bering seas may be allowing polar bears and their prey to prosper despite habitat loss." Regarding Southern Beaufort bears, they state, "Our evaluation of nutritional ecology for polar bears is consistent with lower prey availability in the SB compared to the CS."

These results were unexpected because the Southern Beaufort and Chukchi Seas are considered similar ice ecoregions and polar bears were predicted to respond similarly to summer sea ice loss. Both have been classified as "divergent" ice ecoregions by researchers attempting to predict how polar bear habitat might fare over the next 25 to 95 years based on computer-projected sea ice declines (Amstrup, 2011; Amstrup *et al.,* 2008, 2010; Durner *et al.,* 2009). Durner and colleagues, for example, state, "within the Divergent ecoregion, rates of decline are projected to be greatest in the Southern Beaufort, Chukchi, and Barents Sea subpopulations." Two

conclusions can be drawn from this study: Declines in summer sea ice extent can markedly benefit polar bear survival, and extent of sea ice loss in summer is not the paramount determiner of polar bear health and population status, at least over the short term.

In the eastern Arctic, there also has been recent work done on Davis Strait polar bears, the most southerly polar bear subpopulation. Whereas the southernmost portion of the Southern Hudson Bay region (James Bay) lies at about 52°N and the southernmost portion of Western Hudson Bay lies at about 55°N, bears in the Davis Strait polar bear subpopulation occur regularly to at least 50°N, with some moving as far south in spring as 47°N.

Based on mark-recapture studies undertaken from 1974 to 1979 and from 2005 to 2007, Peacock *et al.* (2013) state, "the overall amount of sea ice declined and breakup has become progressively earlier" since the 1970s. Nonetheless, they "estimated the abundance of the Davis Strait polar bear subpopulation to 2,158, which results in a relatively high population density of polar bears of approximately 5.1 bears/1,000 km^2 of sea ice habitat (Taylor and Lee, 1995). This density is greater than polar bear densities in other seasonal-ice subpopulations, which are approximately 3.5 bears/1,000 km^2." So despite declining sea ice since the 1970s, the density of bears in this region has reached a higher level than any other subpopulation known that loses ice completely in summer. The authors conclude, "survival and reproduction of bears in southern Davis Strait was greater than in the north and tied to a concurrent dramatic increase in breeding harp seals (*Pagophilus groenlandicus*) in Labrador."

They suggest the Davis Strait polar bear sub-population is characterized by "low recruitment rates, average adult survival rates, and high population density." The high density of bears in this region may be affecting recruitment (*i.e.,* reproduction), the authors conclude, "low reproductive rates may reflect negative effects of greater densities or worsening ice conditions." In other words, polar bear populations with a high density of animals may show changes to life history parameters similar to those expected in populations affected by declines in sea ice. However, effects of high density and less time spent feeding due to reduced sea ice appear to be viable explanations for the observed conditions in Davis Strait, and these factors are not necessarily mutually exclusive. Nevertheless, polar bears in Davis Strait appear to be increasing in number, not declining as reported by the IUCN/SSC Polar Bear Specialist Group (Obbard *et al.,* 2010) and others, despite the declines in sea ice.

In a similar study that compared Davis Strait polar bears to those in Baffin Bay to the North, Rode *et al.* (2012) "examined trends in body condition metrics of captured bears and relationships with summertime ice concentration between 1977 and 2010 for the Baffin Bay (BB) and Davis Strait (DS) polar bear populations." Both of these regions are dominated by annual (first year) ice. They conclude, "we suggest that declining body condition in BB may be a result of recent declines in sea ice habitat. In DS, high population density and/or sea ice loss may be responsible for the declines in body condition. ... Though a decline in body condition was observed for DS between 1978 and 1994, there was no relationship between body condition and sea ice concentrations at that time." In other words, the decline in condition of polar bears in Davis Strait may be evidence the population has reached "carrying capacity" despite the declining trend in annual sea ice extent. This result suggests declines in body condition may not necessarily be the harbinger of doom for polar bears some researchers have proposed but instead a signal more bears exist than the local habitat can support.

One of the presumed repercussions of polar bears that end up in poor condition due to nutritional stress, especially if they get to the point of starving, is an increase in propensity for infanticide and cannibalism. These phenomena are well-known in all bears (Taylor *et al.,* 1985), but there have been no long-term, carefully designed scientific studies on infanticide or cannibalism among polar bears, so no baseline data exist with which to compare recent anecdotal reports. This has not stopped some polar bear researchers and conservation advocates from using these anecdotal observations as a kind of "supporting evidence" for contending polar bears are already being negatively impacted by global warming.

Stirling and Derocher (2012) state, "There have been several well-publicized observations that are consistent with predictions of the effects of climate warming on polar bears, but cannot be statistically linked. For example, intraspecific aggression and cannibalism were predicted to increase in polar bears with climate warming (Derocher *et al.*, 2004, Table 1). Observations of infanticide and cannibalism by thin adult males on land during the open water period have been documented (e.g., Lunn and Stenhouse, 1985; Derocher and Wiig, 1999; Amstrup *et al.*, 2006; Stone and Derocher, 2007)."

However, of the references cited, only Lunn and Stenhouse (1985) report a confirmed instance of a thin (*i.e.,* starving) adult male killing and consuming another adult bear during the open water period, and that event occurred in 1984. Amstrup *et al.* (2006), who report three incidents of cannibalism in the Southern Beaufort, did not know the condition of the bears that killed and partially consumed other bears, as no one witnessed these attacks. In addition, contrary to the notion that cannibalism is associated with starvation, in the most recent case published (one not mentioned by Stirling and Derocher), Stirling and Ross (2011) report three cases of cannibalism on the sea ice around Svalbard, all of which involved males in good or very good condition killing other young bears. They say "the three observations we describe are different from most other reports of infanticide and cannibalism in polar bears because they took place between midsummer and early autumn. … All three adult males appeared to be in good physical condition (*i.e.*, not obviously thin), and one was both very large and very fat."

Stirling *et al.* (2008), in a follow-up to the report of Amstrup *et al.* (2006), state, "these observations, along with cannibalized and starved polar bears found on the sea ice in the same general area in the springs of 2004 through 2006, suggest that during those years, polar bears in the southern Beaufort Sea were nutritionally stressed." They point out several severe winter storms piled up thick ridges of sea ice in the landfast ice zone, which made seal hunting difficult for polar bears. They acknowledge the nutritional stress was caused by heavy ice conditions in 2004 and 2005 (confirmed by Harwood *et al.,* 2012 and Melling *et al.,* 2005) but suggest the heavy ice may have been caused by open water many months prior in the Chukchi Sea far to the west. However, there have been heavy ice years in this region every decade since the 1960s (long before there was increased open water in the fall) and starving bears in spring were documented in most of those heavy ice years (Stirling, 2002; Stirling and Lunn, 1997; Stirling *et al.,* 2008), suggesting the cause of heavy spring ice is something other than increased open water in the summer.

The impact of the most recent heavy ice years on ringed seals is documented by Harwood *et al.* (2012), for the Amundson Gulf, which lies in the south half of the Northern Beaufort polar bear subpopulation (and immediately east of the Southern Beaufort areas discussed above). They examined "the relationship between ringed seal body condition and reproduction and spring sea ice conditions in prime ringed seal habitat" in the western Canadian Arctic between 1992 and 2011. They found "failure to ovulate was obvious in 2005, the most extreme late ice clearance year in our series, when only 30.0% of the mature adult

females sampled ovulated." The authors conclude, "Seals sampled in years of late ice clearing had, on average, lower body condition than those sampled in years of earlier ice clearing, particularly in the case of subadults" and for mature females, "marked declines were seen in 1974 (Smith, 1987), in 1987 (Kingsley and Byers, 1998), and in 2005 (this study), all times when seals were in significantly poorer body condition. ... Signals were detected in the most extreme ice years (e.g., when fast ice breakup occurred 3–8 weeks later than the average since 1970) and were linked to the degree of severity of winters, as indicated by the annual ice regime." They note, "In the Beaufort/Amundsen regions, for example, observations over the last 40 years have revealed large fluctuations in ice presence and thickness over intervals of years to decades, with so far only small trends towards earlier ice clearance and longer open water seasons (Melling and Riedel, 2004; Melling *et al.*, 2005)."

Pilfold *et al.* (2012) corroborate the declines in ringed seal pup production documented by Harwood *et al.* (2012) in their study of the age composition of ringed seals killed by polar bears in the eastern Beaufort from 1971 to 2006. They show, in their Figure 3, a higher proportion of pups were killed during the low or average spring ice years of 1971–1973 (when about 45% of seals killed were pups) and 2007–2011 (about 80% pups) than in the heavy spring ice years of 1974 to 1975 (none killed were pups), 1985 to 1987 (about 10% pups), or in 2003 to 2006 (about 40% pups). In other words, since the early 1970s, polar bears killed fewer seal pups in springs with heavy sea ice conditions, suggesting fewer seal pups were available.

Another perspective on these events is provided by Cherry *et al.* (2009), who compared the fasting physiology of eastern Beaufort Sea polar bears during two known heavy spring ice periods: 1985–1986 and 2005–2006. In their analysis of the proportion of urea vs. creatinine (considered an indicator of fasting) from blood samples drawn in the eastern Beaufort Sea (which include the southern portion of the Northern Beaufort subpopulation) in April-May 1985–1986 and 2005–2006, they found "the proportions of polar bears fasting were 9.6% in 1985, 10.5% in 1986, 21.4% in 2005, and 29.3% in 2006. … The increased number of polar bears in a physiological fasting state from all sex, age, and reproductive classes in 2005 and 2006 corresponded with broad scale changes in Arctic sea ice composition, which may have affected prey availability." They write, "none of the bears displayed physical or behavioral traits indicative of an animal in the advanced stages of starvation." This seems to corroborate the finding by Amstrup *et al.* (2006), who found in the spring of 2004, the year before Cherry *et al.* took their samples, "70 of 148 (47%) of bears captured as independent animals (*i.e.*, not including cubs captured with their mothers) were in the lean condition classes 1 and 2." This is perhaps not very surprising, as polar bears are generally at their leanest in March, and if they are slow to put on weight for any reason over the spring months, by April or May they would not yet be in optimum condition (although they might be so a few months later).

Cherry *et al.*'s discussion of the "changes in Arctic sea ice" in their introduction attempts to imply the changes over time in the percentage of fasting bears was caused by reduced ice and more open water. They say, for example, "the Arctic ice-ocean system has been warming faster than global averages since the 1960s." They conclude, "Beaufort Sea bears reach their lightest weights in late March and rely on a 2–3 month spring feeding period, when fat and naïve ringed seal pups are available, to gain the fat reserves necessary for survival and reproduction (Stirling and Øritsland, 1995; Stirling, 2002). ... [T]he recent increase in bears fasting during April and May suggests that there has been a decrease in prey availability at that time of year. ... [T]he precise means through which prey have apparently become less available to polar bears in the Beaufort Sea remains unknown." But as discussed above, "the precise means" have been documented—evidence from this region suggests heavy sea ice in the spring during 2004–2006, which resulted in precipitous declines in ringed seal pup production, was almost certainly the cause of more bears fasting (Harwood *et al.,* 2012; Melling *et al.,* 2005; Stirling, 2002; Stirling *et al.,* 2008).

Regehr *et al.* (2010) provide another attempt to shift attention from heavy ice conditions in spring to low sea ice conditions in late summer. These researchers "evaluated the effects of sea ice conditions on vital rates (survival and breeding probabilities) for polar bears in the southern Beaufort Sea" with models, based on data collected from 2001 to 2006 on polar bears and the number of ice-free days each year. They conclude, "in the most supported models, polar bear survival declined with an increasing number of days per year that waters over the continental shelf were ice free. In 2001–2003, the ice-free period was relatively short (mean 101 days) and adult female survival was high (0·96–0·99, depending on reproductive state). In 2004 and

2005, the ice-free period was longer (mean 135 days) and adult female survival was low (0·73–0·79, depending on reproductive state). Breeding rates and cub litter survival also declined with increasing duration of the ice-free period. Confidence intervals on vital rate estimates were wide."

Regehr *et al.* did not include possible effects of heavy sea ice conditions in spring in their models, which, as shown above, tends to have a direct negative impact on polar bear life history parameters in the eastern Beaufort (Harwood *et al.,* 2012; Melling *et al.,* 2005; Stirling, 2002; Stirling and Lunn, 1997). Regehr *et al.*'s models considered only number of ice-free days in summer as a possible association. As a consequence their results and conclusions add little to our understanding of changes in polar bear survival or body condition in the Southern Beaufort.

It should be noted that despite the repeated bouts of less-than-optimum conditions every decade or so, polar bear numbers in the Southern Beaufort appear to have remained remarkably stable. Obbard *et al.* (2010) note,

> through the 1980s and early 1990s, observations suggested that the SB subpopulation was increasing. Amstrup *et al.* (2001) found the SB subpopulation may have reached as many as 2,500 polar bears in the late 1990s. However, that estimate was not considered reliable due to methodological difficulties, and management decisions continued to be based on a population size of 1,800. Results from an intensive mark-recapture study conducted from 2001–2006 in both the USA and Canada indicated that the SB subpopulation included 1,526 (95% CI = 1,211–1,841) polar bears in 2006 (Regehr *et al.,* 2006). This suggests that the size of the SB subpopulation declined between the late 1990s and 2006, although low precision in the previous estimate of 1,800 precluded a statistical determination."

In other words, although there is evidence of nutritional stress in 2004–2006, it did not result in a statistically significant decline in numbers of polar bears in the Southern Beaufort region.

In addition, polar bears that live in the region around Banks Island and the Amundsen Gulf in the past were often included in studies of the "eastern Beaufort," but they now are considered part of the Northern Beaufort subpopulation, one of the few subpopulations some researchers consider as having a stable population trend (Obbard *et al.,* 2010; Stirling *et al.,* 2011).

Surprisingly, one question seldom addressed in studies on nutritional stress and associated behaviors such as cannibalism is this: Do polar bears ever starve under conditions that cannot be blamed on sea ice changes? Indeed, they do. Amstrup (2003) notes

> starvation of independent young as well as very old animals must account for much of the natural mortality among polar bears. … Also, age structure data show that subadults aged 2–5 years survive at lower rates than adults (Amstrup, 1995), probably because they are still learning hunting and survival skills. … I once observed a 3-year-old subadult that weighed only 70 kg in November. This was near the end of the autumn period in which Beaufort Sea bears reach their peak weights (Durner and Amstrup, 1996), and his cohorts at that time weighed in excess of 200 kg. This young animal apparently had not learned the skills needed to survive and was starving to death**.**

It appears the anecdotal reports of cannibalism, infanticide, and den collapses due to spring rain are being included for their emotional appeal to the public but are not associated with recent declines in local or global sea ice or with recent increases in temperature. Data supporting claims of declines in body condition for Western Hudson Bay polar bears are seriously out of date and/or unpublished, and in the Southern Beaufort, declines in body condition due to heavy ice conditions in spring have been documented every decade since the 1960s. Despite attempts to blame these phenomena on global warming, peer-reviewed research suggest otherwise.

5.8.3.2 Changes in Reproductive Success

A warmer Arctic portending dramatic declines in sea ice is predicted to have significant effects on the reproductive success of polar bears, based on changes already documented in some subpopulations. Stirling and Derocher (2012) have this to say about reproductive success in the western Hudson Bay subpopulation: "the proportion of independent yearlings fell from over 81% before 1980 to a mean of 34% in 1980–1992 (Derocher and Stirling, 1995). By the late 1990s, the proportion of independent yearlings dropped to <10% (Stirling *et al.*, 1999) and by the early 2000s was almost nonexistent (I. Stirling, unpublished data)."

In the 1999 paper the authors cite, Stirling *et al.* say this: "The proportion of yearlings that were independent in the annual capture samples fluctuated widely at 3–4 year intervals, but overall the maximum proportions have declined from about 60% in 1982 to 15–20% since 1991 (Fig. 6). There was no statistically significant relationship between the proportion of lone yearlings and the time of [sea ice] breakup in the same year (r =- 0.205, n = 14, p = 0.46)." More importantly, Stirling *et al* (1999) also point out, "for about the last 12 years [ending 1998], estimates of population size have remained relatively constant (Lunn *et al.*, 1997; this study), indicating that the declines in condition and natality have not led to a decline in population." In other words, the well-documented change from weaning at 2.5 years rather than 1.5 years had no immediate negative impact on the population up to 1992, and any additional data collected on this phenomenon are not available in the peer-reviewed literature.

Derocher and Stirling (1995) state: "the results of our analyses suggest that the unique reproductive characteristics of polar bears in western Hudson Bay in the 1960s and 1970s were either a function of a population increasing from a depleted state and

feeding on a relatively abundant prey base, or density-independent fluctuations in prey population size, or availability due to sea ice variation." Therefore, declining sea ice is not the only reason reproductive parameters, such as age at weaning, might change. And since the assertion that the proportion of independent yearlings was "almost nonexistent" by the early 2000s is based on unpublished data, we cannot be sure the claimed further decline in proportion of independent yearlings has had any significant impact on population size, since previous changes did not.

In addition, it should be noted the proportion of independent yearlings being approximately zero is the norm for virtually all other polar bear subpopulations studied (Ramsay and Stirling, 1988; Van de Velde *et al.,* 2003). Western Hudson Bay always has been anomalous in this feature. In that respect, in weaning their cubs at 2.5 years rather than 1.5 years, Western Hudson Bay polar bears may simply be returning to normal.

Stirling and Lunn (1997) perhaps put it best:

> In the early to mid-1980s, the natality [cub production] of female polar bears in western Hudson Bay was the highest recorded anywhere in polar bear range, and nowhere else did females successfully wean cubs at 1.5 years of age instead of at the normal age of 2.5 years. Subsequently, a long-term decline in condition of adult female polar bears and survival of their cubs was documented from the 1970s through the late 1980s (Derocher and Stirling, 1992), as reflected by a significant decline in condition indices. This decline did not constitute a threat to the population because even when natality was at its lowest in the late 1980s, the rates were still higher than the upper range of values for bears elsewhere in the Arctic (e.g., Stirling *et al.*, 1976, 1980). … The more important (but unanswered) question is probably not why natality declined from the early 1980s but how could natality have been sustained at a level so much higher than other polar bear populations in the first place, what facilitated the successful weaning of yearlings there but nowhere else in their range, and how could females manage these physiological feats in a habitat where pregnant females must also fast for 8 months or more?"

They did not answer their question.

Rode *et al*. (2014), in their recent study of Chukchi Sea polar bears, found "spring COY litter sizes are among the highest reported for 18 of 19 polar bear populations. ... [S]pring litter sizes of CS yearlings from the study were also higher than other

populations." The authors note, "the larger body mass of adult females in the CS corresponded not only with larger litter sizes, but also with heavier yearlings (Fig.5) which have a greater chance of survival" and "body size, condition, and reproductive indices of CS polar bears did not decline over time between 1986–1994 and 2008–2011 despite a 44-day increase in the number of reduced-ice days." In other words, contrary to predictions, reproductive parameters of Chukchi Sea polar bears did not decline, despite marked declines in summer sea ice.

5.8.4 Effects of more open water

Polar bears use sea ice as a platform for hunting, traveling, and denning. They are known to be excellent swimmers, capable of swimming long distances between ice flows. But what happens during the late summer, when the edge of the pack ice is many kilometers offshore for months at a time? Although some polar bears spend this "open water" period on land, is it because they are incapable of swimming to the ice edge once it gets beyond a certain point? Or are polar bears, particularly females with cubs, able to swim hundreds of kilometers from land to the ice edge during the "open water" season if they choose to do so?

Working from three points along the coast of the Beaufort and Chukchi Seas, Alaska (Barrow, Prudhoe Bay, Kaktovik) between 2004 and 2009, Pagano *et al.* (2012) attached radio collars during March through May (but also in August 2008) to 62 female polar bears, some of which had cubs with them. The number of bears successfully monitored for this study varied each year; as only two collars were deployed in 2007 and one of these failed, data from 2007 were excluded. The authors analyzed global positioning system (GPS) data from the 52 radio collars that successfully transmitted signals between 1 June and 31 October each year and compared these to the position of the sea ice edge determined from satellite imagery. Some additional data from bears collared between 1985 and 2009 were used to assess whether an early cessation of signal transmission during the open water period (July through September), from bears that had been at sea and were not later re-sighted, could be assumed to indicate the bears had drowned while swimming.

The authors found 50 "long-distance" swimming events (>50 km) were made by 20 of the bears monitored (38% of the total), and 12 of the 20 bears that swam long distances did so multiple times in the same year. The researchers found the majority of the long-distance swims were from unconsolidated sea ice (ice concentration <50%) to the main pack ice (mean distance 155.9 km, range 114.5–197.4 km, 25 swims). Relatively few bears swam from land to another area of land (mean distance 106.2 km, range 53.7–288.3 km, 7 swims) or from unconsolidated sea ice to land (mean distance 169.1 km, range 69.9–302.6 km, 6 swims). Only three swims involved bears moving from land to unconsolidated sea ice (mean distance 102.3 km, range 68.3–113.7 km), and only two were bears moving from land to the main pack ice (mean distance 402.5 km, range 117.9–687.1 km).

There were no long-distance swimming data prior to 2004 with which to compare this study's data, and sampling differences among years precluded the researchers from determining any trend in their results.

They also found there was no significant difference in the rate of cub mortality between females with cubs that undertook long-distance swims and those that did not. It also appeared premature cessation of radio collar signal transmission did not necessarily indicate a bear had drowned; some bears whose signals stopped prematurely probably drowned, but drowning was not the only explanation for signal failure.

Pagano *et al.* calculated the mean distance between the mainland coast and the sea ice edge at the end of September for each year of the study period. This distance varied from a low of about 200 km (achieved in 2005, 2006, and 2009) and a high of about 430 km (achieved in 2008). Mean distance from the shore to the ice in 2004 was about 300 km, and in 2007 it was about 380 km. Each of these measurements varied somewhat depending on the configuration of the shoreline, but in 2008 the ice edge was definitely farther away than in any other year since 1979. However, the largest number of long-distance swimming events took place in 2009, when the ice edge in this region was about the same distance offshore as in 2005 and 2006. The longest swim was recorded in late August/early September of 2008 at a point where the sea ice was >500 km offshore: a female with a year-old cub swam 687.1 km in just over nine days, as described in detail by Durner *et al.* (2011). This bear was one of only two individuals in the Pagano *et al.* study that swam from land to the main pack ice edge; after a few weeks meandering around at the edge of the pack ice, this bear then walked back to shore on the rapid-forming ice, arriving on land at the end of October. The second-longest swim (366.0 km) was recorded in 2005, when the pack ice edge was about the same distance offshore as in 2009.

Pagano *et al.* state, "we show that both adult female polar bears and their dependent young possess an ability to swim long distances." They also observe, "most of the long-distance swimming events that we identified involved bears swimming from uncon-solidated sea ice to the main pack ice or to land." In other words, few swims recorded were from land to sea ice, indicating that during the open water season most southern Beaufort and Chukchi Sea polar bears are on the sea ice, not on land—a point also made by Durner *et al.* (2011). In addition, the results of this

study suggest that despite there being little or nothing for female polar bears and their cubs to eat on shore during the late summer months in the southern Beaufort Sea, the few bears that remain on shore are apparently not hungry enough to undertake long-distance swims to the pack ice to relieve their fast, although they appear able to do so. Despite an overall decline in September sea ice levels between 1979 and 2010, this study found no significant correlation between increased long-distance swims and increased amounts of open water in this region over time.

Although polar bears are clearly accomplished swimmers, an anecdotal account of polar bears that apparently drowned in open water, purported to be evidence of global warming and declining sea ice effects, has garnered remarkable media attention. Monnett and Gleason (2006) report what appeared at the time to be four dead polar bears that drowned in open water in 2004. The bodies were observed from aircraft while surveying for bowhead whales (*Balaena mysticetus*) after a September storm. However, like the anecdotal accounts of cannibalism and den collapses attributed to global warming by Stirling and Derocher (2012) discussed previously, no baseline scientific studies have quantified the number of swimming polar bears that have drowned under any conditions vs. those that have not. So while these isolated events continue to be touted as probable effects of global warming, there is no scientific evidence they are anything of the sort. Scientists do controlled, well-designed studies precisely because anecdotes cannot be trusted to give an unbiased picture of events. The inclusion of anecdotal events as supporting evidence of global warming is an appeal to emotions, rather than scientific reasoning.

5.9 Reptiles

- Studies of the effects of rising temperatures on reptiles find they often are able to tolerate a greater range of environmental conditions than they have been exposed to in the recent past, demonstrate abilities to thermo-regulate to achieve body temperatures close to their preferred temperatures, and often benefit from warmer temperatures.

Many are the predictions of species decline and possible extinction arising from warming-induced changes in the characteristics of regions to which the species are endemic. Concerns over the fate of reptiles are no exception, yet the results of several research studies conducted on this topic suggest these animals are in no such danger.

Chamaille-Jammes *et al.* (2006) studied four discontinuous subpopulations of the common lizard (*Lacerta vivipara*), a small live-bearing lacertid that lives in peat bogs and heath lands across Europe and Asia, concentrating on a small region near the top of Mont Lozere in southeast France, at the southern limit of the species' range. From 1984 to 2001 they monitored several life-history traits of the sub-populations, including body size, reproduction characteristics, and survival rates, while local air temperatures rose by approximately 2.2°C. They found individual body size increased dramatically in all four lizard populations over the 18-year study period, with snout-vent length expanding by roughly 28 percent. This increase in body size occurred in all age classes and, as they describe it, "appeared related to a concomitant increase in temperature experienced during the first month of life (August)." As a result, they found "adult female body size increased markedly, and, as fecundity is strongly dependent on female body size, clutch size and total reproductive output also increased." In addition, for a population where capture-recapture data were available, they learned "adult survival was positively related to May temperature."

Since all fitness components investigated responded positively to the increase in temperature, the French researchers state, "it might be concluded that the common lizard has been advantaged by the shift in temperature." This finding, they write, stands in stark contrast to the "habitat-based prediction that

these populations located close to mountain tops on the southern margin of the species range should be unable to cope with the alteration of their habitat." They conclude, "to achieve a better prediction of a species persistence, one will probably need to combine both habitat and individual-based approaches." Furthermore, they note individual responses, such as those documented in their study (which were all positive), represent "the ultimate driver of a species response to climate change."

Noting tropical species long have been thought to be "especially sensitive to climatic fluctuations because their narrow thermal tolerances and elevational ranges can restrict their ability to persist in, or disperse across, alternate habitats," Bell *et al*. (2010) compared "responses to historical climate fluctuation in a montane specialist skink, *Lampropholis robertsi*, and its more broadly distributed congener, *L. coggeri*, both endemic to rainforests of northeast Australia." They combined "spatial modeling of potential distributions under representative palaeoclimates, multi-locus phylo-geography and analyses of phenotypic variation." The seven scientists write, "both species exhibit pronounced phylogeographic structuring for mito-chondrial and nuclear genes, attesting to low dispersal and high persistence across multiple isolated regions." Referring specifically to *L. robertsi*, the researchers state their evidence demonstrates "persistence and isolation" of most populations of the montane species "throughout the strong climate oscillations of the late Pleistocene, and likely extending back to the Pliocene."

Noting many of the isolated refugia they studied "are particularly rich in narrowly endemic species," Bell *et al*. state this characteristic has been attributed to "their relative stability during recent episodes of climate change (Williams and Pearson, 1997; Yeates *et al*., 2002; Graham *et al*., 2006; VanDerWal *et al*., 2009)." Furthermore, they say these observations "support the general hypothesis that isolated tropical montane regions harbor high levels of narrow-range taxa because of their resilience to past climate change," citing Fjeldsa and Lovett (1997) and Jetz *et al*. (2004). Thus, "at first sight, species such as *L. robertsi* would seem especially prone to local extinction and loss of considerable genetic diversity with any further warming; yet, these populations and those of other high-montane endemic species (*Cophixalus* frogs; Hoskin, 2004) have evidently persisted through past warming events."

Rodder *et al*. (2010) state, "if the climate changes, island endemics may be restricted in their ability to conduct range shifts depending on the topographic variability and the size of the island," and "species that inhabit islands characterized by low altitudinal variation may be the ones most strongly affected by climate change due to the lack of possibilities for horizontal or upward range shifts." However, they note only a small part of the fundamental niche of a species may currently be available to it, and the species may possess a hitherto-unknown ability to tolerate a much greater range of environmental conditions than that to which it may have been exposed in the recent past. Therefore, in determining what climatic conditions a species may be able to tolerate in the future, they state "a comparison between conditions tolerated in the present and in the past may be helpful."

Focusing on *Phelsuma parkeri*, an endemic gecko species native to the relatively flat (0 to < 100 m elevation) island of Pemba, Tanzania, Rodder *et al*. observed the species and provided information on its current spatial distribution in terms of both physical and environmental space, as well as its adaptability to habitat modification by humans. With respect to past climatic conditions, they employed simulations of the Last Glacial Maximum provided by the Community Climate System Model and the Model for Interdisciplinary Research on Climate, while with respect to the future, they employed climate change predictions based on three other models and the emission scenarios reported in the *Special Report on Emissions Scenarios* by the Intergovernmental Panel on Climate Change.

The three researchers report a comparison of current climatic conditions with those derived from model simulations for 21,000 years ago revealed "no climate conditions analogous to those of today existed during the Last Glacial Maximum," noting there were "decreases of between 1.4 and 2.8°C in the minimum temperature of the coldest month and of between 2.1 and 3.4°C in the maximum temperature of the warmest month throughout the island" compared to the corresponding temperatures of today. As for the future, the climate models they used suggested "the minimum temperature of the coldest month may increase about 1.2 to 3.8°C and the maximum temperature of the warmest month by about 2.0 to 3.7°C." Rodder *et al*. say their results suggest "*P. parkeri* is distributed over the largest part of the island, that it is well adapted to current land use, and that it is most likely not threatened by climate change."

Moreno-Rueda *et al*. (2011) "used data on the distributions of reptiles in Spain during the 20th

century to analyze whether the distributions of these reptiles have changed as climate has changed." They compared "the distributions of reptile species before 1975"—the year, they say, according to IPCC (2007), the current period of warming began—"with distributions during 1991–2005." The authors report, "after controlling for sampling effort, geographic bias in sampling, phylogeny, and spatial autocorrelation, the northern limits of the distribution of reptiles in Spain shifted northward between 1940–1975 and 1991–2005," but "there was no similar shift southward in the southern limits of species' ranges." In addition, the mean latitude of the ranges of the species they examined "shifted northward by an equivalent of 0.5 km/year, which is similar to the magnitude of range shifts in other taxonomic groups (Parmesan and Yohe, 2003)."

Noting they were "the first to show there is a correlation between changes in latitudinal distribution and increases in temperature for a wide variety of species of reptiles in Spain," the four researchers say their "finding that reptiles are expanding their northern ranges, potentially in response to climate change, could mean the probability of extinction associated with increases in temperature may be lower than expected."

According to Amiel and Shine (2012), a hatchling reptile's sex, body size, and shape, as well as its locomotor performance, "can be influenced not only by its genes, but also by the temperature that it experiences during incubation." At the time of their study little was known about whether incubation temperature can also affect a hatchling's cognitive skills. Amiel and Shine examined "whether incubation temperature affects lizards' ability to learn the location of a safe retreat site during a predatory attack," because mastering this cognitive task "is directly relevant to individual survival and therefore fitness," citing Paulissen (2008).

The pair of Australian researchers worked with the scincid lizard *Bassiana duperreyi*, by first "randomly dividing eggs from each clutch between two incubation treatments ('hot' = diel cycle of 22 ± 7.5°C; 'cold' = diel cycle of 16 ± 7.5°C)," treatments that "mimic thermal regimes typical of natural nests at low (hot) versus high (cold) elevations." They then conducted a specific test designed to evaluate the young lizards' cognitive skills and their abilities to act appropriately to escape the perceived danger. Amiel and Shine report finding "hot-incubated lizards achieved higher learning scores than did cold-incubated lizards," and "the number of errors they made decreased more from the first to the second half

of the trials than was the case for cold-incubated lizards." They speculate, based on Ahmad and Zamenhof (1978), Rissman *et al*. (2002), Valenzuela and Lance (2004), and Radder *et al*. (2008), "thermal effects on hormone levels during incubation may induce structural variation in parts of the brain that control behaviors such as learning." Amiel and Shine conclude, "climate change may simultaneously generate novel challenges for post-hatching organisms, while also modifying their ability to respond flexibly to such challenges." They specifically opine, "in *B. duperreyi*, hotter natural nests over recent decades (due to climate change) probably have produced hatchling lizards with enhanced learning abilities."

Clarke and Zani (2012) note observed real-world temperature increases typically have been "asymmetrically distributed over diurnal time frames, with daily minima increasing at a faster rate than daily maxima," citing Karl *et al*. (1991, 1993), Easterling *et al*. (1997, 2000), and DeGaetano and Allen (2002), whereas most previous studies of the effects of global warming on biological systems have boosted temperatures by the same amount during all hours of the day and night. Clarke and Zani conducted their study of the potential impact of global warming on the common side-blotched lizard (*Uta stansburiana*)—which they collected about 20 km south of Burns, Oregon (USA) at the northern edge of the Great Basin Desert—employing the latter, more-realistic imposed mode of asymmetric nighttime-only warming.

Working at their field laboratory, Clarke and Zani simulated observed trends in the asymmetric alteration of the local diurnal temperature range by increasing the nighttime temperatures in the incubators into which they transferred the female lizards (from their daytime cages) during their ovarian cycle. They treated the eggs the female lizards produced in a similar manner during their incubation period, carefully documenting the differences they detected throughout the entire reproductive process between the female parent and progeny lizards of the warmed and control treatments.

The two U.S. researchers discovered higher night-time temperatures during the female lizards' ovarian cycles "increased the probability of reproductive success and decreased the duration of the reproductive cycle." They found the higher temperatures had neither positive nor negative effects on "embryo stage or size at oviposition, clutch size, egg mass or relative clutch mass." They also report "higher incubation temperatures increased hatchling

size and decreased incubation period," noting "subsequent hatchlings were more likely to survive winter if they hatched earlier."

Clarke and Zani state, "as our findings confirm that climate warming is likely to increase the rate of development as well as advance reproductive phenology, we predict that warmer nights during the breeding season will increase reproductive output as well as subsequent survival in many temperate ectotherms, both of which should have positive fitness effects." Thus, they conclude, "these effects are primarily beneficial for this population of northern lizards," and they predict "future changes will continue to benefit the reproduction, growth and survival of individuals at this site."

Leal and Gunderson (2012) write, "the general view is that climate change will have a major impact on biodiversity by increasing the extinction risk of many species or changing their distributions," based on "the implicit assumption that species are relatively fixed entities, unable to respond to rapid changes in ecological conditions, including climatic variables, over an ecological timescale." They state "evidence that some organisms are able to respond to climatic changes over short timescales has begun to emerge (e.g., Grant and Grant, 2002; Walther *et al.*, 2002; Bradshaw and Holzapfel, 2006)."

Nearly 40 years ago, the tropical Caribbean lizard *Anolis cristatellus*, native to an area of xeric forest in northeastern Puerto Rico, was found in Miami, Florida, by Schwartz and Thomas (1975) in a location where minimum temperatures in winter can average 10°C cooler than in Puerto Rico, but where maximum temperatures in summer are much more similar. Taking advantage of this situation, Leal and Gunderson set about to determine whether the cold tolerance or critical thermal minimum temperature (CT_{min}) of the introduced populations had diverged from that of the source populations of *A. cristatellus* since their physical separation in 1975. As a check on their experimental procedures, they also conducted studies to see whether the critical thermal maximum temperature (CT_{max}) of the two groups of lizards remained about the same.

They found "the introduced population tolerates significantly colder temperatures (by ~3°C) than does the Puerto Rican source population," while the maximum temperatures tolerated "did not differ." These observations "demonstrate that changes in thermal tolerance occurred relatively rapidly (~35 generations), which strongly suggests that the thermal physiology of tropical lizards is more labile than previously proposed." They conclude, "regardless of

the mechanism, the adaptive lability of thermal tolerance in *A. cristatellus* over an ecological timescale" provides "a glimpse of hope for tropical lizards under the current conditions of rapid climate change."

Valdecantos *et al.* (2013) note "temperature has a great impact on ectotherms, affecting physiological, behavioral and life history traits such as reproductive timing (Zug *et al.*, 2001; Labra and Bozinovic, 2002), reproductive mode (Shine, 2004), growth rate, survivorship (Huey, 1982), locomotion (Hertz *et al.*, 1983; Angilleta *et al.*, 2002) and diet (Espinoza *et al.*, 2004)." They note late twentieth century global warming "has been suggested as a potential threat for lizards at a global scale," citing Sinervo *et al.* (2010).

The researchers studied four related species— *Liolaemus irregularis*, *L. albiceps*, *L. multicolor*, and *L. yanalcu*—that inhabit high-elevation desert areas in Northwestern Argentina, Northern Chile, and Southwestern Bolivia, working both in the laboratory and at four sites near San Antonio de los Cobres in Salta, Argentina, where they measured body temperatures (Tb), air temperatures (Ta), soil temperatures (Ts), operative temperatures in the field (Te), and preferred body temperatures (Tpref) for all four species.

The four Argentine researchers report their study revealed all four species, "despite living at high elevation and harsh climatic conditions," were able to "behaviorally or physiologically thermo-regulate to achieve body temperatures close to their preferred temperatures." They conclude, "as proposed by Labra *et al.* (2009)," "many species are conservative in some aspects (e.g. Tpref), yet labile in others (e.g. Tb)," thus "allowing them to inhabit a wide range of environments."

Moritz *et al.* (2012) note it is often assumed large central populations of a species have higher genetic diversity and, therefore, greater potential for adaptive response to environmental change. But they state "this is not always the case," and "lineages that have persisted as isolates in peripheral areas through past climate change might well have genotypes that will confer greater resistance to future warming and which could be exploited for genetic translocation," citing Chown *et al.* (2010).

Moritz *et al.* (2012) tested this hypothesis through comparative assays of minimum and maximum critical thermal limits (CT_{min} and CT_{max}), as well as optimal performance parameters, including CT_{opt}, across central and peripheral lineages of three species of ground-dwelling skinks (scincid lizards) endemic to the rainforests of northeast Australia:

Gnypetoscincus queenslandiae, Carlia rubrigularis, and *Saproscincus basiliscus.*

Results of the analysis indicate "peripheral lineages show significantly increased optimal performance temperatures (T_{opt}) relative to central populations, as well as elevated CT_{min}." Moritz *et al.* conclude the peripheral lineages they examined "appear to have evolved higher thermal optima relative to centrally located lineages," noting this finding "contrasts with the usual assumption that local adaptation of peripheral populations will be overwhelmed by gene flow from the center of the species range or, in the absence of immigration, will experience higher extinction rates." Thus the authors state, "long-isolated populations in peripheral rainforests harbor genotypes that confer resilience to future warming."

Sea turtles, like many other reptiles, have what is called "temperature-dependent sex determination" (TSD), which means the temperature experienced by each developing embryo (within its individual eggshell casing, laid within a nest built by the mother on a terrestrial beach) determines its sex (Janzen, 1994). In turtles, males require somewhat cooler embryonic conditions than females: a temperature of 29°C generates a sex ratio among hatchlings of about 50:50, whereas at higher temperatures, more females are produced (Hawkes *et al.*, 2009). (Strangely enough, in the tuatara, another TSD reptile, the opposite is true: more males are produced at higher temperatures.) As a result, strongly skewed offspring sex ratios are common in TSD reptiles.

The amount of global warming predicted for the next century by some climate scientists is considered a threat to TSD-species because it is feared the higher temperatures will generate such extreme sex ratio biases (e.g. 100% females) that extinction will be inevitable (e.g. Fuentes *et al.*, 2010; Janzen, 1994; Witt *et al.*, 2010). As a highly female-skewed hatchling sex ratio already occurs in marine turtles (Hawkes *et al.* 2009), "predicted increases in global temperatures are expected to exacerbate this trend," say Wright *et al.*, 2012.

Although living sea turtle species have survived substantial temperature fluctuations in the recent past (Janzen and Paukstis, 1988), Wright *et al.* (2012) investigated whether they will be able to adapt to future warming. Wright *et al.* examined the mating behavior of green sea turtles (*Chelonia mydas*) to see if it was compensating for the extreme female-skewed sex ratios of hatchlings currently produced in the Mediterranean (86–96% female). They undertook genetic typing of tissue samples taken in 2008 from 20 nesting females and 809 of their offspring (from 37 clutches of eggs), from a single rookery beach in northern Cyprus. Paternity analysis of the hatchlings allowed the researchers to determine how many males had mated with the females they sampled. They also put a satellite transmitter on a single male to map his movements during the breeding season.

Sea surface temperatures at the study site rose by, on average, less than 1°C over the past 50 years, and the female bias that exists today in adult green sea turtles is probably the result of a similar extent of female bias among hatchlings produced approximately 30 years ago (due to the late age at sexual maturity in this species)—that is, the authors assumed many more breeding-aged adult turtles in the population were female than were male.

They found, "despite an offspring sex ratio of 95 per cent females, there were at least 1.4 reproductive males to every breeding female"—28 males breeding with 20 females tested. The authors suggest males may breed more often than females (females breed every 2–4 years). In addition, the male they tracked visited a number of rookeries in the region, suggesting males may mate with females on a number of different beaches. Together, the authors suggest, these mating behaviors partially compensate for the lower abundance of males within the population, so "male mating patterns have the potential to buffer the disruptive effects of climate change on marine turtle populations, many of which are already seriously threatened." Furthermore, Wright *et al.* conclude, "current mating patterns will help to preserve genetic variation that may be critical if marine turtles are to adapt behaviorally or physiologically to a warming climate and have, no doubt, contributed to their persistence through historical climatic upheaval."

Citing Lavergne *et al.* (2010), Refsnider and Janzen (2012) also studied turtles, writing, "adaptation to climate change may be impossible even when high genetic variation is present if the rate of environmental change is too rapid and the population demography is insufficiently dynamic," adding, "species with temperature-dependent sex determination may be particularly threatened by climate change, because altered temperatures could skew sex ratios." Refsnider and Janzen experimentally tested nest-site choice in the long-lived turtle *Chrysemys picta*, to see whether nesting behavior "could compensate for potential skews in sex ratios caused by rapid climate change." They collected females from five populations spread across the species' range, housed them in a semi-natural common garden, and waited to see what would

happen.

The two researchers report "females from transplanted populations showed similar choice of shade cover over nests to local females," which suggests, in their words, "behavioral phenotypic plasticity in female choice of shade cover over the nest site may comprise an immediate mechanism by which long-lived reptiles with temperature-dependent sex determination can avoid skews in sex ratio potentially caused by rapid climate change."

5.10 Worms

- It appears earthworms and soil nematodes respond to increases in the air's CO_2 content, via a number of plant-mediated phenomena, in ways that further enhance the positive effects of atmospheric CO_2 enrichment on plant growth and development, while helping to sequester more carbon more securely in the soil and thereby reducing the potential for CO_2-induced global warming.

"Earthworms," writes Edwards (1988), "play a major role in improving and maintaining the fertility, structure, aeration and drainage of agricultural soils." As noted by Sharpley *et al.* (1988), for example, "by ingestion and digestion of plant residue and subsequent egestion of cast material, earthworms can redistribute nutrients in a soil and enhance enzyme activity, thereby increasing plant availability of both soil and plant residue nutrients," as others also have demonstrated (Bertsch *et al.*, 1988; McCabe *et al.*, 1988; Zachmann and Molina, 1988). Kemper (1988) describes how "burrows opened to the surface by surface-feeding worms provide drainage for water accumulating on the surface during intense rainfall," noting "the highly compacted soil surrounding the expanded burrows has low permeability to water which often allows water to flow through these holes for a meter or so before it is absorbed into the surrounding soil."

Hall and Dudas (1988) report the presence of earthworms appears to mitigate the deleterious effects of certain soil toxins. Logsdon and Lindon (1988) describe a number of other beneficial effects of earthworms, including enhancement of soil aeration, since under wet conditions earthworm channels do not swell shut as many soil cracks do; enhancement of soil water uptake, since roots can explore deeper soil layers by following earthworm channels; and enhancement of nutrient uptake, since earthworm casts and channel walls have a more neutral pH and higher available nutrient level than bulk soil.

In light of these observations, there is great interest about what may happen to earthworms as the air's CO_2 content and temperature rise.

With respect to how rising atmospheric CO_2 concentrations might impact earthworms, Edwards (1988) writes, "the most important factor in maintaining good earthworm populations in agricultural soils is that there be adequate availability of organic matter." Hendrix *et al.* (1988) and Kladivko (1988) report greater levels of plant productivity promote greater levels of earthworm activity. Consequently, since the most ubiquitous and powerful effect of atmospheric CO_2 enrichment is its stimulation of plant productivity (see Chapter 1, this volume), which leads to enhanced delivery of organic matter to soils, it logically follows this aerial fertilization effect of the ongoing rise in the air's CO_2 content should increase earthworm populations and amplify the many beneficial services they provide for plants.

Then there's the second most significant and common impact of atmospheric CO_2 enrichment on plants: its antitranspirant effect, whereby elevated levels of atmospheric CO_2 reduce leaf stomatal apertures and slow the rate of evaporative water loss from the vast bulk of Earth's vegetation. Growth chamber studies and field experiments that have studied this phenomenon provide voluminous evidence it often leads to increased soil water content in many terrestrial ecosystems (see Section 2.33, this volume), which is something earthworms favor.

Zaller and Arnone (1997) fumigated open-top and -bottom chambers they established in a calcareous grassland near Basal, Switzerland with air of either 350 or 600 ppm CO_2 for an entire growing season. They found the mean annual soil moisture content in the CO_2-enriched chambers was 10% greater than that observed in the ambient-air chambers. They note cumulative surface earthworm cast production after only one year was 35% greater in the CO_2-enriched chambers than in the control chambers. In addition, because earthworm casts are rich in organic carbon and nitrogen, the cumulative amount of these important nutrients on a per-land-area basis was found to be 28% greater in the CO_2-enriched chambers than in the ambient-air chambers. In a subsequent study of the same grassland, Zaller and Arnone (1999) report plants growing in close proximity to the earthworm casts produced more biomass than similar plants growing further away from them. They also found the CO_2-induced growth stimulation experienced by the various grasses was greater for those plants growing nearer the earthworm

casts.

These observations show atmospheric CO_2 enrichment sets in motion a self-enhancing cycle of positive biological phenomena whereby increases in the air's CO_2 content stimulate plant productivity and reduce plant evaporative water loss, which results in more organic matter entering the soil and a longer soil moisture retention time and/or greater soil water contents. All of this leads to the development of larger and more active earthworm populations, which enhance many important soil properties, including fertility, structure, aeration, and drainage. These improved properties further enhance the growth of the plants.

There are additional reasons for optimism regarding this process. As Jongmans *et al*. (2003) point out, "the rate of organic matter decomposition can be decreased in worm casts compared to bulk soil aggregates (Martin, 1991; Haynes and Fraser, 1998)." They conducted a micro-morphological investigation of structural development and organic matter distribution in two calcareous marine loam soils on which pear trees had been grown for 45 years. One of the soils exhibited little or no earthworm activity and the other exhibited high earthworm activity, due to different levels of heavy metal contamination of the soils as a consequence of the prior use of different amounts of fungicides. Based on their results and other studies they cite, they conclude, "earthworms play an important role in the intimate mixing of organic residues and fine mineral soil particles and the formation of organic matter-rich micro-aggregates and can, therefore, contribute to physical protection of organic matter, thereby slowing down organic matter turnover and increasing the soil's potential for carbon sequestration." That is, atmospheric CO_2 enrichment that stimulates the activity of earthworms also leads to more—and more secure—sequestration of carbon in Earth's soils, thereby reducing the potential for CO_2-induced global warming.

Cole *et al*. (2002) report, "in the peatlands of northern England, which are classified as blanket peat, it has been suggested that the potential effects of global warming on carbon and nutrient dynamics will be related to the activities of dominant soil fauna, and especially enchytraeid worms." Cole *et al*. say they hypothesized warming would lead to increased enchytraeid worm activity, which would lead to higher grazing pressure on microbes in the soil, and since enchytraeid grazing has been observed to enhance microbial activity (Cole *et al*., 2000), they further hypothesized more carbon would be liberated in dissolved organic form, "supporting the view that global warming will increase carbon loss from blanket peat ecosystems."

The scientists constructed small microcosms from soil and litter they collected near the summit of Great Dun Fell, Cumbria, England. Subsequent to "defaunating" this material by reducing its temperature to -80°C for 24 hours, they thawed and inoculated it with native soil microbes. Half of the microcosms were incubated in the dark at 12°C and half at 18°C, the former temperature being approximately equal to mean August soil temperature at a depth of 10 cm at the site of soil collection, and the latter being "close to model predictions for soil warming that might result from a doubling of CO_2 in blanket peat environments."

Ten seedlings of an indigenous grass of blanket peat were then transplanted into each of the microcosms, while 100 enchytraeid worms were added to each of half of the mini-ecosystems. These procedures resulted in the creation of four experimental treatments: ambient temperature, ambient temperature + enchytraeid worms, elevated temperature, and elevated temperature + enchytraeid worms. The resulting 48 microcosms—sufficient to destructively harvest three replicates of each treatment four times throughout the course of the 64-day experiment—were arranged in a fully randomized design and maintained at either 12 or 18°C with alternating 12-hour light and dark periods. In addition, throughout the course of the study the microcosms were given distilled water every two days to maintain their original weights.

Contrary to their hypothesis, the scientists found elevated temperature reduced the ability of the enchytraeid worms to enhance the loss of carbon from the microcosms. At the normal ambient temperature, for example, the presence of the worms enhanced dissolved organic carbon (DOC) loss by 16%, and at the elevated temperature expected for a doubling of the air's CO_2 content, the worms had no effect at all on DOC. In addition, Cole *et al*. note, "warming may cause drying at the soil surface, forcing enchytraeids to burrow to deeper subsurface horizons." Hence, since the worms are known to have little influence on soil carbon dynamics below a depth of 4 cm (Cole *et al*., 2000), the scientists conclude this additional consequence of warming would further reduce the ability of enchytraeids to enhance carbon loss from blanket peatlands.

Summarizing their findings, Cole *et al*. say, "the soil biotic response to warming in this study was negative." That is, it resulted in a reduced loss of carbon to the atmosphere, which would tend to slow

the rate of rise of the air's CO_2 content, as was suggested by the study of Jongmans *et al*.

Maraldo *et al*. (2010) also studied enchytraeids, recognizing their important contribution "to the decomposition processes and nutrient mineralization." Such activities have been shown to lead to increased nutrient availability and uptake by plants (Laakso and Setala, 1999; Cragg and Bardgett, 2001). Enchytraeids provide these benefits directly, as Maraldo *et al*. describe it, "by consuming large amounts of organic matter," and indirectly "by their feeding activity and modifications of soil structure." They note, "the presence of enchytraeids is especially important in nutrient poor ecosystems" such as "temperate heathland and northern coniferous forests, where their biomass dominates the soil faunal community," citing Cragg (1961) and Swift *et al*. (1998).

Working on a hilly, nutrient-poor, sandy soil with a dry heath/grassland cover at Brandbjerg, Denmark, Maraldo *et al*. conducted an experiment beginning October 2005 and extending through 2007. The seven scientists studied the individual and combined effects of soil warming, drought, and atmospheric CO_2 enrichment.

They warmed the soil so as to achieve a mean daily temperature increase of 0.3°C in winter and 0.7°C in summer at a depth of 5 cm, using a scaffolding that carried a curtain, which reflected the outgoing infrared radiation from the soil/plant surface back toward the ground, that was automatically pulled over the vegetation at sunset and retracted at sunrise. They achieved drought conditions by reducing peak soil water content by 11 percent and 13 percent compared to control plots in 2006 and 2007, using waterproof curtains that were automatically pulled over the vegetation during rain events. And they used a free-air CO_2 enrichment (FACE) system to increase the air's CO_2 concentration from 382 to 481 ppm.

Maraldo *et al*. report their experimentally imposed warming had no significant impact on enchytraeid biomass production, but their drought treatment decreased it by 40 percent. The extra 99 ppm of CO_2 stimulated enchytraeid biomass by 40 percent. At certain times this latter phenomenon was "especially positive," as in the summer of 2007, when "the total enchytraeid biomass in the CO_2 plots was increased by 108% compared to ambient plots." They found no interactions among the three factors, so "the positive effect of increased CO_2 [+40%] and the negative effect of drought [-40%] were cancelled out when applied in combination."

Bossuyt *et al*. (2005) note "earthworms ingest large quantities of organic materials that are mixed and excreted as casts (Parmelee *et al*., 1990; Martin and Marinissen, 1993; Jegou *et al*., 1998) and improve stable macroaggregation (Guggenberger *et al*., 1996; Marinissen and Hillenaar, 1996; Scullion and Malik, 2000)," as also has been found by van Rhee (1977), De Vleesschauwer and Lal (1981), and McKenzie and Dexter (1987). In addition, they remark, "the retention of organic C in soil is becoming more important since the rise in atmospheric CO_2 and global warming are recent concerns," and "earthworms are known to play a role in aggregate formation and soil organic matter (SOM) protection." However, they say, "it is still unclear at what scale and how quickly earthworms manage to protect SOM." They conducted a pair of experiments to address that question.

In the first experiment, Bossuyt *et al*. measured soil aggregate size distribution and total C and ^{13}C in three treatments—control soil, soil + ^{13}C-labeled sorghum leaf residue, and soil + ^{13}C-labeled residue + earthworms—after 20 days of incubation, where earthworms were added after the eighth day. In the second experiment, they determined the protected C and ^{13}C pools inside the newly formed casts and macro- and micro-soil-aggregates. They found the proportion of large water-stable macroaggregates was on average 3.6 times greater in the soil-residue samples that contained earthworms than in those that lacked earthworms, and the macroaggregates in the earthworm treatment contained approximately three times more sequestered carbon.

Bossuyt *et al*. state, "earthworms were found to form a significant pool of protected C in microaggregates within large macroaggregates after 12 days of incubation," thereby demonstrating the rapidity with which earthworms perform their vital function of sequestering carbon in soils when plant residues become available to them.

Don *et al*. (2008) studied the effects of anecic earthworms—which generally inhabit a single vertical burrow throughout their entire lives that can be as much as five meters in depth but is generally in the range of one to two meters—on soil carbon stocks and turnover at two extensively managed grassland sites in Thuringia, Germany. Analyzing enzyme activity, stable isotopes, nuclear magnetic resonance spectroscopy, and the ^{14}C age of the earthworm burrow linings, the seven German scientists found "the carbon distribution in soils is changed by anecic earthworms' activity with more carbon stored in the subsoil where earthworms slightly increase the carbon stocks." They also state "the translocation of carbon

from [the] organic layer to the subsoil will decrease the carbon vulnerability to mineralization," because "carbon in the organic layer and the surface soil is much more prone to disturbances with rapid carbon loss than subsoil carbon."

Don *et al.* note "earthworms are present in almost all ecosystems around the globe with particularly high abundances in grasslands, where they increase productivity (Partsch *et al.*, 2006)" and where "100–800 burrows per square meter have been reported by Lavelle (1988)." The presence and activity of earthworms play important roles in helping Earth's soils store and preserve carbon—and thereby mitigate the rate of rise of the atmosphere's CO_2 concentration.

Yeates *et al.* (2003) report a number of results they obtained from a season-long FACE study of a 30-year-old New Zealand pasture, where three experimental plots were maintained at the ambient atmospheric CO_2 concentration of 360 ppm and three others at a concentration of 475 ppm (a CO_2 enhancement of only 32%) for a period of four to five years. The pasture contained about 20 species of plants, including C_3 and C_4 grasses, legumes, and forbs, but the scientists' attention was focused more on what happened to the microfauna inhabiting the soil in which the plants grew.

Nematode populations increased significantly in response to the 32% increase in the air's CO_2 concentration. Of the various feeding groups studied, Yeates *et al.* report the relative increase "was lowest in bacterial-feeders (27%), slightly higher in plant (root) feeders (32%), while those with delicate stylets (or narrow lumens; plant-associated, fungal-feeding) increased more (52% and 57%, respectively)." The greatest nematode increases were recorded among omnivores (97%) and predators (105%). Most dramatic, root-feeding populations of the *Longidorus* nematode taxon rose by 330%. Also increasing in abundance were earthworms: *Aporrectodea caliginosa* by 25% and *Lumbricus rubellus* by 58%. Enchytraeids decreased in abundance, by approximately 30%.

Yeates *et al.* note the introduction of lumbricids has been demonstrated to improve soil conditions in New Zealand pastures (Stockdill, 1982), which helps pasture plants grow. Hence, the CO_2-induced increase in earthworm numbers observed in Yeates *et al.*'s study would be expected to do more of the same, and the reduced abundance of enchytraeids they documented in the CO_2-enriched pasture would lead to less carbon being released to the air from the soil, as per the known ability of enchytraeids to promote

carbon loss from British peat lands under current temperatures.

Larsen and Clarke (2002) fed diets with and without coenzyme Q to wild-type nematodes (*Caenorhabditis elegans*) and several mutants during the adult phases of their lives, recording the lengths of time they survived. They found "withdrawal of coenzyme Q (Q) from the diet of wild-type nematodes extends adult life-span by ~60%." They also report the lifespans of the four mutants they studied were extended by a Q-less diet. More detailed analyses of their results led them to conclude the lifespan extensions were due to reduced generation and increased scavenging of reactive oxygen species.

The results and conclusions of this study are similar to those of Melov *et al.* (2000), who also studied *C. elegans*, testing the theory reactive oxygen species cause aging by examining the effects of two superoxide dismutase-/catalase-like mimetics (EUK–8 and EUK–134) on the lifespans of normal and mutant *C. elegans* worms that ingested various amounts of the mimetics. In every experiment, treatment of normal worms with the antioxidant mimetics significantly increased both mean and maximum lifespan. Treatment of normal worms with but 0.05 mM EUK–134, for example, increased their mean lifespan by fully 54%; in mutant worms whose normal lifespan was genetically shortened by 37%, treatment with 0.5 mM EUK–134 restored their lifespan to normal by increasing their mutation-reduced lifespan by 67%. They also determined these effects were not caused by a reduction in worm metabolism, which could have reduced the production of oxygen radicals, but "by augmenting natural antioxidant defenses without having any overt effects on other traits."

Melov *et al.* say their results "suggest that endogenous oxidative stress is a major determinant of the rate of aging." The significance of this statement resides in the fact that antioxidants tend to reduce such stresses in animals, and in the observation atmospheric CO_2 enrichment has been shown to significantly enhance the concentrations of many of these plant constituents (see Antioxidants, Section 7.3.1) as well as the concentrations of several substances that have been proven effective in fighting cancers, viral infections, and other animal maladies (see Health Effects of CO_2, Section 7.3).

It appears earthworms and soil nematodes respond to increases in the air's CO_2 content, via a number of plant-mediated phenomena, in ways that further enhance the positive effects of atmospheric CO_2 enrichment on plant growth and development,

while helping to sequester more carbon more securely in the soil and thereby reducing the potential for CO_2-induced global warming.

Aquatic Life

Key Findings

Introduction

Key Findings

The key findings of this chapter, which challenge the alarming and negative projections of United Nations' Intergovernmental Panel on Climate Change (IPCC), are presented in the bullet points below.

- Multiple studies from multiple ocean regions confirm ocean productivity tends to increase with temperature. Subjects of this research include phytoplankton and macroalgae, corals, crustaceans, and fish.

- Rising seawater temperature is conducive to enhanced coral calcification, leading some experts

to forecast coral calcification will increase by about 35% beyond pre-industrial levels by 2100, and no extinction of coral reefs will occur in the future.

- Many aquatic species demonstrate the capability to adjust their individual critical thermal maximum (the upper temperature at which the onset of behavioral incapacitation occurs) upwards in response to temperature increases of the amount forecast by IPCC.

- Aquatic life has survived decadal, centennial, and millennial-scale climate oscillations that have

persisted for millions of years. Evidence indicates they are well-equipped to adapt to forecasted increases in temperature, if necessary.

- Caution should be applied when interpreting results from laboratory-based studies of lower seawater pH levels. Such studies often are incapable, or fall far short, of mimicking conditions in the real world, and thus they frequently yield results quite different than what is observed in nature.

- Rising atmospheric CO_2 levels do not pose a significant threat to aquatic life. Many aquatic species have shown considerable tolerance to declining pH values predicted for the next few centuries, and many have demonstrated a likelihood of positive responses in empirical studies.

- The projected decline in ocean pH levels in the year 2100 (as compared to preindustrial times) may be significantly overstated, amounting to only half of the 0.4 value IPCC predicts.

- The natural variability of oceanic pH is often much greater than the change in pH levels forecast by IPCC.

- Natural fluctuations in pH may have a large impact on the development of resilience in marine populations, as heterogeneity in the environment with regard to pH and pCO_2 exposure may result in populations that are acclimatized to variable pH or extremes in pH.

- For those aquatic species showing negative responses to pH declines in experimental studies, there are adequate reasons to conclude such responses will be largely mitigated through phenotypic adaptation or evolution during the many decades to centuries the pH concentration is projected to fall.

Introduction

Some observers have suggested rising atmospheric carbon dioxide (CO_2) concentrations may harm aquatic life via global warming, in which the temperatures of the world's water bodies rise, and through the absorption of additional CO_2 from the air into water, thereby lowering the pH of the waters to which aquatic life is accustomed. IPCC projects

marine and freshwater species will be negatively affected by these processes and will experience future declines, in some instances so severe as to cause species extinctions.

In contrast, the material presented in this chapter, representing the findings of hundreds of peer-reviewed research analyses, suggests a much better future is in store for Earth's aquatic life. Many laboratory and field studies have demonstrated growth and developmental improvements in response to higher temperatures and reduced water pH levels. Other research has illustrated the capability of marine and freshwater species to tolerate and adapt to rising temperature and pH decline of the planet's water bodies. When such observations are considered, the pessimistic projections of IPCC give way to considerable optimism with respect to the future of the planet's marine life.

This chapter begins by summarizing research on the impact of rising ocean temperatures on phytoplankton and macroalgae, corals, crustaceans, fish, and other marine species. Researchers have found repeatedly that many species benefit rather than suffer from rising temperatures, including temperature increases forecast by IPCC. Section 6.2 examines research on the effects of warmer temperatures on freshwater species. Much less research has been conducted in this area, but it too highlights beneficial effects of warming on phytoplankton, several species of fish, and freshwater mussels.

Section 6.3 addresses the threat of so-called "ocean acidification." The phrase is an improper choice because natural seawater is basic (alkaline), with an average pH level typically around 8.1, and the oceans will never become acidic (below 7.0) due to IPCC's worst-case scenarios of future anthropogenic CO_2 emissions. The prospect of oceans and lakes becoming "acidic" is frightening to the general public, and rightly so. While many scientists conducting research in this area use the term, perhaps to attract public attention to their work, more accurate and less judgmental phrases are "lower oceanic pH," "lower seawater pH levels," and "ocean pH reduction." The research summarized in this section makes it clear that rising atmospheric CO_2 levels do not pose as significant a threat to aquatic life as claimed by IPCC. Many aquatic species have shown considerable tolerance to declining pH values predicted for the next few centuries, and many have demonstrated a likelihood of positive responses in empirical studies.

Section 6.4 summarizes research on freshwater

"acidification." The number of studies examining this topic is dramatically smaller than the number concerning oceans, but those highlighted here reveal findings typically more positive than negative.

Section 6.5 investigates research on the combined effects of rising temperatures and falling pH levels on marine plants and animals. Research in this area is not as plentiful, but what exists is generally reassuring: Many studies show the combination of higher temperatures and falling pH levels to be beneficial, not harmful, to marine life.

6.1 Ocean Warming

According to IPCC, global warming will warm the planet's oceans, resulting in catastrophic effects on marine plants and animals. In a draft of the Summary for Policymakers of its contribution to IPCC's Fifth Assessment Report, Working Group II claims "Open-ocean net primary production is projected to redistribute and to fall globally by 2100 under RCP8.5. Climate change adds to threats of over-fishing and other non-climatic stressors, thus complicating marine management regimes (*high confidence*)" (IPCC 2014-II, p. 9). More warnings along these lines appear in Working Group II's draft full report, as shown by excerpts presented at the beginning of Section 6.1.2 below.

IPCC's frequent description of the modern rise in global temperature as "unprecedented" suggests there already should be signs of negative impacts on oceanic productivity and marine life, but a review of the scholarly literature on this subject reveals just the opposite: Productivity is rising and species are flourishing, except in cases where human activities such as over-fishing, pollution, generation of silt, and other damaging practices are to blame. The studies highlighted in this section yield little evidence to support IPCC's point of view.

6.1.1 Phytoplankton and Macroalgae

This section examines research on the impacts of ocean warming on marine phytoplankton and macroalgae. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings.

- Multiple studies from multiple ocean regions confirm ocean productivity tends to increase with temperature.

- Several observation-based analyses reveal phytoplankton productivity has increased over the past several decades in response to the instrumental-era rise in temperature.

- Evidence suggests marine plants are well-equipped to adapt and evolve to forecasted increases in future temperature, as they have done so in responding to decadal, centennial, and millennial-scale climate oscillations that have persisted for millions of years.

Sarmiento *et al*. (2004) conducted a massive computational study employing six coupled climate model simulations to determine the biological response of the global ocean to climate warming they simulated from the beginning of the Industrial Revolution to the year 2050. Based on vertical velocity, maximum winter mixed-layer depth, and sea-ice cover, they defined six biomes and calculated how their surface geographies would change in response to their calculated changes in global climate. Next, they used satellite ocean color and climato-logical observations to develop an empirical model for predicting surface chlorophyll concentrations from the final physical properties of the world's oceans as derived from their global warming simulations. They then used three primary production algorithms to estimate the response of oceanic primary production to climate warming based on their calculated chloro-phyll concentrations. The 13 scientists from Australia, France, Germany, Russia, the United Kingdom, and the United States arrived at a global warming-induced increase in global ocean primary production ranging from 0.7 to 8.1%.

In addition to Sarmiento *et al*.'s model-based study, a number of real-world observations also suggest IPCC's concerns about future declines in ocean productivity in response to rising temperatures are unfounded. Goes *et al*. (2005) analyzed seven years (1997–2004) of satellite-derived ocean surface phytoplankton productivity data, as well as associated sea surface temperatures (SSTs) and winds in the Arabian Sea. They report for the region located between 52 to 57°E and 5 to 10°N, "the most conspicuous observation was the consistent year-by-year increase in phytoplankton biomass over the 7-year period." This change was so significant that by the summer of 2003, they write, "chlorophyll *a* concentrations were >350% higher than those observed in the summer of 1997." They also report the increase in chlorophyll *a* was "accompanied by an intensification of sea surface winds, in particular of

the zonal (east-to-west) component," noting these "summer monsoon winds are a coupled atmosphere-land-ocean phenomenon, whose strength is significantly correlated with tropical SSTs and Eurasian snow cover anomalies on a year-to-year basis." They write, "reduced snow cover over Eurasia strengthens the spring and summer land-sea thermal contrast and is considered to be responsible for the stronger southwest monsoon winds." They note "the influence of southwest monsoon winds on phytoplankton in the Arabian Sea is not through their impact on coastal upwelling alone but also via the ability of zonal winds to laterally advect newly upwelled nutrient-rich waters to regions away from the upwelling zone." They conclude, "escalation in the intensity of summer monsoon winds, accompanied by enhanced upwelling and an increase of more than 350% in average summertime phytoplankton biomass along the coast and over 300% offshore, raises the possibility that the current warming trend of the Eurasian landmass is making the Arabian Sea more productive."

Drinkwater (2006) examined marine ecosystems of the North Atlantic, determining "in the 1920s and 1930s, there was a dramatic warming of the air and ocean temperatures in the northern North Atlantic and the high Arctic, with the largest changes occurring north of 60°N." This warming "led to reduced ice cover in the Arctic and subarctic regions and higher sea temperatures," as well as northward shifts of multiple marine ecosystems. This early twentieth century warming "contributed to higher primary and secondary production," Drinkwater writes, and "with the reduced extent of ice-covered waters, more open water allow[ed] for higher production than in the colder periods."

McGregor *et al.* (2007) state, "coastal upwelling occurs along the eastern margins of major ocean basins and develops when predominantly along-shore winds force offshore Ekman transport of surface waters, which leads to the ascending (or upwelling) of cooler, nutrient-rich water." They note these regions of coastal upwelling account for about 20% of the global fish catch while constituting less than 1% of the area covered by the world's oceans. To better understand this productivity-enhancing phenomenon of great practical and economic significance, they studied its long-term history along the northwest coast of Africa—in the heart of the Cape Ghir upwelling system off the coast of Morocco—by analyzing two sediment cores having decadal-or-better resolution that extend from the late Holocene to the end of the twentieth century—from 520 BC to AD 1998.

The four researchers found an anomalous cooling of sea surface temperatures during the twentieth century, which they say "is consistent with increased upwelling." They note, the "upwelling-driven sea surface temperatures also vary out of phase with millennial-scale changes in Northern Hemisphere temperature anomalies and show relatively warm conditions during the Little Ice Age and relatively cool conditions during the Medieval Warm Period."

McGregor *et al.* offer an explanation for how this happens, posing a scenario that starts with an impetus for warming that leads to near-surface air temperatures over land becoming warmer than those over the ocean. The greater warming over the land "deepens the thermal low-pressure cell over land while a higher-pressure center develops over the slower-warming ocean waters." As this occurs, "winds blow clockwise around the high and anticlockwise around the continental low." With the coast representing the boundary between the two centers, the resulting wind is "oriented alongshore and southward (equator-ward), which thus drives the upwelling and negative sea surface temperature anomalies."

McGregor *et al.* say similar anti-phased thermal behavior—the cooling of coastal waters that leads to enhanced coastal upwelling during periods of hemispheric or global warming—has been observed in the Arabian Sea and along the Iberian margin, as well as in parts of the California Current and the Peru-Chile Current. This suggests as global warming enhances the upwelling of cooler nutrient-rich waters along the eastern margins of major ocean basins, it helps to significantly enhance global-ocean primary productivity, which leads to an increase in global-ocean secondary productivity, as represented by the global fish catch.

Boyd *et al.* (2007) reported somewhat analogous findings in their review of iron enrichment experiments conducted between 1993 and 2005. These experiments conclusively demonstrate, they write, "phytoplankton grow faster in warmer open-ocean waters, as predicted by algal physiological relationships." These findings indicate total ocean productivity should have benefited immensely from twentieth century global warming and likely will continue to benefit from continued global warming.

Marasovic *et al.* (2005) analyzed monthly observations of basic hydrographic, chemical, and biological parameters, including primary production, made since the 1960s at two oceanographic stations, one near the coast of Croatia (Kastela Bay) and one in the middle Adriatic Sea. They found mean annual

primary production in Kastela Bay averaged about 430 mg C m^{-2} d^{-1} over the period 1962–1972, exceeded 600 mg C m^{-2} d^{-1} in 1972–1982, and rose to more than 700 mg C m^{-2} d^{-1} in 1982–1996, accompanied by a similar upward trend in percent oxygen saturation of the surface water. The initial value of primary production in the open sea was much less (approximately 150 mg C m^{-2} d^{-1}), but it began to follow the upward trend of the Kastela Bay data after about one decade. Marasovic *et al.* conclude, "even though all the relevant data indicate that the changes in Kastela Bay are closely related to an increase of anthropogenic nutrient loading, similar changes in the open sea suggest that primary production in the Bay might, at least partly, be due to global climatic changes," which are "occurring in the Mediterranean and Adriatic Sea open waters" and may be directly related to "global warming of air and ocean" because "higher temperature positively affects photosynthetic processes."

Raitsos *et al.* (2005) investigated the relationship between Sea-viewing Wide Field-of-view Sensor (SeaWiFS) chlorophyll *a* measurements in the Central Northeast Atlantic and North Sea (1997–2002) and simultaneous measurements of the Phytoplankton Color Index (PCI) collected by the Continuous Plankton Recorder survey, an upper-layer plankton monitoring program that has operated in the North Sea and North Atlantic Ocean since 1931. By developing a relationship between the two databases over their five years of overlap, the scientists were able to produce a Chl-*a* history for the Central Northeast Atlantic and North Sea for the period 1948–2002. Of this record they say "an increasing trend is apparent in mean Chl-*a* for the area of study over the period 1948–2002." They report "there is clear evidence for a stepwise increase after the mid–1980s, with a minimum of 1.3mg m^{-3} in 1950 and a peak annual mean of 2.1 mg m^{-3} in 1989 (62% increase)." Alternatively, the data may represent a steadier long-term upward trend upon which is superimposed a decadal-scale oscillation. In a final comment on their findings, they note, "changes through time in the PCI are significantly correlated with both sea surface temperature and Northern Hemisphere temperature," citing Beaugrand and Reid (2003).

Antoine *et al.* (2005) applied revised data-processing algorithms to two ocean-sensing satellites, the Coastal Zone Color Scanner (CZCS) and SeaWiFS, over the periods 1979–1986 and 1998–2002, respectively, to provide an analysis of the decadal changes in global oceanic phytoplankton biomass. The results showed "an overall increase of the world ocean average chlorophyll concentration by about 22%" over the two decades under study.

Hirawake *et al.* (2005) analyzed chlorophyll *a* data obtained from Japanese Antarctic Research Expedition cruises made on the Southern Ocean by the Fuji and Shirase icebreakers between Tokyo and Antarctica from 15 November to 28 December of nearly every year between 1965 and 2002 in a study of interannual variations of phytoplankton biomass, calculating results for the equatorial region between 10°N and 10°S, the Subtropical Front (STF) region between 35°S and 45°S, and the Polar Front (PF) region between 45°S and 55°S. They found an increase in chl *a* "in the waters around the STF and the PF, especially after 1980 around the PF in particular," and "in the period between 1994 and 1998, the chl *a* in the three regions exhibited rapid gain simultaneously." They also found "significant correlations between chl *a* and year through all of the period of observation around the STF and PF, and the rates of increase are 0.005 and 0.012 mg chl *a* m^{-3} y^{-1}, respectively." They report the satellite data of Gregg and Conkright (2002) "almost coincide with our results." The Japanese scientists note, "simply considering the significant increase in the chl *a* in the Southern Ocean, a rise in the primary production as a result of the phytoplankton increase in this area is also expected."

Sepulveda *et al.* (2005) presented "the first reconstruction of changes in surface primary production during the last century from the Puyuhuapi fjord in southern Chile, using a variety of parameters (diatoms, biogenic silica, total organic carbon, chlorins, and proteins) as productivity proxies." Noting the fjord is located in "a still-pristine area," they state it is "suitable to study changes in past export production originating from changes in both the paleo-Patagonian ice caps and the globally important Southern Ocean."

They found the productivity of the Puyuhuapi fjord "was characterized by a constant increase from the late 19th century to the early 1980s, then decreased until the late 1990s, and then rose again to present-day values." For the first of these periods (1890–1980), they report "all proxies were highly correlated (r > 0.8, p < 0.05)" and "all proxies reveal an increase in accumulation rates." From 1980 to the present, the pattern differed among the various proxies. The researchers state, "considering that the top 5 cm of the sediment column (~10 years) are diagenetically active, and that bioturbation by benthic organisms may have modified and mixed the sedi-

mentary signal, paleo-interpretation of the period 1980–2001 must be taken with caution." Their work provides substantial solid evidence that, for the first 90 years of the 111-year record, surface primary production in the Puyuhuapi fjord rose dramatically, and with lesser confidence it appears to have leveled out over the past two decades.

While IPCC worries recent "unprecedented" increases in mean global air temperature and CO_2 concentration have been bad for the biosphere, Sepulveda *et al*. present yet another case of an ecosystem apparently thriving in such conditions. Nevertheless, claims of impending ocean productivity declines have not ceased, and the study of Behrenfeld *et al*. (2006) is often cited as support of such claims. Working with NASA's Sea-viewing Wide Field-of-view Sensor (SeaWiFS), the team of 10 U.S. scientists calculated monthly changes in net primary production (NPP) from similar changes in upper-ocean chlorophyll concentrations detected from space over the past decade. They report this period was dominated by an initial NPP increase of 1,930 teragrams of carbon per year (Tg C yr^{-1}), which they attributed to the significant cooling of "the 1997 to 1999 El Niño to La Niña transition," and they note this increase was "followed by a prolonged decrease averaging 190 Tg C yr^{-1}," which they attributed to subsequent warming.

The researchers' explanation for the means by which changing temperatures drove the two trends in NPP is based on their presumption a warming climate increases the density contrast between warmer surface waters and cooler underlying nutrient-rich waters. The enhanced stratification that occurs with warming, they say, "suppresses nutrient exchange through vertical mixing," which decreases NPP by reducing the supply of nutrients to the surface waters where photosynthesizing phytoplankton predominantly live. The scientists suggest "surface cooling favors elevated vertical exchange," by contrast, which increases NPP by enhancing the supply of nutrients to the ocean's surface waters, which have a greater concentration of phytoplankton than the underlying waters do because of light requirements for photosynthesis.

Real-world observations raise questions about that explanation. From approximately the middle of 2001 to the end of the data series in early 2006 (which accounts for more than half the data record), there has been, if anything, a slight increase in global NPP. Does this observation mean there has been little or no net global warming since mid-2001? Or does it mean the global ocean's mean surface temperature declined over that five-year period? Neither alternative accords

with the model-based projections of CO_2-induced climate warming.

The relationship between global warming and oceanic productivity may not be nearly as strong as what Behrenfeld *et al*. suggest. They leave themselves significant wiggle room in this regard, stating, "modeling studies suggest that shifts in ecosystem structure from climate variations may be as [important as] or more important than the alterations in bulk integrated properties reported here," noting some "susceptible ecosystem characteristics" that might shift include "taxonomic composition, physiological status, and light absorption by colored dissolved organic material." Given enough time, then, the phenomena Behrenfeld *et al*. describe could result in important "shifts in ecosystem structure" that could compensate, or even overcompensate, for what might initially appear to be negative warming-induced consequences.

Another reason for not concluding too much from the Behrenfeld *et al*. oceanic NPP dataset is that it may be of too short a duration to reveal what might be occurring on a longer timescale throughout the world's oceans, or its position in time may prevent the detection of greater short-term changes of the opposite sign that may have occurred a few years earlier or might occur in the near future. The central regions of the world's major oceans were long thought to be essentially vast biological deserts (Ryther, 1969), but several studies of primary photosynthetic production conducted in those regions in the 1980s (Shulenberger and Reid, 1981; Jenkins, 1982; Jenkins and Goldman, 1985; Reid and Shulenberger, 1986; Marra and Heinemann, 1987; Laws *et al*., 1987; Venrick *et al*., 1987; Packard *et al*., 1988) yielded results that suggest marine productivity at that time was at least twice as great as it likely was for a long time before 1969, causing many scientists of that day to speculate "the ocean's deserts are blooming" (Kerr, 1986).

Of even greater interest, perhaps, the 1970–1988 dataset of Jones *et al*. (1999) indicates Earth underwent a linear-regression-derived global warming of 0.333°C; the database of the Global Historical Climatology Network indicates the planet experienced a similarly calculated global warming of 0.397°C. The mean of these two values (0.365°C) is nearly twice as great as the warming that occurred over the post-1999 period studied by Behrenfeld *et al*., yet this earlier much larger warming—which Behrenfeld *et al*.'s work suggests should have produced a major decline in ocean productivity—was accompanied by a huge increase in ocean produc-

tivity. It would appear Behrenfeld *et al*. got the cause-and-effect relationship between global warming and ocean productivity exactly backwards.

Since publication of the Behrenfeld *et al*. study, other researchers have found no cause for alarm with respect to ocean productivity and rising global temperatures. Arrigo *et al*. (2008) write, "between the late 1970s and the early part of the 21st century, the extent of Arctic Ocean sea ice cover has declined during all months of the year, with the largest declines reported in the boreal summer months, particularly in September (8.6 ± 2.9% per decade)," citing Serreze *et al*. (2007). To "quantify the change in marine primary productivity in Arctic waters resulting from recent losses of sea ice cover," the authors "implemented a primary productivity algorithm that accounts for variability in sea ice extent, sea surface temperature, sea level winds, downwelling spectral irradiance, and surface chlorophyll *a* concentrations," and "was parameterized and validated specifically for use in the Arctic (Pabi *et al*., 2008) and utilizes forcing variables derived either from satellite data or NCEP reanalysis fields."

Arrigo *et al*. determined "annual primary production in the Arctic increased yearly by an average of 27.5 Tg C per year since 2003 and by 35 Tg C per year between 2006 and 2007." Thirty percent of the increase was attributable to decreased minimum summer ice extent, and 70% was due to a longer phytoplankton growing season. Arrigo *et al*. conclude if the trends they discovered continue, "additional loss of ice during Arctic spring could boost productivity >3-fold above 1998–2002 levels." If the 26% increase in annual net CO_2 fixation in the Arctic Ocean between 2003 and 2007 continues, they state, "this would represent a weak negative feedback on climate change."

Smith and Comiso (2008) employed phytoplankton pigment assessments, surface temperature estimates, modeled irradiance, and observed sea ice concentrations—all derived from satellite data—and incorporated them into a vertically integrated production model to estimate primary productivity trends according to the technique of Behrenfeld *et al*. (2002). The two authors state "the resultant assessment of Southern Ocean productivity is the most exhaustive ever compiled and provides an improvement in the quantitative role of carbon fixation in Antarctic waters."

Over the nine years (1997–2006) analyzed in the study, "productivity in the entire Southern Ocean showed a substantial and significant increase," and this increase can be calculated from the graphical representation of their results as ~17% per decade. The two researchers note "the highly significant increase in the productivity of the entire Southern Ocean over the past decade implies that long-term changes in Antarctic food webs and biogeochemical cycles are presently occurring," and these changes are positive.

Peck *et al*. (2010) note the loss of glaciers and ice shelves at the Antarctic Peninsula is often thought of as something that "will predominantly increase warming of the Earth because of changes in albedo and heat uptake by newly uncovered ground and ocean." They state an important opposing effect of this phenomenon "is the opening up of new areas for biological productivity."

Working with the database of Cook *et al*. (2005), which contains a detailed centennial history of changes in all coastal ice fronts associated with the Antarctic Peninsula compiled from historical accounts, aerial photographs, and satellite imagery, Peck *et al*. developed a time series of changes in the surface ice/water boundary surrounding the Antarctic Peninsula since the early twentieth century. Complementing this information with a 10-year time series of chlorophyll depth profiles (1997–2007) from a near-shore site in northern Marguerite Bay developed by Clarke *et al*. (2008), Peck *et al*. reconstructed the magnitude of new oceanic production that developed around the Antarctic Peninsula as sea ice progressively gave way to open water.

The five researchers with the British Antarctic Survey report as the ice cover along the Antarctic Peninsula has retreated over the past 50 years, "more than 0.5 Mtonnes of carbon has been incorporated into biological standing stock that was not there previously, 3.5 Mtonnes is fixed by phytoplankton blooms and 0.7 Mtonnes deposited to the seabed." They state if only 15% of the remaining ice-covered areas act in the same way, "over 50 Mtonnes of new carbon would be fixed annually and around 10 Mtonnes of this deposited to the seabed in coastal or adjacent areas," and "over 9 Mtonnes of carbon would be locked up in biological communities in the water column or on the sea bed." They suggest over a period of tens, hundreds, or thousands of years, "this process may act as a climate control mechanism."

Brown *et al*. (2011) investigated the widespread assumption the Bering Sea is "rapidly warming and losing sea ice" by employing "satellite-derived sea ice concentration, sea surface temperature, and ocean color data as input to a primary productivity algorithm to take stock of environmental change and

primary production" in this region. As the three U.S. researchers report, "rather than declining," they found mean annual sea ice extent in the Bering Sea "has exhibited no significant change over the satellite sea ice record (1979–2009)," because significant warming during the satellite sea surface temperature record (1982–2009) "is mainly limited to the summer months." In addition, and despite certain hotspots of primary production and a strong pulse in the spring, they also determined "the rate of annual area-normalized primary production in the Bering Sea (124 g C per m^2 per year) is below the global mean (140 g C per m^2 per year)." By "comparing warm, low-ice years (2001–2005) with cold, high-ice years (1998–2000 and 2006–2007)," they conclude "Bering Sea primary productivity is likely to rise under conditions of future warming and sea ice loss." That rise could be substantial, as they report, "basin-wide annual primary production ranged from 233 to 331 Tg C per year under the influence of highly variable sea ice and temperature conditions."

Chavez *et al*. (2011) reviewed the concepts and methods used to estimate ocean primary production (PP), after which they used the modern global instrumental record of sea surface temperature (SST) to analyze the principal modes of interannual to multidecadal climate and ocean variability. They then compared spatiotemporal patterns derived from *in situ* and satellite time-series of PP with the known time-series of climate and ocean variability, to identify the processes responsible for the observed patterns in PP. They introduced paleoclimate studies into their work to broaden the temporal context and "lead into speculation regarding century-scale variability."

Based on the first part of their analysis, the three researchers from the Monterey Bay Aquarium Research Institute of Moss Landing, California (USA) write, "general conclusions from the satellite and *in situ* time-series presented here are that PP is increasing globally," and they note global marine PP appears to have risen over the past several decades in association with multidecadal variations in climate. They report data from Continuous Plankton Recorder surveys conducted in the north Atlantic depict "increases in chlorophyll from the 1950s to the present," citing McQuatters-Gollop *et al*. (2007).

In the second part of their analysis, Chavez *et al*. report ocean sediment cores containing an "undisturbed history of the past" have been analyzed for variations in PP over timescales that include the Little Ice Age (LIA, ~1400–1800; Gutierrez *et al*., 2009). Based on reconstructed flux rates of total organic carbon (Sifeddine *et al*., 2008); diatoms, silica, and

fish scales; bones; and vertebrae, they determined during the LIA the ocean off Peru had "low PP, diatoms and fish," but "at the end of the LIA, this condition changed abruptly to the low subsurface oxygen, eutrophic upwelling ecosystem that today produces more fish than any region of the world's oceans (Chavez *et al*., 2008)." The researchers conclude, "in coastal environments, PP, diatoms and fish and their associated predators are predicted to decrease and the microbial food web to increase under global warming scenarios," citing Ito *et al*. (2010). However, they write, "present-day trends and the sedimentary record seem to indicate that the opposite might occur."

Tremblay *et al*. (2011) note the Canadian Beaufort Shelf and adjacent bays make up a small part of the Arctic Ocean but are of "prime social, economical and cultural importance" for coastal communities because they are "hotspots of marine productivity and staging" and "feeding areas for large aggregations of resident and migrant marine birds and mammals," citing Carmack and MacDonald (2002). Wondering what would happen to the productivity of this important coastal region if it were to warm further, Tremblay *et al*. set out to compare time series of ice cover, wind forcing, and satellite-based assessments of photosynthetic carbon production for the years 2002–2008 with corresponding *in situ* measurements of salinity, nutrients, new production, biological stocks, and biogenic fluxes obtained during overwintering surveys in 2003–2004 and 2007–2008.

In 2007–2008, the 15 researchers report, in areas where ice was no longer present due to enhanced seasonal warming, there was significant wind-induced upwelling of growth-promoting nitrates, which were brought up from deep and dark waters into the euphotic zone, where photosynthesis occurs. As a result of this fertilization effect, the herbivorous copepod *Calanus glacialis*—which they say is "the key link between diatom production and apex consumers on Arctic shelves," citing Soreide *et al*. (2010)—experienced a total abundance "3 to 33 times higher than in 2003 during mid-fall and 1.6 to 13 fold higher than in 2004 during early summer."

On the region's central shelf, they observed "sedimentary chlorophyll *a* was over 20-fold higher than at any station not influenced by upwelling," and "benthic carbon demand was among the highest ever observed in the Arctic ocean," citing Clough *et al*. (2005). The end result of these related phenomena was the "repeated instances of ice ablation and upwelling during fall 2007 and summer 2008 multiplied the production of ice algae, phytoplankton,

zooplankton and benthos by 2 to 6 fold."

Tremblay *et al*. conclude the phenomena they observed are "likely to prevail with the increasingly deep and frequent seaward retreat of the central ice pack and the greater incidence of upwelling-favorable winds," as described in detail by Yang (2009), and "new production is also bound to rise as winds gain in intensity and upwelling draws deeper into the nutrient-rich, upper Pacific halocline."

McMinn and Martin (2013) note "most algae regularly experience periods of darkness ranging from a few hours to a few days," during which time "they are unable to photosynthesize, and so must consume stored energy products." The scientists note "some organisms such as polar algae and some microalgal cysts and spores are exposed to darkness for months to years, and these must use alternative strategies to survive." McMinn and Martin—who work at the University of Tasmania's Institute for Marine and Antarctic Studies—reviewed the scientific literature on this subject and found "some taxa, such as dinoflagellates, form cysts and become dormant," while "others use physiological methods or adopt mixotrophy," and "the longest documented survival of more than a century was for dinoflagellates buried in sediments in a Norwegian fjord." In the future, they opine, polar microalgae will have to survive "the same period of seasonal darkness but at higher temperatures, and this will require a greater drawdown of stored energy." McMinn and Martin report "recent experimental work has shown that both Arctic [Martin *et al*., 2012] and Antarctic [Reeves *et al*., 2011] phytoplankton are able to survive increases of up to 6°C in the dark." Because such a temperature increase is "unlikely to be experienced in a few centuries as a result of climate change," polar microalgae should be safe for a long, long time to come.

According to Aberle *et al*. (2012), in places such as the Baltic Sea a "temporal match of zooplankton peaks with the spring phytoplankton bloom is required to provide an efficient energy transfer up the food web at the start of the growing season," but some scientists have predicted "warming will affect the different trophic levels unequally" and result in a counterproductive "temporal mismatch between predators and their prey." Aberle *et al*. conducted a set of indoor mesocosm experiments "to analyze time-lags between phytoplankton and micro-zooplankton during the spring succession of Baltic Sea plankton in relation to changing temperature [0 and 6°C above the decadal mean] and light conditions," along with "model simulations using a modified Rosenzweig and MacArthur (1963) predator-prey model incorporating temperature-dependent growth, grazing and mortality rates of autotrophic and heterotrophic components."

The five German scientists say "during the experiments, we observed reduced time-lags between the peaks of phytoplankton and protozoan biomass in response to warming," adding "warming induced a shift in micro-zooplankton phenology leading to a faster species turnover." The models they employed also "predicted reduced time-lags between the biomass peaks of phytoplankton and its predators (both micro-zooplankton and copepods) with warming." Aberle *et al*. conclude their study shows "instead of a mismatch, warming might lead to a stronger match between protist grazers and their prey."

Renaudie *et al*. (2010) conducted a quantitative micropalaeontological analysis of siliceous phytoplankton remains found in a sediment core extracted from the seabed at an ocean depth of 2,549 meters at ODP Site 1260 (~9.2°N, 54.65°W) on the Demerara Rise, a continental shelf located off the coast of Surinam, focusing on a 200,000-year period of warmth during the Eocene between approximately 40.0 and 40.2 million years ago. The five French scientists found "the pre-warming flora, dominated by cosmopolitan species of the diatom genus *Triceratium*, was replaced during the warming interval by a new and more diverse assemblage, dominated by *Paralia sulcata* (an indicator of high productivity) and two endemic tropical species of the genus *Hemiaulus*." They found "the critical warming interval was characterized by a steady increase in tropical species of the genus *Hemiaulus*." They also state, "the microflora preserved above the critical interval was once again of low diversity and dominated by various species of the diatom genus *Hemiaulus*." Renaudie *et al*.'s findings establish warmer is better, a maxim exemplified in the current case by the greater productivity of the tropical ocean during the warmer period and the ocean's continuous upward trend in the diversity of phytoplanktonic species throughout the period of warming.

Cermeño (2011) states "micro-organisms dominate terrestrial, aquatic and aerial ecosystems and largely rule our planet's life by playing pivotal roles in global biogeochemical cycles," citing Staley and Fuhrman (2002) and Falkowski *et al*. (2008). He declares these facts indicate "life on Earth is microbe dependent." Cermeño used records of climatic variability and microfossil data from the world's oceans covering the past 65 million years to "explore the

linkage between the rate of climate change and the probability of extinction, origination and net diversification of marine planktonic diatoms and calcareous nannoplankton," analyzing the evolutionary dynamics of the two phytoplankton groups throughout the 65-million-year period of study and comparing the results with the climate change record.

Cermeño states his findings demonstrate "the probability of extinction of microbial plankton species did not increase during periods of enhanced climatic instability over the past 65 million years." He says his results show "exceptional climatic contingencies, such as those occurring across the Late Palaeocene-Eocene and the Eocene-Oligocene boundary transitions, caused substantial morphological diversification." Cermeño concludes, "to the extent that contemporaneous trends in climate change have analogies with the climates of the geological period analyzed here, my results suggest that these microbial plankton groups will persist in the future ocean, perhaps even expanding their ranges of morphological diversity."

Cannariato *et al*. (1999) provide additional evidence marine biota are well-equipped to adapt to rising temperatures. They investigated the character, magnitude, and speed of responses of benthic foraminifera to millennial-scale climate oscillations manifest in data obtained from an ocean sediment core in the Santa Barbara Basin of the Northeast Pacific that covered the most recent 60,000 years. Although a number of rapid climatic switches were noted throughout the record, representing periods of "extreme environmental variability," the scientists found no extinctions, and the benthic ecosystems "appear to be both resilient and robust in response to rapid and often extreme environmental conditions." Although faunal turnovers occurred within decades, they did so "without extinction or speciation."

Ladah *et al*. (1999) examined the density and population structure of giant kelp "forests" located near Bahia Tortugas, Baja California, Mexico, before, during, and after the 1998 El Niño. At the height of the extreme warming event, sea surface temperatures (SSTs) were 3°C higher than the previous 10-year average for this region, and they led to the complete disappearance of the giant kelp that historically had inhabited the area. However, when the SST anomalies subsided, the giant kelp were once again found to be growing there, and from evidence derived from population structure data and the rapidity with which the plants reestablished themselves, Ladah *et al*. deduced "a microscopic stage that was not visible during dive surveys survived the stressful conditions

of ENSO and caused the recruitment event, supporting the hypothesis that a bank of microscopic forms can survive conditions stressful to macroscopic algae." They note there was independent evidence to suggest "microscopic stages may subsist in nature under low light intensities in a semi-dormant state until conditions become favorable."

In a follow-up study published several years later, Ladah and Zertuche-Gonzalez (2004) found a second and more likely predominant means by which the return of the giant kelp was made possible. Although all giant kelp growing at 15 m depth or shallower died during the peak warmth of the El Niño, the pair of researchers discovered there were numerous large fertile adults located between 25 and 40 m depth unaffected by the high surface water temperatures. Although the upper 15 meters of these plants died and sloughed off, regenerated fronds reached the surface of the sea by the fall of 1998.

The two scientists write, "survival in deep water during this extreme El Niño may have been due to local hydrography, such as internal waves bringing cool nitrate-rich water into the deeper regions of the shelf from below the thermocline, providing a refugium against the warm temperatures, low nutrients, and heavy wave action associated with warming events." They also note "the increased light that often occurs after canopy removal apparently resulted in ... recruitment events ... from newly produced spores from nearby fertile individuals surviving in deeper waters." They conclude "deep-water populations may regularly survive El Niño warming in this region due to internal wave activity, and go undetected due to the depth at which they occur and the sloughing of the shallow (<15 m) biomass."

Zheng *et al*. (2012) state dinoflagellates "are generally believed to prefer warm temperatures and presumably may do better in the face of temperature increases," noting *Prorocentrum donghaiense* was able to grow at temperatures ranging from 10 to 27°C and achieved its maximum specific growth rate at the latter temperature (Xu *et al*., 2010). For *P. minimum,* they note, "growth rates increased from 0.25/day at 4°C to 0.98/day at 20°C," citing Lomas and Gilbert (1999a,b). They report the composition of phytoplankton exposed to a temperature rise in the vicinity of a nuclear power plant's thermal effluent "tipped toward dinoflagellates both in terms of species number and cell abundance (Li *et al*., 2011)," probably because "some dinoflagellates were found to produce heat-shock proteins to stabilize protein secondary structure in response to thermal stress

(Alexandrov, 1994)." They further note, "heat shock protein 70 was induced in *Alexandrium tamarense* when subjected to a 10°C jump from its acclimated temperature of 20°C (Kobiyama *et al.*, 2010)."

Zheng *et al.* studied the effects of temperature shock on the growth of the dinoflagellate *Polarella glacialis*, "by monitoring its physiological and biochemical responses to temperature rises from 4°C to 10 and 15°C" while examining the growth rate and expression of two important genes for this alga. The three researchers state, "it is noteworthy that in the present study the cultures were directly transferred from 4°C to 10 and 15°C without progressive intermediate steps," and in response to these sudden temperature shifts, "the cultures first experienced a period of declination, then cell density tended to become stable, a sign that a part of the cell population survived." Zheng *et al.* conclude, "if the species can survive such heat shock in the long term, there is good opportunity that it can be transported from polar regions to temperate or even warmer waters," which perhaps explains why "taxa closely related to this species occur in temperate aquatic environments (Lin *et al.*, 2009, 2010)." If *P. glacialis* and related species can do that, they should have no problem coping with projected global warming.

Clark *et al.* (2013) used "a quantitative genetic breeding design to establish whether there is a heritable variation in thermal sensitivity in two populations of a habitat-forming intertidal macroalga, *Hormosira banksii* (Turner) Descaisne," in which "gametes from multiple parents were mixed and growth and photosynthetic performance were measured in the resulting embryos, which were incubated under control and elevated temperatures (20°C and 28°C)." The four researchers report "significant interactions between male genotype and temperature in one population indicated the presence of genetic variation in thermal sensitivity," such that "selection for more tolerant genotypes thus has the ability to result in the evolution of increased thermal tolerance." They found "genetic correlations between embryos grown in the two temperatures were positive, indicating that those genotypes that performed well in elevated temperature also performed well in control temperature." Clark *et al.* conclude their "finding of genetic variation in thermal tolerance of *H. banksii* embryos suggests resilience to thermal stresses."

6.1.2 Corals

Perhaps no other species of marine life is projected by IPCC to experience as much hardship and degradation in response to rising temperatures as corals. Several statements from a draft of Working Group II's contribution to IPCC's *Fifth Assessment Report* illustrate these concerns:

> The frequency and magnitude of coral bleaching and mortality will increase in the next few decades (*very high confidence*).

> Under the A1B CO_2 emission scenario, 99% of the grid cells experience at least one severe bleaching event over 2090–2099.

> Half of the coral reefs may avoid high frequency bleaching through 2100 assuming hypothetical

acclimation and/or adaptation (*limited evidence, low agreement*).

— Chapter 5, Coastal Systems and Low-Lying Areas, Working Group II, IPCC *Fifth Assessment Report*, draft dated March 28, 2013, p. 19.

> It is *very likely* that coral reef ecosystems will not survive changes in sea temperature beyond an additional increase of 1°C.

> Combining the known sensitivity of coral reefs within the Caribbean and Coral Triangle sub-regions, with the exposure to higher temperatures that are projected under medium (RCP4.5) to high (RCP8.5) scenarios, reveals that both coral reef rich regions are *virtually certain* to experience levels of thermal stress that cause coral bleaching every 1–2 years by the mid to late part of this century (*robust evidence, high levels of agreement, very high confidence*).

> The frequency of mass mortality events (DHM > 5; Figure 30–11 A,C) climbs towards events that occur every 1–2 years by mid to late of this century under low to high climate change scenarios (*robust evidence, high levels of agreement, very high confidence*).

> Mass mortality events that impact coral reefs will result in changes to community composition in the short term (2010–2039) and a continuing downward trend in reef building coral stocks in the longer term.

— Chapter 30, The Ocean, Working Group II, IPCC *Fifth Assessment Report*, draft dated March 28, 2013, p. 35.

> There is *robust evidence* and *high agreement* that coral reefs are one of the most vulnerable marine ecosystems.

> Even under optimistic assumptions regarding corals being able to rapidly adapt to thermal stress, one-third (9–60%, 68% uncertainty range) of the world's coral reefs are projected to be subject to long-term degradation under the RCP3-PD scenario. Under the RCP4.5 scenario, this fraction increases to two-thirds (30–88%, 68% uncertainty range).

> If present day corals have residual capacity to acclimatize and/or adapt, half of the coral reefs may avoid high frequency bleaching through 2100 (*limited evidence, limited agreement*). Evidence of

corals adapting rapidly, however, to climate change is missing or equivocal.

— Technical Summary, Working Group II, IPCC *Fifth Assessment Report*, draft dated March 28, 2013, pp. 67–68.

This section examines the future of Earth's corals in response to possible global warming, beginning with a review of the literature on the many suspected causes of coral bleaching, almost all of which have been attributed (often implausibly) to CO_2-induced global warming. Thereafter, the discussion turns to the possibility corals can adapt to the various environmental threats they face, followed by an examination of whether the widespread bleaching events seen in recent decades are indeed caused by global warming. The discussion concludes with a brief examination of an indirect temperature-related threat to corals—rising sea levels—which IPCC predicts will occur to a significant degree over the twenty-first century and beyond as global warming melts large portions of the ice presently stored in the world's glaciers and ice sheets.

This survey offers a much different perspective on the future of Earth's corals than that predicted by IPCC. Though rising temperatures have challenged and may continue to challenge Earth's corals, a large body of evidence indicates many corals can adapt to and even overcome the temperature-related challenges they are projected to face in response to CO_2-induced global warming. In reaching its overly pessimistic conclusions about corals, IPCC has clearly and improperly ignored the weight of the many research findings summarized here.

6.1.2.1 Causes of Coral Bleaching

This section reviews studies examining the causes of coral bleaching. The key findings are as follows:

- Many studies attribute high sea water temperatures as the primary cause of coral bleaching. However, the crucial link between temperature and coral reef bleaching may not reside in the absolute temperature of the water surrounding the corals but in the rapidity with which the temperature either rises above or falls below the temperature regime to which the corals are normally adapted.

- A number of studies have provided evidence inconsistent with the global-warming-induced coral bleaching hypothesis, pointing to other important factors and causes of coral bleaching, including solar irradiance, a solar radiation-temperature stress synergism, changes in salinity, bacterial infections, increased sedimentation, and exposure to toxicants.

- Many sources of coral stress and survival have little or nothing to do with rising CO_2 concentrations or temperatures.

Coral bleaching ranks among the more frequently cited negative consequences projected to result from CO_2-induced global warming. A loss of color in certain reef-building corals occurs when algal symbionts, or zooxanthellae, living within the host corals are subjected to various stresses and expelled from them, resulting in a loss of photosynthetic pigments from the coral colony. If the stress is mild, or short in duration, the affected corals often recover and regain their normal complement of zooxanthellae. If the stress is prolonged, or extreme, the corals eventually die, being deprived of their primary food source.

One of the most frequently cited causes of coral bleaching is anomalously high water temperature (Linden, 1998). The origin of this attribution can be traced to the strong El Niño event of 1982–1983, in which widespread bleaching was reported in corals exposed to unusually high surface water temperatures (Glynn, 1988). Since then, a number of other such observations have been made (Cook *et al*., 1990; Glynn 1991; Montgomery and Strong, 1994; Brown *et al*., 1996), and several laboratory studies have demonstrated elevated seawater temperatures can indeed induce bleaching in corals (Hoegh-Guldberg and Smith, 1989; Jokiel and Coles, 1990; Glynn and D'Croz, 1990).

Anomalously *low* seawater temperatures also have been identified with coral bleaching (Walker *et al*., 1982; Coles and Fadlallah, 1990; Muscatine *et al*., 1991; Gates *et al*., 1992; Saxby *et al*., 2003; Hoegh-Guldberg and Fine 2004; Yu *et al*., 2004; Kemp *et al*., 2011). These observations suggest the crucial link between temperature and coral reef bleaching may not be in the absolute temperature of the water surrounding the corals, but in the rapidity with which the temperature varies from the temperature regime to which the corals are normally adapted.

Winter *et al*. (1998), for example, studied relationships between coral bleaching and nine temperature indices, concluding, although "prolonged heat stress may be an important precondition for

bleaching to occur," sharp temperature changes act as the "immediate trigger." Jones (1997) reported coral bleaching on a portion of Australia's Great Barrier Reef just after average daily sea water temperature rose by 2.5°C over a brief period of eight days. Kobluk and Lysenko (1994) observed severe coral bleaching after an 18-hour *decline* of 3°C in seawater temperature. Because the corals studied by the latter researchers had experienced massive bleaching two years earlier as a result of an anomalous 4°C *increase* in water temperature, the authors conclude coral bleaching is more a function the rapidity of a temperature change than of the absolute magnitude or sign of the change, of heating or cooling.

Podesta and Glynn (1997) provided further evidence seawater temperatures *per se* are not the critical factors in coral bleaching. They examined a number of temperature-related indices of surface waters near Panama over the period 1970–1994. Their analysis revealed for the two years of highest maximum monthly sea surface temperature, 1972 and 1983, coral bleaching was reported only in 1983; 1972 produced no bleaching whatsoever, even though water temperatures that year were just as high as they were in 1983.

Another prominent cause of coral bleaching is solar radiation, a link dating back more than a century to when MacMunn (1903) postulated ultraviolet radiation could damage corals. It wasn't until half-a-century later that scientists began to confirm this suspicion (Catala-Stucki, 1959; Siebeck, 1988; Gleason and Wellington, 1995).

Many investigators of the solar irradiance-coral reef bleaching link have studied the phenomenon by transplanting reef corals from deep to shallow waters. Gleason and Wellington (1993), for example, transplanted samples of the reef-building coral *Montastrea annularis* from a depth of 24 meters to depths of 18 and 12 meters. Using sheets of acrylic plastic to block out ultraviolet radiation on some of the coral samples, they found the shielded corals experienced less bleaching than the unshielded corals, and the unshielded corals at the 12-meter depth had significantly lower amounts of zooxanthellae and chlorophyll per square centimeter than all other treatment and control groups. Similarly, Hoegh-Guldberg and Smith (1989) reported bleaching in the corals *Stylophora pistillata* and *Seriatopora hystrix* when they were moved from a depth of 6 meters to 1.2 meters. Vareschi and Fricke (1986) obtained similar results when moving *Plerogyra sinuosa* from a depth of 25 meters to 5 meters. As in the case of temperature stress, Glynn (1996) notes artificially

reduced light levels also have been observed to cause coral bleaching.

A number of laboratory studies have provided additional evidence for a link between intense solar irradiance and coral reef bleaching, but identifying a specific wavelength or range of wavelengths as the cause of the phenomenon has proven difficult. Fitt and Warner (1995), for example, reported the most significant decline in symbiont photosynthesis in the coral *Montastrea annularis* occurred when it was exposed to ultraviolet and blue light, but other studies have reported coral bleaching to be most severe at shorter ultraviolet wavelengths (Droller *et al.*, 1994; Gleason and Wellington, 1995). Still others have found it to be most strongly expressed at longer photosynthetically active wavelengths (Lesser and Shick, 1989; Lesser *et al.*, 1990; Brown *et al.*, 1994).

As additional studies provided evidence for a solar-induced mechanism of coral reef bleaching (Brown *et al.*, 1994; Williams *et al.*, 1997; Lyons *et al.*, 1998), some also provided evidence for a synergism of solar radiation and temperature stress (Gleason and Wellington, 1993; Rowan *et al.*, 1997; Jones *et al.*, 1998). Researchers have found a number of situations, for example, in which corals underwent bleaching when changes in both of these parameters combined to produce particularly stressful conditions (Lesser *et al.*, 1990; Glynn *et al.*, 1992; Brown *et al.*, 1995), such as during periods of low wind velocity and calm seas, which favor the intense heating of shallow waters and concurrent strong penetration of solar radiation.

This two-parameter interaction has much to recommend it as a primary cause of coral bleaching. It is the mechanism favored by Hoegh-Guldberg (1999), who claimed, in one of the strongest attempts made to that point in time to portray global warming as the cause of bleaching in corals, "coral bleaching occurs when the photosynthetic symbionts of corals (zooxanthellae) become increasingly vulnerable to damage by light at higher than normal temperatures."

The story is considerably more complicated than that. In a review paper on coral bleaching, Brown (1997) listed several potential causes, including elevated seawater temperature, decreased seawater temperature, intense solar radiation, the combination of intense solar radiation and elevated temperature, reduced salinity, and bacterial infections. In a similar review, Meehan and Ostrander (1997) added increased sedimentation and exposure to toxicants.

With respect to seawater salinity, Meehan and Ostrander (1997) note, as with temperature, both high and low values have been observed to cause coral

bleaching. Low values typically occur as a result of seawater dilution caused by high precipitation or storm runoff; high values are much rarer, typically occurring only near desalinization plants.

A number of studies also have described the role of bacterial infections in causing coral reef bleaching (Ritchie and Smith, 1998). This phenomenon, too, may have a connection to high seawater temperatures. In a study of the coral *Oculina patagonica* and the bacterial agent *Vibrio* AK–1, for example, Kushmaro *et al.* (1996, 1997) conclude bleaching of colonies of this coral along the Mediterranean coast has its origin in bacterial infection, and that warmer temperatures may lower the resistance of the coral to infection and/or increase the virulence of the bacterium. In subsequent studies of the same coral and bacterium, Toren *et al.* (1998) and Kushmaro *et al.* (1998) further demonstrated this high temperature effect may operate by enhancing the ability of the bacterium to adhere to the coral.

Kushmaro *et al.* (1998) comment on the "speculation that increased seawater temperature, resulting from global warming or El Niño events, is the direct cause of coral bleaching." Against this presumption, they cite several studies of coral bleaching events not associated with any major sea surface temperature anomalies, and they explicitly state, "it is not yet possible to determine conclusively that bleaching episodes and the consequent damage to reefs is due to global climate change." Likewise, Toren *et al.* (1998) note the extensive bleaching that occurred on the Great Barrier Reef during the summer of 1982 was not associated with any major sea surface temperature increase, and "several authors have reported on the patchy spatial distribution and spreading nature of coral bleaching." They note this observation conflicts with the global-warming-induced coral bleaching hypothesis. Instead, they write, "the progression of observable changes that take place during coral bleaching is reminiscent of that of developing microbial biofilms," a point that will later be seen to be of great significance.

High rates of sedimentation have been demonstrated to lead to coral bleaching (Wesseling *et al.*, 1999), and most historical increases in sedimentation rates are clearly human-induced. Umar *et al.* (1998), for example, listed such contributing anthropogenic activities as deforestation, agricultural practices, coastal development, construction, mining, drilling, dredging, and tourism. Nowlis *et al.* (1997) discussed "how land development can increase the risk of severe damage to coral reefs by sediment runoff during storms." However, it has been difficult to determine just how much these phenomena have varied over the past few centuries.

McCulloch *et al.* (2003) recreated a 250-year record of sediment transfer to Havannah Reef—a site on the inner Great Barrier Reef of northern Queensland, Australia—by flood plumes from the Burdekin River. They found sediments suspended in the Burdekin River contain barium (Ba), which is desorbed from the particles that carry it as they enter the ocean, where growing corals incorporate it into their skeletons along with calcium (Ca). When more sediment is carried to the sea by periodic flooding and more gradual longer-term changes in land use that exacerbate soil erosion, the resultant increases in sediment load are recorded in the Ba/Ca ratio of coral skeleton material. McCulloch *et al.* measured Ba/Ca ratios in a 5.3-meter-long coral core from Havannah Reef that covered the period from about 1750 to 1985, as well as in some shorter cores from Havannah Reef and nearby Pandora Reef that extended the proxy sediment record to 1998.

The results revealed before the time of European settlement, which began in the Burdekin catchment in 1862, there was "surprisingly little evidence for flood-plume related activity from the coral Ba/Ca ratios." Soon after, land clearance and domestic grazing intensified, and the soil became more vulnerable to monsoon-rain-induced erosion. By 1870, baseline Ba/Ca ratios had risen by 30%, and "within one to two decades after the arrival of European settlers in northern Queensland, there were already massive impacts on the river catchments that were being transmitted to the waters of the inner Great Barrier Reef." During subsequent periods of flooding, the transport of suspended sediment to the reef increased by five- to ten-fold over what had been characteristic of pre-European settlement times.

In a companion article, Cole (2003) report corals from East Africa "tell a similar tale of erosion exacerbated by the imposition of colonial agricultural practices in the early decades of the twentieth century." There, similar coral data from Malindi Reef, Kenya, indicate "a low and stable level of barium before about 1910 which rises dramatically by 1920, with a simultaneous increase in variance," which was also evident in the Australian data.

Cole concludes "human activity, in the form of changing land use, has added sedimentation to the list of stresses experienced by reefs." As land-use intensification is a widespread phenomenon, she notes, "many reefs close to continents or large islands are likely to have experienced increased delivery of sediment over the past century," which suggests the

stress levels produced by this phenomenon are likely to have increased over the past century as well. Cole concludes as coastal populations continue to rise, "this phenomenon is likely to expand."

A number of poisonous substances are known to induce coral bleaching. Some—such as herbicides, pesticides, and even excess nutrients that make their way from farmlands to the sea (Simkiss, 1964; Pittock, 1999)—are of human origin. Other poisons originate in the sea itself, many the result of metabolic waste products of other creatures (Crossland and Barnes, 1974) and some a by-product of the coral host itself (Yonge, 1968). Each of these toxicants presents the coral community with its own distinct challenge.

Taken together, these findings identify a number of sources of stress on coral survival and growth that have little or nothing to do with rising CO_2 concentrations or temperatures. They also clearly indicate human population growth and economic development have predisposed coral reefs to incidences of bleaching and subsequent mortality via a gradual intensification of near-coastal riverine sediment transport rates.

6.1.2.2 Responses to Temperature-Related Stresses

Considering the many threats to the health of corals outlined in the previous section, many have questioned how these repositories of underwater bio-diversity could possibly escape irreversible bleaching and death. In response to such concerns, Glynn (1996) noted, "numerous reef-building coral species have endured three periods of global warming, from the Pliocene optimum (4.3–3.3 million years ago) through the Eemian interglacial (125 thousand years ago) and the mid-Holocene (6000–5000 years ago), when atmospheric CO_2 concentrations and sea tem-peratures often exceeded those of today." Glynn observed "an increase in sea warming of less than 2°C would result in a greatly increased diversity of corals in certain high latitude locations."

Living organisms are resilient. Various life forms can tolerate temperatures from below freezing to the boiling point of water; others inhabit niches where light intensity varies from complete darkness to full sunlight. Given time to adapt, nearly all living organisms can learn to survive in conditions well outside their normal zones of environmental tolerance. As Gates and Edmunds (1999) note, numerous studies indicate "corals routinely occupy a physically hetero-geneous environment," which "suggests they should possess a high degree of biological flexibility." Their successful responses to the different threats that cause coral bleaching prove that flexibility and are examined in the subsections below.

6.1.2.2.1 Thermal Adaptation

The studies reviewed in this section examine the concept of thermal adaptation, which refers to the ability of corals to adapt to temperature stresses in the future of similar or even greater magnitude than what they have experienced in the past. The key findings are presented in the bullet points below followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- As living entities, corals are not only affected by the various elements of their environment, they also react or respond to them. When changes in environmental factors pose a challenge to their continued existence, they sometimes take major defensive or adaptive actions, including thermal adaptation, to ensure their survival.

- Multiple studies demonstrate corals are thermally adapting to rising sea water temperatures. Bleaching at many reefs is either reduced or no longer occurs at temperatures that previously caused it.

- Cold water coral species also have been shown to display resilience in adapting to temperature increases as large as 5°C.

- Coral genera most susceptible to thermal stress sometimes display the greatest increase in thermal tolerance.

- Genotypic analyses suggest "the physiological plasticity of the host and/or symbiotic components" plays an important role in thermal adaptation.

- There is "a growing body of evidence to support the notion that corals inhabiting more thermally unstable habitats outperform conspecifics from reefs characterized by more stable temperatures when exposed to elevated temperatures."

- "Previous exposure to an environmentally variable microhabitat adds substantially to coral-algal thermal tolerance, beyond that provided by heat-resistant symbionts alone." Similarly, the thermal adaptive capacity of some corals "is likely facilitated by a combination of short-term acclimation in individuals during acute environmental conditions (e.g., recurrent bleaching events) and long-term adaptation among coral populations to chronic environmental conditions (e.g., extreme temperatures)."

- "It is premature to suggest that widespread reef collapse is a certain consequence of ongoing bleaching, or that this will inevitably lead to fisheries collapses."

Fang *et al*. (1997) experimented with samples of *Acropora grandis* taken from the hot water outlet of a nuclear power plant near Nanwan Bay, Taiwan. In 1988, the year the power plant began full operation, the coral samples were completely bleached within two days of exposure to a temperature of 33°C. Two years later, however, "samples taken from the same area did not even start bleaching until six days after exposure to 33°C temperatures," illustrating their ability to thermally adapt.

Middlebrook *et al*. (2008) reported similar findings. They collected multiple upward-growing branch tips of the reef-building coral *Acropora aspera* from three large colonies at the southern end of Australia's Great Barrier Reef and placed them on racks immersed in running seawater within four 750-liter tanks maintained at the mean local ambient tem-

perature (27°C) and exposed to natural reef-flat summer daily light levels. Two weeks before a simulated bleaching event—where water temperature was raised to a value of 34°C for six days—they boosted the water temperature in one of the tanks to 31°C for 48 hours, and in another tank they boosted it to 31°C for 48 hours one week before the simulated bleaching event. In the third tank they had no pre-heating treatment, and in the fourth tank they used no pre-heating nor any simulated bleaching event. At different points throughout the study, they measured photosystem II efficiency, xanthophyll and chlorophyll *a* concentrations, and *Symbiodinium* densities.

Middlebrook *et al*. found the symbionts of the corals exposed to the 48-hour pre-bleaching thermal stress "were found to have more effective photo-protective mechanisms," including "changes in non-photochemical quenching and xanthophyll cycling." They determined "these differences in photo-protection were correlated with decreased loss of symbionts, with those corals that were not pre-stressed performing significantly worse, losing over 40% of their symbionts and having a greater reduction in photosynthetic efficiency," whereas "pre-stressed coral symbiont densities were unchanged at the end of the bleaching." Middlebrook *et al*. say their study "conclusively demonstrates that thermal stress events two weeks and one week prior to a bleaching event provide significantly increased thermal tolerance to the coral holobiont, suggesting that short time-scale thermal adaptation can have profound effects on coral bleaching."

In another laboratory-based study, Bellantuono *et al*. (2012) "tested the response of *Acropora millepora* to thermal preconditioning by exposing coral nubbins to 28°C (3°C below bleaching threshold) for 10 days, prior to challenging them with water temperatures of 31°C for 8 days," while "in another treatment (non-preconditioned), corals were exposed to 31°C without prior exposure to the 28°C treatment." They conducted these procedures in a set of "transparent tanks plumbed into flowing sea water, with four replicate tanks for each treatment."

The three researchers discovered short-term preconditioning to higher-than-ambient temperatures (but still 3°C below the experimentally determined bleaching threshold) for 10 days provided thermal tolerance for the scleractinian coral and its symbionts. Based on various genotypic analyses they conducted, they determined "the acclimatization of this coral species to thermal stress does not come down to simple changes in *Symbiodinium* symbiont shuffling and/or the bacterial communities that associate with

reef-building corals bacterial shuffling." These findings, Bellantuono *et al*. write, suggest "the physiological plasticity of the host and/or symbiotic components appears to play an important role in responding to ocean warming." They describe real-world examples of this phenomenon possibly playing a crucial role in preserving corals exposed to extreme warm temperatures in the past (Fang *et al*., 1997; Middlebrook *et al*., 2008; Maynard *et al*., 2008b).

South of Malta in the Mediterranean Sea, Naumann *et al*. (2013) collected live specimens of two scleractinian cold-water coral (CWCs) species, *Dendrophyllia cornigera* and *D. dianthus*. They transferred the specimens into two identically equipped and darkened 100-L flow-through aquaria through which Mediterranean subsurface seawater was continuously pumped from a 50-meter depth and supplied to the tanks at a rate of about one liter per minute. They maintained this water at a temperature of 12.5 ± 0.1°C for approximately 30 months before initiating the primary phase of their experiment, which was to increase the temperature of one of the aquariums by 0.5°C per day up to 17.5 ± 0.1°C, thereafter maintaining it for a further 87 days, while conducting "daily visual assessments of coral health (i.e. tentacle protrusion, suspension feeding and mortality/survival) and monthly growth measurements by the buoyant weight technique (Davies, 1989)," ultimately translating the latter into coral dry weight data.

The three researchers write, "over the entire experimental period, both CWC species showed neither differences in tentacle protrusion and suspension feeding nor mortality at ambient (12.5°C) or elevated (17.5°C) seawater temperatures." They state, "*D. cornigera* specimens developed a non-quantified number of new polyps at both temperatures suggesting efficient thermal acclimatization." They report "*D. dianthus* exhibited growth rates for ambient and elevated temperatures of 0.23 ± 0.08% per day and 0.19 ± 0.06% per day, whereas *D. cornigera* grew at 0.05 ± 0.01% per day under ambient and 0.14% ± 0.07% per day under elevated temperature conditions." Their findings "suggest that *D. dianthus* and *D. cornigera* may be capable of surviving in warmer environments than previously reported, and thus challenge temperature as the paramount limiting environmental factor for the occurrence of some CWC species."

Multiple researchers have confirmed the phenomenon of thermal adaptation in corals in response to real-world temperature-related stresses. Brown *et al*. (2002) conducted a 17-year study of coral reef flats at Ko Phuket, Thailand, assessing reef changes in response to elevated sea temperatures in 1991, 1995, 1997, and 1998. Although the authors state many corals bleached "during elevated sea temperatures in May 1991 and 1995," they report "no bleaching was recorded in 1997." In addition, they write, "in May 1998 very limited bleaching occurred although sea temperatures were higher than previous events in 1991 and 1995 (Dunne and Brown, 2001)." When bleaching did take place, they note, "it led only to partial mortality in coral colonies, with most corals recovering their color within 3–5 months of initial paling."

Riegl (2003) reviewed what was known at the time about the responses of coral reefs to high-temperature-induced bleaching, focusing primarily on the Arabian Gulf, which they note "has recently experienced high-frequency recurrences of temperature-related bleaching (1996, 1998, 2002)." Riegl reports in each of the three high-temperature years, sea surface temperature (SST) anomalies of 2 to 2.5°C above average *in situ* measured summer maximum SSTs persisted from April to September, and local maxima of *in situ* measured SSTs were 35.5°C in 1996 and 37°C in 2002. In response to these high-temperature events, *Acropora*, which during the 1996 and 1998 events always bleached first and suffered heaviest mortality, bleached less than all other corals in 2002 at Sir Abu Nuair (an offshore island of the United Arab Emirates) and recovered along the coast of Dubai between Jebel Ali and Ras Hasyan. Riegl states, "the unexpected resistance of Sir Abu Nuair *Acropora* to bleaching in 2002 might indicate support for the hypothesis of Baker (2001) and Baker *et al*. (2002) that the symbiont communities on recovering reefs of the future might indeed be more resistant to subsequent bleaching," and "the Arabian Gulf perhaps provides us with some aspects which might be described as a 'glimpse into the future,' with ... hopes for at least some level of coral/zooxanthellae adaptation."

Jimenez and Cortes (2003a) documented coral cover variability in the Pacific between 1992 and 2001, when the El Niño warming events of 1991–1992 (weak) and 1997–1998 ("the strongest in recorded history") affected coral communities along the Costa Rican central Pacific coast, after which they reported their observations and those of other scientists pertaining to these and earlier warming events caused by the El Niños of 1982–1983 (very strong) and 1986–1987 (moderate). The authors report there was a "paucity of bleaching and mortality in the study area in 1987 despite sea temperature

anomalies similar to or higher than in other years in which bleaching and mortality occurred," and this situation "may have been the result of the higher cloud cover and runoff which, in combination, decreased solar radiation stress." They suggest "similar atmospheric conditions during 1998 may explain the considerably small number of corals that bleached that year in the upwelling area of [Costa Rica's] Golfo de Papagayo," where they report "few corals bleached, even though sea temperature anomalies were higher than in autumn 1997."

As to the 1997–1998 El Niño, considered to be "the strongest event on record (McPhaden, 1999; Enfield, 2001)," the authors report "mortality of entire colonies associated with this event was remarkably low in Costa Rica, less than 6% (Jimenez *et al*., 2001)," and "only one coral species, *Psammocora stellata*, disappeared at one locality (Cambutal) after the 1997–1998 warming event." This disappearance "did not have an effect on the percent of total cover, which was not significantly dissimilar to previous years." They report "this species was not affected in Mexico by the 1997–1998 warming episode (Carriquiry *et al*., 2001)."

Jimenez and Cortes note conspecific corals "have shown differences in susceptibility to bleach, mortality rates and recovery capabilities (Brown, 1997; Hoegh-Guldberg, 1999; Marshall and Baird, 2000; Fitt *et al*., 2001; Glynn *et al*., 2001)," which may "reflect corals' adaptation to local conditions, different warming intensities at each locality, thermal acclimation, and presence of several clades of symbionts." They state moderate warming events "may positively affect coral reef communities," noting "increases in growth rates, reproductive activity and recruitment pulses have been observed after some El Niño episodes (Glynn *et al*., 1991, 1994; Feingold, 1995; Guzman and Cortes, 2001; Vargas-Angel *et al*., 2001; Jimenez and Cortes, 2003b)."

Guzman and Cortes (2007) note coral reefs of the eastern Pacific Ocean "suffered unprecedented mass mortality at a regional scale as a consequence of the anomalous sea warming during the 1982–1983 El Niño." At Cocos Island (5°32'N, 87°04'W), in particular, where they conducted a survey of three representative reefs in 1987, they found remaining live coral cover was only 3% of what it had been before the great El Niño four years earlier (Guzman and Cortes, 1992). Based on this finding and the similar observations of other scientists at other reefs, they predicted "the recovery of the reefs' framework would take centuries, and recovery of live coral

cover, decades." In 2002, nearly 20 years after the disastrous coral-killing warming, they returned to see how correct they were after their initial assessment of the El Niño damage, quantifying "the live coral cover and species composition of five reefs, including the three previously assessed in 1987."

Regarding thermal tolerance, the most interesting aspect of their study was the occurrence of a second major El Niño between the two assessment periods. Guzman and Cortes state "the 1997–1998 warming event around Cocos Island was more intense than all previous El Niño events," noting temperature anomalies "above 2°C lasted 4 months in 1997–1998 compared to 1 month in 1982–83." Nevertheless, they report, "the coral communities suffered a lower and more selective mortality in 1997–1998, as was also observed in other areas of the eastern Pacific (Glynn *et al*., 2001; Cortes and Jimenez, 2003; Zapata and Vargas-Angel, 2003)," indicating some type of thermal adaptation occurred after the 1982–1983 El Niño.

Maynard *et al*. (2008a) question the wisdom of "popularizing predictions based on essentially untested assumptions," among which they list IPCC-held claims, "all corals live close to their thermal limits" and "corals cannot adapt/acclimatize to rapid rates of change."

In discussing the first of these "untested assumptions," the three Australian researchers say "predictions that reefs will disappear as a result of global warming are based, at least in part, on the assumption corals are living close to their maximum thermal limits." However, they note, "the severity of bleaching responses varies dramatically within and among taxa," citing McClanahan *et al*. (2009), and "such variable bleaching susceptibility implies that there is a considerable variation in the extent to which coral species are adapted to local environmental conditions."

The three scientists report little is known about the sensitivity of coral population response to climate-induced changes in growth, mortality, and fecundity, but they state a large body of evidence "supports temperature tolerance varying among species, populations, communities, and reef regions (Marshall and Baird, 2000; Coles and Brown, 2003)." They conclude, "even in the absence of an adaptive response, a change in the relative abundance of species is a far more likely outcome of climate change than the disappearance of reef corals," citing Loya *et al*. (2001), McClanahan (2002), and Hughes *et al*. (2003).

The three researchers clearly accept there is "an

adaptive response," in contradiction of the second untested assumption Maynard *et al.* (2008a) discuss, stating "a number of studies suggest that bleaching mortality rates have declined and thermal tolerance has increased in some regions." They report, for example, "mortality rates in the Eastern Pacific were significantly lower in 1998 when compared with 1982 and 1983 (Glynn *et al.*, 2001)," and "Maynard *et al.* (2008b) found thermal tolerance of three common coral genera on the Great Barrier Reef to be greater in 2002 than that expected from the relationship between temperature stress and bleaching severity observed in 1998."

The Australian scientists say there is "circumstantial evidence for ongoing evolution of temperature tolerance between both species and reefs," citing Coles and Brown (2003). In addition, they suggest "symbiont shuffling from less to more stress-resistant clades is another mechanism by which corals may increase the thermal tolerance of the holobiont." And they declare "there is growing evidence that such shuffling can increase thermal tolerance, at least in the short term (Berkelmans and van Oppen, 2006)." Thus Maynard *et al.* (2008a) conclude, "it is premature to suggest that widespread reef collapse is a certain consequence of ongoing bleaching, or that this will inevitably lead to fisheries collapses."

Adjeroud *et al.* (2009) observed coral reefs of the Tiahura outer reef sector at the western end of the north shore of Moorea, French Polynesia, a region they say is "largely free of direct anthropogenic disturbances." They describe the results of detailed observations made there periodically since the early 1970s and annually since 1991. This history, they write, "constitutes one of the longest records of coral reef dynamics." Concentrating on the period of detailed annual observations (1991 onward), the 10 researchers report a significant decline in coral cover followed the two disturbances of 1991 (a major bleaching event and a cyclone), when "coral cover (pooled among genera) declined from 51.0 ± 9.5% in early 1991 to 24.2 ± 14.4% in 1992, and 22.5 ± 9.3% in 1993." This decline, they write, was "among the most rapid of this magnitude recorded following natural disturbances." In contrast, they found "the bleaching events of 1994, 2002 and 2003 had no detectable effects on coral cover, even though the thermal anomalies causing these events and their short-term impacts in terms of bleaching prevalence were similar to the 1991 bleaching event."

Adjeroud *et al.* say their results reveal "corals can recover rapidly following a dramatic decline," noting

similar recoveries of coral cover have been documented at several other locations, citing Connell (1997), Halford *et al.* (2004), Emslie *et al.* (2008), and Sheppard *et al.* (2008). They state their work "supports the hypothesis that some reefs will undergo gradual changes in structure of their coral communities in response to major stress rather than collapse abruptly," citing Loya *et al.* (2001), Hughes *et al.* (2003), and Wakeford *et al.* (2008).

Maynard *et al.* (2008b) analyzed the bleaching severity of three genera of corals (*Acropora*, *Pocillopora,* and *Porites*) along five sites in the central section of Australia's Great Barrier Reef in late February and March of 1998 and 2002. Regarding the influence of temperature, the four researchers report "the amount of accumulated thermal stress (as degree heating days) in 2002 was more than double that in 1998 at four of the five sites," and "average surface irradiance during the 2002 thermal anomaly was 15.6–18.9% higher than during the 1998 anomaly." They found "in 2002, bleaching severity was 30–100% lower than predicted from the relationship between severity and thermal stress in 1998, despite higher solar irradiances during the 2002 thermal event." In addition, "coral genera most susceptible to thermal stress (*Pocillopora* and *Acropora*) showed the greatest increase in tolerance."

Maynard *et al.* state their findings are "consistent with previous studies documenting an increase in thermal tolerance between bleaching events (1982–1983 vs. 1997–1998) in the Galapagos Islands (Podesta and Glynn, 2001), the Gulf of Chiriqi, the Gulf of Panama (Glynn *et al.*, 2001), and on Costa Rican reefs (Jimenez *et al.*, 2001)." They also note "Dunne and Brown (2001) found similar results … in the Andaman Sea, in that bleaching severity was far reduced in 1998 compared to 1995 despite sea-temperature and light conditions being more con-ducive to widespread bleaching in 1998."

The Australian scientists say "the range in bleaching tolerances among corals inhabiting different thermal realms suggests that at least some coral symbioses have the ability to adapt to much higher temperatures than they currently experience in the central Great Barrier Reef," citing Coles and Brown (2003) and Riegl (1999, 2002). They note, "even within reefs there is a significant variability in bleaching susceptibility for many species (Edmunds, 1994; Marshall and Baird, 2000), suggesting some potential for a shift in thermal tolerance based on selective mortality (Glynn *et al.*, 2001; Jimenez *et al.*, 2001) and local population growth alone." Their results suggest "a capacity for acclimatization or

adaptation." Maynard *et al.* (2008b) conclude "there is emerging evidence of high genetic structure within coral species (Ayre and Hughes, 2004)," suggesting "the capacity for adaptation could be greater than is currently recognized." As Skelly *et al.* (2007) state, "on the basis of the present knowledge of genetic variation in performance traits and species' capacity for evolutionary response, it can be concluded that evolutionary change will often occur concomitantly with changes in climate as well as other environmental changes."

Focusing more on such evolutionary possibilities, Meyer *et al.* (2009) "performed controlled crosses between three genetically distinct colonies of the branching coral *Acropora millepora*," and then "compared the families of larvae (which in this species naturally lack symbionts) for several physiological traits." They conducted this work at two water temperatures—the standard culturing temperature of 28°C and an elevated temperature of 32°C—as well as an even higher temperature of 34°C maintained for two full days.

Results of the U.S., Canadian, and Australian researchers' analysis confirmed the existence of phenotypic variance for several pertinent thermal and dispersive factors among the families of coral they studied. This finding, they write, "suggests the existence of considerable heritable variation in natural coral populations," and this in turn supports "the possibility of effective adaptive responses to climate change." In addition, they report other analyses of the species they studied have found "high levels of genetic diversity both within and between reefs (Smith-Keune and van Oppen, 2006)," and "studies in other coral species have also uncovered substantial genetic diversity within populations (Ayre and Hughes, 2000; Underwood, 2009; Wang *et al.*, 2009)." Myer *et al.* conclude "additive genetic variance exists within coral populations for several traits that might reasonably be expected to have fitness consequences during global climate change," which "supports the possibility of effective adaptive responses to climate change."

Grimsditch *et al.* (2010) say "it has been shown that it is possible for colonies to acclimatize to increased temperatures and high irradiance levels so that they are able to resist bleaching events when they occur." They note "threshold temperatures that induce coral bleaching-related mortality vary worldwide—from 27°C in Easter Island (Wellington *et al.*, 2001) to 36°C in the Arabian Gulf (Riegl, 1999)—according to the maximum water temperatures that are normal in the area, implying a capacity of corals and/or

zooxanthellae to acclimatize to high temperatures depending on their environment."

Grimsditch *et al.* examined "bleaching responses of corals at four sites (Nyali, Mombasa Marine Park, Kanamai and Vipingo) representing two distinct lagoon habitats on the Kenyan coast (deeper and shallower lagoons)." This was done for the coral community as a whole, and zooxanthellae densities and chlorophyll levels were monitored for three target species (*Pocillopora damicornis*, *Porites lutea,* and *Porites cylindrica*) during a non-bleaching year (2006) and a mild bleaching year (2007). They found "during the 2007 bleaching season, corals in the shallow lagoons of Kanamai and Vipingo were more resistant to bleaching stress than corals in the deeper lagoons of Mombasa Marine Park and Nyali." This result suggests, they write, "corals in the shallower lagoons have acclimatized and/or adapted to the fluctuating environmental conditions they endure on a daily basis and have become more resistant to bleaching stress."

Osborne *et al.* (2011) note "coral decline is frequently described as ongoing with the integrity and persistence of the reef system threatened by a number of different stressors," citing Bellwood *et al.* (2004), and "climate change is widely regarded as the single greatest threat to coral reef ecosystems." They also note "the scale and extent of bleaching on the GBR [Great Barrier Reef] since 1998 is unprecedented (Oliver *et al.*, 2009)," "coral disease is an emerging stressor that was first recorded on the GBR in the early 1990s (Willis *et al.*, 2004; Lough, 2007)," and various harmful environmental disturbances "appear to be increasing in frequency and severity."

To quantify the trend in live coral cover of the Great Barrier Reef between 1995 and 2009, which IPCC contends was the warmest decade-and-a-half experienced by the planet in the past millennium, the scientists surveyed coral communities annually on 47 reefs in six latitudinal sectors across 1300 km of the GBR, surveying between two and five reefs in each sub-region. They did so at three sites on the northeast flank of each reef, with each site consisting of five 50-m transects marked by steel rods at depths between six and nine meters. They note "percent cover of live hard coral was estimated from a randomly selected sequence of images taken along the transects using a point-sampling technique in a quincunx pattern (Adbo *et al.*, 2004)."

They found "coral cover increased in six sub-regions and decreased in seven sub-regions," with some of the changes "being very dynamic and others changing little." With respect to the entire reef

system, they report "overall regional coral cover was stable (averaging 29% and ranging from 23% to 33% across years) with no net decline between 1995 and 2009." They state they found "no evidence of consistent, system-wide decline in coral cover since 1995." In spite of the purportedly unprecedented negative influences arrayed against them over the past decade-and-a-half, GBR corals appear to have held their own, adapting to the purported onslaught of stresses and maintaining a stable presence.

According to Oliver and Palumbi (2011), "the vast majority of studies that investigate the effects of fluctuating thermal regimes on thermal tolerance have examined daily thermal cycles in which the hottest temperatures lasted on the timescale of hours," and in eight of 10 such studies—performed on taxa as diverse as corals, crustaceans, fish, and amphibians— "organisms that were acclimated to a daily fluctuating thermal regime showed thermal tolerance or tolerance-relevant gene expression (e.g., heat shock proteins) that was equal to, or greater than, that of organisms acclimated to a thermal regime held constant at the maximum temperature of the fluctuating regime," citing Hutchison and Ferrance (1970), Otto (1974), Sastry (1979), Thorp and Wineriter (1981), Threader and Houston (1983), Podrabsky and Somero (2004), Schaefer and Ryan (2006), and Putnam et al. (2010).

Studying back-reef pools in American Samoa that differ in diurnal thermal variation, Oliver and Palumbi experimentally heat-stressed *Acropora hyacinthus* corals from a thermally moderate lagoon pool and a more thermally variable pool that naturally experienced two- to three-hour high temperature events during summer low tides. They compared coral mortality and photosystem II photochemical efficiency of colony fragments collected from each of these lagoons that they exposed to either ambient (28.0°C) or elevated (31.5°C) water temperatures. The two researchers report in the heated treatment, "moderate pool corals showed nearly 50% mortality whether they hosted heat-sensitive or heat-resistant symbionts," whereas "variable pool corals, all of which hosted heat-resistant symbionts, survived well, showing low mortalities statistically indistinguishable from controls held at ambient temperatures." Also in the heated treatment, they state, "moderate pool corals hosting heat-sensitive algae showed rapid rates of decline in algal photosystem II photochemical efficiency," whereas those "hosting heat-resistant algae showed intermediate levels of decline." They found "variable pool corals hosting heat-resistant algae showed the least decline."

Oliver and Palumbi say their results suggest "previous exposure to an environmentally variable microhabitat adds substantially to coral-algal thermal tolerance, beyond that provided by heat-resistant symbionts alone," indicating a latent potential of Earth's corals to adapt to warmer temperatures than scientists believed possible in the past, should they gradually begin to experience recurring daily episodes of greater warmth in a gradually warming world.

In a study designed to investigate how coral assemblages in the Persian Gulf might cope with global warming via reproductive biology, Bauman *et al.* (2011) examined six locally common coral species on two shallow reef sites in Dubai, United Arab Emirates, in 2008 and 2009, to investigate their patterns of reproduction, focusing primarily on the timing and synchrony of spawning. They found the reproductive biology of the six coral species in the southern Persian Gulf "appears to be well adapted to extreme annual environmental fluctuations" and is "remarkably similar to conspecifics elsewhere in the Indo-Pacific (Baird *et al.*, 2009a,b)." They also found "the adaptive capacity of corals in the Persian Gulf is likely facilitated by a combination of short-term accli-mation in individuals during acute environmental conditions (e.g., recurrent bleaching events) and long-term adaptation among coral populations to chronic environmental conditions (e.g., extreme tempera-tures)."

Bauman *et al.* state their work "confirms that corals are capable of reproductive activities under extreme environmental conditions," as Coles and Fadlallah (1991) and Coles and Brown (2003) also found. They conclude "coral populations can survive and proliferate in extreme conditions that are pro-jected to occur in many other regions of the world by the end of this century," noting, "the recovery of these coral assemblages following mortality induced by a number of recent temperature-related bleaching events (1996, 1998 and 2002) suggests these assemblages are also resilient to extreme fluctuations in water temperature," citing Riegl (1999, 2003) and Burt *et al.* (2008).

Serrano *et al.* (2013) investigated the adaptation of corals to temperature-related stresses through range expansion or migration. The team of researchers state, "despite the evidence that some coral species appear to be responding to climatic warming by expanding their distributions toward the poles (Wooddroffe, 2011), it has been argued that latitudinal migration is unlikely to occur rapidly enough to respond to the current projected temperature change (3–6°C over the next 100 years (IPCC, 2007)) due to the significant

distance involved (i.e., the latitudinal temperature gradient is ~1.5°C/1000 km), the effects of temperature on reproduction, and the decrease in carbonate ion concentrations at high latitudes." Serrano *et al.* analyzed a long-term, large-scale observational dataset to characterize the dynamics of a hermatypic coral (*Oculina patagonica*) in regard to its "recent northward range shift along the coast of Catalonia," while examining "the main factors that could have influenced this spread," which they did "by monitoring 223 locations including natural and artificial habitats along >400 km of coastline over the last 19 years (1992–2010)."

The six Spanish scientists report *Oculina patagonica* "increased from being present in one location in 1992 to occur on 19% of the locations in 2010, and exhibited an acceleration of its spreading over time driven by the joint action of neighborhood and long-distance dispersal." They further note the "northward expansion has occurred at the fastest rate (22 km per year) reported for a coral species thus far." Serrano *et al.* write, "a coral species with particular biological characteristics that allow it to withstand the temperature challenge that accompanies northward migration as well as the natural and anthropogenic side effects that this type of migration involves (i.e., competition with macroalgae, high sediment loads, turbidity, water chemistry) has accomplished a successful northward expansion and may be able to keep pace with the global warming prediction of ~3°C over the next 100 years."

Yamano *et al.* (2011) report "although most studies of climate change effects on corals have focused on temperature-induced coral bleaching in tropical areas, poleward range shifts and/or expansions may also occur in temperate areas, as suggested by geological records and present-day eyewitnesses in several localities," citing Greenstein and Pandolfi (2008) and Precht and Aronson (2004). Yamano *et al.* collected records of coral species occurrence from eight temperate regions of Japan along a latitudinal gradient, where they obtained what they describe as "the first large-scale evidence of the poleward range expansion of modern corals, based on 80 years of national records ... where century-long measurements of *in situ* sea-surface temperatures have shown statistically significant rises."

They found "four major coral species categories, including two key species for reef formation in tropical areas, showed poleward range expansions since the 1930s, whereas no species demonstrated southward range shrinkage or local extinction," adding "the speed of these expansions reached up to

14 km per year," which they say "is far greater than that for other species." They note, "in regions with poleward current flows (east coast of the United States [Precht and Aronson, 2004], east coast of South America, east coast of Africa and east coast of Australia [Figueira and Booth, 2010]) the speed would be much greater."

The Japanese scientists conclude their results, "in combination with recent findings suggesting range expansions of tropical coral-reef associated organisms, strongly suggest that rapid, fundamental modifications of temperate coastal ecosystems could be in progress." They suggest "temperate areas may serve as refugia for tropical corals in an era of global warming."

Van Woesik *et al.* (2012) examined the response of more than 30,000 coral colonies at 80 sites in Palau during a regional thermal-stress event in 2010, to determine "whether any habitats were comparatively resistant to thermal stress." The six scientists discovered "bleaching was most severe in the northwestern lagoon, in accordance with satellite-derived maximum temperatures and anomalous temperatures above the long-term averages," noting corals there "suffered the most extensive bleaching and the highest mortality." But "in the bays where temperatures were higher than elsewhere, bleaching and mortality were low." They suggest "constant exposure to high temperatures, and high vertical attenuation of light caused by naturally high suspended particulate matter buffered the corals in bays from the 2010 regional thermal-stress event." Van Woesik *et al.* conclude their study shows "reefs around bays were more resistant to regional thermal stress than patch and outer reefs," and "nearshore reefs in the bays are therefore valuable refuges to buffer coral-reef ecosystems against climate change-induced disturbances." Those bays "should be given high conservation status because they provide refugia for coral populations as the oceans continue to warm."

Carilli *et al.* (2012) note "observations indicating that mass bleaching events have recently become more common, combined with projected increases in heat stress, have prompted dire predictions for the future of coral reefs under unabated greenhouse gas emissions scenarios," citing Hoegh-Guldberg (1999) and Donner *et al.* (2005). They point out, "there is evidence that corals may adapt to better withstand heat stress via a number of mechanisms," as "corals might acquire more thermally-resistant symbionts (Buddemeier and Fautin, 1993; Rowan, 2004), or might increase their own physiological mechanisms

to reduce bleaching susceptibility by producing oxidative enzymes (Coles and Brown, 2003) or photoprotective compounds (Salih *et al.*, 2000)." They emphasize there is evidence suggesting the susceptibility of a given coral or reef to bleaching depends on the thermal history of that coral or reef (Thompson and Van Woesik, 2009; Donner, 2011; Brown *et al.*, 2002).

Carilli *et al.* "collected cores from massive *Porites sp.* corals in the Gilbert Islands of Kiribati to determine how corals along a natural gradient in temperature variability responded to recent heat stress events" and "examined changes in coral skeletal growth rates and partial mortality scars (Carilli *et al.*, 2010) to investigate the impact of the bleaching event in 2004 (Donner, 2011) on corals from different temperature variability regimes."

The three researchers—from Australia, Canada, and the United States—discovered the spatial patterns in skeletal growth rates and partial mortality scars found in corals from the central and northern islands suggest "corals subject to larger year-to-year fluctuations in maximum ocean temperature were more resistant to a 2004 warm-water event," and "a subsequent 2009 warm event had a disproportionately larger impact on those corals from the island with lower historical heat stress." Carilli *et al.* conclude, "coral reefs in locations with more frequent warm events may be more resilient to future warming."

Penin *et al.* (2013) "compared variations in spatial and taxonomic patterns between two bleaching events at the scale of an island (Moorea Island, French Polynesia)," where "nine stations involving three locations (Haapiti, Tiahura, and Viapahu) and three depths (6, 12, and 18 m) have been routinely surveyed for various scientific purposes since 2001," as described by Penin *et al.* (2007a, 2010). They measured bleaching intensity "two weeks following the first signs of bleaching (Penin *et al.*, 2007b)" for six coral genera (*Acropora*, *Montipora*, *Montastrea*, *Pavona*, *Pocillopora,* and *Porites*) at each of the nine stations in 2002 and 2007. The six coral genera accounted for 88% of the total coral assemblage.

Their measurements showed the "thermal stress was similar between the two years studied," but "the bleaching intensity was lower in 2007 (25–49%) than in 2002 (39–72%)" and "the response to elevated temperature was delayed in the latter year." They note "the outer slopes at Moorea Island are located in an oligotrophic oceanic environment and are not under terrestrial influence, which makes it unlikely that there was any effect of nutrients on the response of the corals, as has been proposed for other reef eco-

systems (Wooldridge and Done, 2009)." The three researchers conclude "it is likely that the observed decrease in stress response was the result of acclimatization of the coral/algal holobionts (Berkelmans *et al.*, 2004; Maynard *et al.*, 2008) or an influx of thermo-tolerant colonies between 2002 and 2007." They note several "similar decreases in susceptibility to thermal stress have been documented between successive bleaching events, including between 1991 and 1994 at Moorea Island (Adjeroud *et al.*, 2002), between 1998 and 2002 on the Great Barrier Reef in Australia (Maynard *et al.*, 2008b), and between 1982–83 and 1997–98 in Panama (Glynn *et al.*, 2001), Costa Rica (Jimenez *et al.*, 2001), and at the Galapagos Islands (Podesta and Glynn, 2001)."

Mayfield *et al.* (2013) write, "recent work has found that pocilloporid corals from regions characterized by unstable temperatures, such as those exposed to periodic upwelling, display a remarkable degree of phenotypic plasticity," and "some recent works have shown that not all corals bleach, or even manifest signs of stress, at elevated temperatures predicted to characterize reefs in the coming decades (Barshis *et al.*, 2013)." They also note "corals from highly variable temperature environments of both American Samoa (Oliver and Palumbi, 2011) and southern Taiwan (Mayfield *et al.*, 2011, 2013) have previously been shown to withstand exposure to temperatures (e.g., 30–31°C) that induce bleaching or even mortality in conspecifics from other regions (Jokiel and Coles, 1990; Brown, 1997)."

To "uncover the long-term impacts of elevated temperature exposure to corals from reefs that experience episodic upwelling," Mayfield *et al.* conducted a mesocosm-based experiment in which *P. damicornis* specimens collected from an upwelling coral reef on Houbihu (a small embayment within Nanwan Bay, southern Taiwan) were exposed for nine months to nearly 30°C, a temperature that the corals normally encounter *in situ* for just a few hours per year (Mayfield *et al.*, 2012). The three researchers write, "upon nine months of exposure to nearly 30°C, all colony (mortality and surface area), polyp (*Symbiodinium* density and chlorophyll *a* content), tissue (total thickness), and molecular (gene expression and molecular composition)-level parameters were documented at similar levels between experimental corals and controls incubated at 26.5°C, suggesting that this species can readily acclimate to elevated temperatures that cause significant degrees of stress, or even bleaching and mortality, in conspecifics of other regions of the Indo-Pacific."

Mayfield *et al.* state, "there is now a growing

body of evidence to support the notion that corals inhabiting more thermally unstable habitats out-perform conspecifics from reefs characterized by more stable temperatures when exposed to elevated temperatures," citing Coles (1975), Castillo and Helmuth (2005), and Oliver and Palumbi (2011). They also report, "in other systems, provocative gene expression changes, such as the constitutive up-regulation of genes involved in thermotolerance (e.g., *hsps*; Heath *et al.*, 1993; Feder, 1996), underlie the capacity for organisms to inhabit high and/or variable temperature environments," as Barshis *et al.* (2013) also documented in corals.

6.1.2.2.2 Symbiont Shuffling

The studies reviewed in this section examine symbiont shuffling, the ability of corals to replace the zooxanthellae expelled during a stress-induced bleaching episode with one or more varieties of zooxanthellae more tolerant of that particular stress. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings.

- Zooxanthellae that reside within the cells of host corals are highly diverse, comprising perhaps hundreds of species, of which several are typically found in each species of coral.

- Many corals respond to stress by replacing the zooxanthellae expelled during a stress-induced bleaching episode with one or more varieties of zooxanthellae more tolerant of that stress.

- Coral bleaching is an adaptive strategy for "shuffling" symbiont genotypes to create associations better adapted to new environmental conditions, as opposed to "a breakdown of a stable relationship that serves as a symptom of degenerating environmental conditions."

- Multiple studies confirm the strategy of symbiont shuffling is occurring in nature.

- Symbiont shuffling "represents a mechanism for rapid acclimatization of the holobiont to environmental change."

Although once considered to be members of the single species *Symbiodinium microadriacticum*, the zooxanthellae that reside within membrane-bound vacuoles in the cells of host corals are highly diverse, comprising perhaps hundreds of species, with each species of coral typically possessing several of these species (Trench, 1979; Rowan and Powers, 1991; Rowan *et al.*, 1997). One way corals respond to stress is to replace the zooxanthellae expelled by the coral host during a stress-induced bleaching episode with one or more varieties of zooxanthellae more tolerant of that particular stress.

Rowan *et al.* (1997) suggest this phenomenon

occurs in many of the most successful Caribbean corals that act as hosts to dynamic multispecies communities of symbionts, and "coral communities may adjust to climate change by recombining their existing host and symbiont genetic diversities," thereby reducing the amount of damage that might be expected from another occurrence of anomalously high temperatures. Buddemeier and Fautin (1993) propose coral bleaching is an adaptive strategy for "shuffling" symbiont genotypes to create associations better adapted to new environmental conditions. Kinzie (1999) suggests coral bleaching "might not be simply a breakdown of a stable relationship that serves as a symptom of degenerating environmental conditions," but also "may be part of a mutualistic relationship on a larger temporal scale, wherein the identity of algal symbionts changes in response to a changing environment."

The findings of Rowan and Knowlton (1995) and Gates and Edmunds (1999) provide additional evidence of this process of replacing less-stress-tolerant symbionts with more-stress-tolerant ones. The process seems to be successful, for as Glynn (1996) observed, "despite recent incidences of severe coral reef bleaching and mortality, no species extinctions have yet been documented."

These observations accord well with the experimental findings of Fagoonee *et al.* (1999), who suggest coral bleaching events "may be frequent and part of the expected cycle." Gates and Edmunds (1999) report "several of the prerequisites required to support this hypothesis have now been met"; after describing them in some detail, they conclude "there is no doubt that the existence of multiple *Symbiodinium* clades, each potentially exhibiting a different physiological optima, provide corals with the opportunity to attain an expanded range of physiological flexibility which will ultimately be reflected in their response to environmental challenge." This phenomenon may explain the paradox posed by Pandolfi (1999): "a large percentage of living coral reefs have been degraded, yet there are no known extinctions of any modern coral reef species." This result is exactly what would be expected if periods of stress lead to the acquisition of more-stress-resistant zooxanthellae by coral hosts.

Hoegh-Guldberg (1999) challenged the symbiont shuffling hypothesis by noting the stress-induced replacement of less-stress-tolerant varieties of zooxanthellae by more-stress-tolerant varieties "has never been observed." Although that was true at the time it was written, subsequent studies have produced the long-sought proof that transforms the hypothesis

into fact.

Baker (2001) transplanted corals of different combinations of host and algal symbiont from shallow (2–4 m) to deep (20–23 m) water and vice versa. After eight weeks, nearly half of the corals transplanted from deep to shallow water had experienced partial or severe bleaching, whereas none of the corals transplanted from shallow to deep water bleached. After one year, and despite even more bleaching at shallow depths, upward transplants showed no mortality, but nearly 20% of downward transplants had died.

The symbiont shuffling hypothesis explains Baker's results as follows. The corals transplanted upwards were presumed to have adjusted their algal symbiont distributions, via bleaching, to favor more-tolerant species, whereas the corals transplanted downward were assumed to have not done so, since they did not bleach. Baker suggests these findings "support the view that coral bleaching can promote rapid response to environmental change by facilitating compensatory change in algal symbiont communities." Without bleaching, he continues, "suboptimal host-symbiont combinations persist, leading eventually to significant host mortality." Baker proposed coral bleaching may "ultimately help reef corals to survive." It may also explain why reefs, though depicted by IPCC as environmentally fragile, have survived the large environmental changes experienced throughout geologic time.

Adjeroud *et al.* (2002) provided additional evidence for the veracity of the symbiont shuffling hypothesis through their study of the interannual variability of coral cover on the outer slope of the Tiahura sector of Moorea Island, French Polynesia, between 1991 and 1997, which focused on the impacts of bleaching events caused by thermal stress when sea surface temperatures rose above 29.2°C. Soon after the start of their study, they observed a severe decline in coral cover following a bleaching event that began in March 1991, which was followed by another bleaching event in March 1994. They report the latter bleaching event "did not have an important impact on coral cover," even though "the proportion of bleached colonies ... and the order of susceptibility of coral genera were similar in 1991 and 1994 (Gleason, 1993; Hoegh-Guldberg and Salvat, 1995)." Between 1991 and 1992 total coral cover dropped from 51.0 to 24.2%, but "coral cover did not decrease between 1994 and 1995."

Adjeroud *et al.* note a "possible explanation of the low mortality following the bleaching event in 1994 is that most of the colonies in place in 1994

were those that survived the 1991 event or were young recruits derived from those colonies," and "one may assume that these coral colonies and/or their endosymbiotic zooxanthellae were phenotypically and possibly genotypically resistant to bleaching events," exactly what the symbiont shuffling hypothesis would predict. They say "this result demonstrates the importance of understanding the ecological history of reefs (i.e., the chronology of disturbances) in interpreting the specific impacts of a particular disturbance."

Brown *et al*. (2002) published the results of a 17-year study of coral reef flats at Ko Phuket, Thailand, in which they assessed coral reef changes in response to elevated water temperatures in 1991, 1995, 1997, and 1998. They write, "many corals bleached during elevated sea temperatures in May 1991 and 1995, but no bleaching was recorded in 1997." They report, "in May 1998 very limited bleaching occurred although sea temperatures were higher than previous events in 1991 and 1995 (Dunne and Brown, 2001)"; when bleaching did take place, "it led only to partial mortality in coral colonies, with most corals recovering their color within 3–5 months of initial paling.

Riegl (2003) reviewed what is known about the responses of real-world coral reefs to high-temperature-induced bleaching, focusing primarily on the Arabian Gulf, which experienced high-frequency recurrences of temperature-related bleaching in 1996, 1998, and 2002. *Acropora*, which during the 1996 and 1998 events always bleached first and suffered heaviest mortality, bleached less than all other corals in 2002 at Sir Abu Nuair (an offshore island of the United Arab Emirates) and recovered along the coast of Dubai between Jebel Ali and Ras Hasyan. Riegl writes, "the unexpected resistance of Sir Abu Nuair *Acropora* to bleaching in 2002 might indicate support for the hypothesis of Baker (2001) and Baker *et al*. (2002) that the symbiont communities on recovering reefs of the future might indeed be more resistant to subsequent bleaching," and "the Arabian Gulf perhaps provides us with some aspects which might be described as a 'glimpse into the future,' with ... hopes for at least some level of coral/zooxanthellae adaptation."

Kumaraguru *et al*. (2003) assessed the damage inflicted on a number of coral reefs within Palk Bay (located on the southeast coast of India just north of the Gulf of Mannar) by a major warming event that produced monthly mean sea surface temperatures of 29.8 to 32.1°C from April through June 2002, after which they studied the degree of recovery of the reefs. They determined "a minimum of at least 50% and a maximum of 60% bleaching were noticed among the six different sites monitored." They continue, "the corals started to recover quickly in August 2002 and as much as 52% recovery could be noticed." By comparison, they note, "recovery of corals after the 1998 bleaching phenomenon in the Gulf of Mannar was very slow, taking as much as one year to achieve similar recovery." The Indian scientists state, "the process of natural selection is in operation, with the growth of new coral colonies, and any disturbance in the system is only temporary." They conclude, "the corals will resurge under the sea."

Rowan (2004) described how he measured the photosynthetic responses of two zooxanthellae genotypes or clades—*Symbiodinium C* and *Symbiodinium D*—to increasing water temperature and found the photosynthetic prowess of the former decreased at higher temperatures whereas that of the latter increased. He notes "adaptation to higher temperature in *Symbiodinium D* can explain why *Pocillopora* spp. hosting them resist warm-water bleaching whereas corals hosting *Symbiodinium C* do not," and "it can also explain why *Pocillopora* spp. living in frequently warm habitats host only *Symbiodinium D,* and, perhaps, why those living in cooler habitats predominantly host *Symbiodinium C*." These observations, he concludes, "indicate that symbiosis recombination may be one mechanism by which corals adapt, in part, to global warming."

Baker *et al*. (2004) "undertook molecular surveys of *Symbiodinium* in shallow scleractinian corals from five locations in the Indo-Pacific that had been differently affected by the 1997–98 El Niño-Southern Oscillation (ENSO) bleaching event." Along the coasts of Panama, they surveyed ecologically dominant corals in the genus *Pocillopora* before, during, and after ENSO bleaching, finding "colonies containing *Symbiodinium* in clade D were already common (43%) in 1995 and were unaffected by bleaching in 1997, while colonies containing clade C bleached severely." They found "by 2001, colonies containing clade D had become dominant (63%) on these reefs."

After describing similar observations in the Persian (Arabian) Gulf and the western Indian Ocean along the coast of Kenya, Baker *et al*. summarize say their results indicate "corals containing thermally tolerant *Symbiodinium* in clade D are more abundant on reefs after episodes of severe bleaching and mortality, and that surviving coral symbioses on these reefs more closely resemble those found in high-temperature environments," where clade D predom-

inates. They conclude by noting the symbiont changes they observed "are a common feature of severe bleaching and mortality events," and they predict "these adaptive shifts will increase the resistance of these recovering reefs to future bleaching."

Lewis and Coffroth (2004) described a controlled experiment in which they induced bleaching in a Caribbean octocoral (*Briareum* sp.) and then exposed it to exogenous *Symbiodinium* sp. containing rare variants of the chloroplast 23S ribosomal DNA (rDNA) domain V region (cp23S-genotype), after which they documented the symbionts' repopulation of the coral, whose symbiont density had been reduced to less than 1% of its original level by the bleaching. In an analogous study, Little *et al*. (2004) investigated the acquisition of symbionts by juvenile *Acropora tenuis* corals growing on tiles they attached to different portions of reef at Nelly Bay, Magnetic Island (an inshore reef in the central section of Australia's Great Barrier Reef).

Lewis and Coffroth state their results show "the repopulation of the symbiont community involved residual populations within *Briareum* sp., as well as symbionts from the surrounding water," noting "recovery of coral-algal symbioses after a bleaching event is not solely dependent on the *Symbiodinium* complement initially acquired early in the host's ontogeny," but "these symbioses also have the flexibility to establish new associations with symbionts from an environmental pool." Similarly, Little *et al*. report, "initial uptake of zooxanthellae by juvenile corals during natural infection is nonspecific (a potentially adaptive trait)," and "the association is flexible and characterized by a change in (dominant) zooxanthella strains over time."

Lewis and Coffroth conclude "the ability of octocorals to reestablish symbiont populations from multiple sources provides a mechanism for resilience in the face of environmental change." Little *et al*. conclude the "symbiont shuffling" observed by both groups "represents a mechanism for rapid acclimatization of the holobiont to environmental change."

Chen *et al*. (2005) reported on their study of the seasonal dynamics of *Symbiodinium* algal phylotypes via bimonthly sampling over an 18-month period of *Acropora palifera* coral on a reef flat at Tantzel Bay, Kenting National Park, southern Taiwan, in an attempt to detect real-world symbiont shuffling. They found two levels of symbiont shuffling in host corals: between *Symbiodinium* phylotypes C and D, and among different variants within each phylotype. The most significant changes in symbiont composition occurred at times of significant increases in seawater temperature during late spring and early summer, perhaps as a consequence of enhanced stress experienced at that time, leading Chen *et al*. to state their work revealed "the first evidence that the symbiont community within coral colonies is dynamic ... involving changes in *Symbiodinium* phylotypes."

Van Oppen *et al*. (2005) sampled zooxanthellae from three common species of scleractinian corals at 17 sites along a latitudinal and cross-shelf gradient in the central and southern sections of the Great Barrier Reef four to five months after the major bleaching event of 2002, recording the health status of each colony at the time of its collection and identifying its zooxanthella genotypes, of which there are eight distinct clades (A-H) with clade D being the most heat-tolerant. They found "there were no simple correlations between symbiont types and either the level of bleaching of individual colonies or indicators of heat stress at individual sites." They write, "there was a very high post-bleaching abundance of the heat tolerant symbiont type D in one coral population at the most heat-stressed site."

The Australian researchers say they suspect the post-bleaching abundance of clade D zooxanthellae at the high heat-stress site was due to "a proliferation in the absolute abundance of clade D within existing colonies that were previously dominated by clade C zooxanthellae." In the four to five months before sampling them, the writers note, "mixed C-D colonies that had bleached but survived may have shifted (shuffling) from C-dominance to D-dominance, and/or C-dominated colonies may have suffered higher mortality during the 2002 bleaching event" and subsequently been repopulated by a predominance of clade D genotypes.

Berkelmans and van Oppen (2006) investigated the thermal acclimatization potential of *Acropora millepora* corals at Australia's Great Barrier Reef to rising temperatures through transplantation and experimental manipulation. They found the adult corals "are capable of acquiring increased thermal tolerance and that the increased tolerance is a direct result of a change in the symbiont type dominating their tissues from *Symbiodinium* type C to D." Two years later, working with an expanded group of authors (Jones *et al*., 2008), the two researchers reported similar findings following the occurrence of a natural bleaching event.

Before that bleaching event, Jones *et al*. report, "*A. millepora* at Miall reef associated predominantly with *Symbiodinium* type C2 (93.5%) and to a much lesser extent with *Symbiodinium* clade D (3.5%) or mixtures of C2 and D (3.0%)." During the bleaching

event, they report, "the relative difference in bleaching susceptibility between corals predominated by C2 and D was clearly evident, with the former bleaching white and the latter normally pigmented," whereas corals harboring a mix of *Symbiodinium* C2 and D were "mostly pale in appearance." Three months after the bleaching event, they observed "a major shift to thermally tolerant type D and C1 symbiont communities ... in the surviving colonies"; the latter types had not been detected in any of the corals before bleaching. They report, "this shift resulted partly from a change of symbionts within coral colonies that survived the bleaching event (42%) and partly from selective mortality of the more bleaching-sensitive C2-predominant colonies (37%)." All of the colonies that harbored low levels of D-type symbionts before the bleaching event survived and changed from clade C2 to D predominance.

Jones *et al.* write, "as a direct result of the shift in symbiont community, the Miall Island *A. millepora* population is likely to have become more thermo-tolerant," as they note "a shift from bleaching-sensitive type C2 to clade D increased the thermal tolerance of this species by 1–1.5°C." They say their results "strongly support the reinterpreted adaptive bleaching hypothesis of Buddemeier *et al.* (2004), which postulates that a continuum of changing environmental states stimulates the loss of bleaching-sensitive symbionts in favor of symbionts that make the new holobiont more thermally tolerant." They state their observations "provide the first extensive colony-specific documentation and quantification of temporal symbiont community change in the field in response to temperature stress, suggesting a population-wide acclimatization to increased water temperature."

Lien *et al.* (2007) examined the symbiont diversity in a scleractinian coral, *Oulastrea crispata*, throughout its entire latitudinal distribution range in the West Pacific, from tropical peninsular Thailand (<10°N) to high-latitudinal outlying coral communities in Japan (>35°N). Those results convincingly demonstrate, the six scientists write, "that phylotype D is the dominant *Symbiodinium* in scleractinian corals throughout tropical reefs and marginal outlying non-reefal coral communities." They learned this particular symbiont clade "favors 'marginal habitats' where other symbionts are poorly suited to the stresses, such as irradiance, temperature fluctuations, sedimentation, etc." As a major component of the symbiont repertoire of most scleractinian corals in most places, the apparent near-universal presence of *Symbiodinium* phylotype D thus provides, Lien *et al.*

write, "a flexible means for corals to routinely cope with environmental heterogeneities and survive the consequences (e.g., recover from coral bleaching)."

Also in 2007, Mieog *et al.* (2007) utilized a newly developed real-time polymerase chain reaction assay, which they say "is able to detect Symbiodinium clades C and D with >100-fold higher sensitivity compared to conventional techniques," to test 82 colonies of four common scleractinian corals (*Acropora millepora*, *Acropora tenuis*, *Stylophora pistillata,* and *Turbinaria reniformis*) from 11 locations on Australia's Great Barrier Reef for evidence of the presence of background *Symbiodinium* clades. They found "ninety-three percent of the colonies tested were dominated by clade C and 76% of these had a D background." The latter symbionts, they write, "are amongst the most thermo-tolerant types known to date," being found "on reefs that chronically experience unusually high temperatures or that have recently been impacted by bleaching events, suggesting that temperature stress can favor clade D." Mieog *et al.* conclude the clade D symbiont backgrounds detected in their study may act as a safety net, "allowing corals to become more thermo-tolerant through symbiont shuffling as seawater temperatures rise due to global warming." They suggest symbiont shuffling is likely to play a role in the way "corals cope with global warming conditions," leading to new competitive hierarchies and, ultimately, "the coral community assemblages of the future."

Despite the hope symbiont shuffling provides—that corals will be able to cope with any future global warming, whether anthropogenic or natural—some researchers have claimed few coral symbioses host more than one type of symbiont, which has led some commentators to argue symbiont shuffling is not an option for most coral species to survive the coming thermal onslaught of global warming. That claim has been shown to be incorrect.

Working with samples of the widely distributed massive corals *Porites lobata* and *Porites lutea*—collected from Kaneohe Bay, Hawaii—Apprill and Gates (2007) compared the identity and diversity of *Symbiodinium* symbiont types obtained using cloning and sequencing of internal transcribed spacer region 2 (ITS2) with those obtained using the more commonly applied downstream analytical techniques of denaturing gradient gel electrophoresis (DGGE). The results revealed "a total of 11 ITS2 types in *Porites lobata* and 17 in *Porites lutea* with individual colonies hosting from one to six and three to eight ITS2 types for *P. lobata* and *P. lutea*, respectively." The two authors

report, "of the clones examined, 93% of the *P. lobata* and 83% of the *P. lutea* sequences are not listed in GenBank," noting they resolved "sixfold to eightfold greater diversity per coral species than previously reported."

In a "perspective" that accompanied Apprill and Gates' paper, van Oppen (2007) wrote, "the current perception of coral-inhabiting symbiont diversity at nuclear ribosomal DNA is shown [by Apprill and Gates] to be a significant underestimate of the wide diversity that in fact exists." These findings, in her words, "have potentially far-reaching consequences in terms of our understanding of *Symbiodinium* diversity, host-symbiont specificity and the potential of corals to acclimatize to environmental perturbations through changes in the composition of their algal endosymbiont community."

Baird *et al*. (2007) also discount the argument symbiont shuffling is not an option for most coral species, because it is the sub-clade that must be considered within this context, citing studies that indicate "there are both heat tolerant and heat susceptible sub-clades within both clades C and D *Symbiodinium*." Hence, the more relevant question becomes: How many coral species can host more than one sub-clade? The answer is that most, if not all, likely do. As Baird *et al.* note, "biogeographical data suggest that when species need to respond to novel environments, they have the flexibility to do so."

Although most prior research into how and when such sub-clade changes might occur has been on adult colonies switching symbionts in response to warming-induced bleaching episodes, Baird *et al*. suggest "change is more likely to occur between generations," because initial coral infection typically occurs in larvae or early juveniles, which are much more flexible than adults. They note, "juveniles of *Acropora tenuis* regularly harbor mixed assemblages of symbionts, whereas adults of the species almost invariably host a single clade," and larvae of *Fungia scutaria* ingest symbionts from multiple hosts, although they generally harbor but one symbiont as adults.

The Australian researchers say there is no need for an acute disturbance, such as bleaching, to induce clade or sub-clade change. Instead, if ocean temperatures rise in the future, they foresee juveniles naturally hosting more heat-tolerant sub-clades and maintaining them into adulthood.

In a further assessment of the size of the symbiont diversity reservoir, especially among juvenile coral species, Pochon *et al*. (2007) collected more than 1,000 soritid specimens over a depth of 40 meters on a single reef at Gun Beach on the island of Guam, Micronesia, throughout an entire year. They studied the specimens by means of molecular techniques to identify unique internal transcribed spacer–2 (ITS–2) types of ribosomal DNA (rDNA), in a project self-described as "the most targeted and exhaustive sampling effort ever undertaken for any group of *Symbiodinium*-bearing hosts."

Pochon *et al*. identified 61 unique symbiont types in only three soritid host genera, making the Guam *Symbiodinium* assemblage the most diverse derived to date from a single reef. They report, "the majority of mixed genotypes observed during this survey were usually harbored by the smallest hosts." The authors speculate "juvenile foraminifera may be better able to switch or shuffle heterogeneous symbiont communities than adults," so as juveniles grow, "their symbiont communities become 'optimized' for the prevailing environmental conditions," suggesting this phenomenon "may be a key element in the continued evolutionary success of these protests in coral reef ecosystems worldwide."

The work of Mumby (1999), who analyzed the population dynamics of juvenile corals in Belize both before and after a massive coral bleaching event in 1998, supports that statement. Although 70 to 90% of adult coral colonies were severely bleached during the event, only 25% of coral recruits exhibited signs of bleaching. One month after the event, they concluded "net bleaching-induced mortality of coral recruits ... was insignificant," demonstrating the ability of juvenile corals to successfully weather such bleaching events.

Fitt *et al*. (2009) note the various *Symbiodinium* clades that comprise the algal symbiont found in their coral host have been thought "to exert a major influence on the ability of reef-building corals to survive high-temperature stress." They add that if the host itself plays a role in this process, "the hypothesis that corals simply shuffle or swap their *Symbiodinium* for clades that are more thermally tolerant does not tell the whole story." In fact, it suggests corals may be even more adept at coping with rising temperatures than scientists previously believed.

Fitt *et al*. studied a number of coral host and *Symbiodinium* properties and processes in two ubiquitous Indo-Pacific reef corals known to be either very susceptible (*Stylophora pistillata*) or resistant (*Porites cylindrica*) to heat stress, exposing them to seawater temperatures of either 28°C (normal ambient) or 32°C (elevated) for five days before returning them to the normal ambient temperature. The 16 scientists report finding "both physiological

and biochemical differences of both symbiont and host origin in the response to high-temperature stress." They say "hypotheses that talk only in terms of the thermal characteristics of the symbiont may miss critical information concerning questions surrounding the thermal tolerance of corals in the coming century." They note "there are dynamic photoprotective mechanisms in both the host and zooxanthellae that include ultraviolet radiation absorbing mycosporine-like amino acids (Shick and Dunlap, 2002; Lesser, 2004), excess excitation energy dissipation in photosystem II via the xanthophyll cycle (Brown *et al*. 1999; Gorbunov *et al*., 2001), the expression of heat-shock proteins and other stress markers (Black *et al*., 1995; Downs *et al*., 2000; Lesser and Farrell, 2004), the up-regulation of antioxidant enzymes (Lesser, 1996; Lesser and Farrell, 2004; Lesser, 2006), host energy reserve utilization (Porter *et al*., 1989; Grottoli *et al*., 2004, 2006), and heterotrophic plasticity (Grotolli *et al*., 2006)." All of these phenomena, they write, "presumably have underlying influences on any response to thermal stress, and hence, contribute to the overall differences within and between species in regard to their bleaching sensitivity." This diverse group of phenomena that can help both the coral host and its algal symbionts adjust to rising temperatures indicate Earth's corals are well-equipped to deal with whatever further warming may come their way.

Silverstein *et al*. (2012) state many reef-building corals "have been shown to respond to environmental change by shifting the composition of their algal symbiont (genus *Symbiodinium*) communities," and "these shifts have been proposed as a potential mechanism by which corals might survive climate stressors, such as increased temperatures." They say "conventional molecular methods suggest this adaptive capacity may not be widespread because few (~25%) coral species have been found to associate with multiple *Symbiodinium* clades." They hasten to add, "these methods can fail to detect low abundance symbionts (typically less than 10–20% of the total algal symbiont community)."

To determine whether additional *Symbiodinium* clades might be present but undetected in various corals using conventional discovery and identification techniques, Silverstein *et al*. "applied a high-resolution, real-time PCR [polymerase chain reaction] assay to survey *Symbiodinium* (in clades A-D) from 39 species of phylogenetically and geographically diverse scleractinian corals." This survey, they write, "included 26 coral species thought to be restricted to hosting a single *Symbiodinium* clade," referring to the latter corals as symbiotic specialists.

The three U.S. scientists say they "detected at least two *Symbiodinium* clades (C and D) in at least one sample of all 39 coral species tested," and "all four *Symbiodinium* clades were detected in over half (54%) of the 26 symbiotic specialist coral species." They report, "on average, 68% of all sampled colonies within a given coral species hosted two or more symbiont clades." Silverstein *et al*. conclude, "the ability to associate with multiple symbiont clades is common in scleractinian (stony) corals," and in regard to coral-algal symbiosis, "specificity is rarely absolute." They conclude "the potential for reef corals to adapt or acclimatize to environmental change via symbiont community shifts may therefore be more phylogenetically widespread than has previously been assumed."

Cumbo *et al*. (2013) note "coral reefs thrive in part because of the symbiotic partnership between corals and *Symbiodinium*," but "the point at which symbiosis is established (i.e., larva vs. juvenile) remains uncertain, as does the source of free-living *Symbiodinium* in the environment." They investigated "the types of symbionts taken up by *Acropora* larvae exposed to sediments collected from three different locations on the Great Barrier Reef, and compared this to the *Symbiodinium* types within adult cnidarians for each location." In addition, they "tested whether the *Symbiodinium* types changed during ontogeny by comparing types within the larvae, juvenile and adults of the same species at each location."

The three researchers report, "*Symbiodinium* clearly reside in the sediments of shallow reef communities and are capable of initiating symbiosis with aposymbiotic coral larvae," and "the larvae of many species of corals are promiscuous, associating with multiple *Symbiodinium* types independent of coral species or location." Cumbo *et al*. say their findings suggest "as sea surface temperatures rise, the promiscuity of larvae could benefit corals by allowing them to acquire symbionts with the greatest heat tolerance in each new generation (LaJeunesse *et al*., 2004; Baird *et al*., 2007)." In addition, although "this mechanism of acclimatization will most likely be restricted to species that show horizontal transmission of symbionts," they note such species account for approximately 85% of all species.

6.1.2.2.3 Other Stress Response Strategies

The studies reviewed in this section examine other stress response strategies known to operate in corals under stressful conditions. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings.

- Some corals increase their expression of heat shock proteins that help repair heat-damaged constituents of their bodies as another strategy to cope with heat stress.

- The coral probiotic hypothesis, or bacterial shuffling, posits that many corals rearrange their bacterial populations in a manner akin to symbiont shuffling as another response to environmental stress.

- Corals employ other strategies of coping with and adapting to environmental stresses, further suggesting they will be able to continue to cope with the many environmental threats they face now and may face in the future.

In addition to thermal acclimation and symbiont shuffling, corals have other means to cope with and adapt to environmental stresses. One such mechanism is the production of heat shock proteins that help repair heat-damaged constituents of their bodies (Black *et al.*, 1995; Hayes and King, 1995; Fang *et al.*, 1997). Sharp *et al.* (1997), for example, demonstrated sub-tidal specimens of *Goniopora djiboutiensis* typically have much lower constitutive levels of a 70-kD heat shock protein than do their intertidal conspecifics, and they have shown corals transplanted from subtidal to intertidal locations (where temperature extremes are greater and more common) typically increase their expression of this heat shock protein.

Roberts *et al.* (1997) reported similar results in field work with *Mytilus californianus*. Gates and Edmunds (1999) observed an increase in the 70-kD heat shock protein after six hours of exposure of *Montastraea franksi* to a 2–3°C increase in temperature, followed by another heat shock protein increase at the 48-hour point of exposure to elevated water temperature. They state the first of these protein increases "provides strong evidence that changes in protein turnover during the initial exposure to elevated temperature provides this coral with the biological flexibility to acclimatize to the elevation in sea water temperature," and the second increase "indicates another shift in protein turnover perhaps associated with an attempt to acclimatize to the more chronic level of temperature stress."

Reshef *et al.* (2006) discussed another adaptive bleaching mechanism, developing a case for what they call the coral probiotic hypothesis, which might also be referred to as bacterial shuffling. This concept, they write, "posits that a dynamic relation-

ship exists between symbiotic microorganisms and environmental conditions which brings about the selection of the most advantageous coral holobiont." It is analogous to the adaptive bleaching hypothesis of Buddemeier and Fautin (1993), or what was referred to in the preceding section as symbiont shuffling, in which corals exposed to some type of stress—such as that induced by exposure to unusually high water temperatures or solar irradiance—first lose their dinoflagellate symbionts (bleach) and then regain a new mixture of zooxanthellae better suited to the stress conditions. The two phenomena work in precisely the same way, in one case by the corals rearranging their zooxanthellae populations (symbiont shuffling) and in the other by the corals rearranging their bacterial populations (bacterial shuffling).

The team of Israeli researchers looked for examples of corals developing resistance to emerging diseases. Corals lack an adaptive immune system—they possess no antibodies (Nair *et al.*, 2005)—and therefore can protect themselves against specific diseases in no other way than to adjust the relative sizes of the diverse bacterial populations associated with their mucus and tissues so as to promote the growth of those types of bacteria that tend to mitigate most effectively against the specific disease that happens to be troubling them.

Reshef *et al.* described the discovery that bleaching of *Oculina patagonica* corals in the Mediterranean Sea was caused by the bacterium *Vibrio shiloi*, together with the finding that bleaching of *Pocillopora damicornis* corals in the Indian Ocean and Red Sea was the result of an infection with *Vibrio coralliilyticus*. They report "during the last two years *O. patagonica* has developed resistance to the infection by *V. shiloi*," "*V. shiloi* can no longer be found on the corals," and "*V. shiloi* that previously infected corals are unable to infect the existing corals." They write, "by some unknown mechanism, the coral is now able to lyse the intracellular *V. shiloi* and avoid the disease." Because corals lack the ability to produce antibodies and have no adaptive immune system, the only logical conclusion to be drawn from these observations is that bacterial shuffling must be at work.

The Israeli scientists note "Hoegh-Guldberg (1999, 2004) has predicted that coral reefs will have only remnant populations of reef-building corals by the middle of this century," based on "the assumption that corals cannot adapt rapidly enough to the predicted temperatures in order to survive." They report considerable evidence has been collected in support of the adaptive bleaching hypothesis, and

they emphasize the hundreds of different bacterial species associated with corals "give the coral holobiont an enormous genetic potential to adapt rapidly to changing environmental conditions." They state, "it is not unreasonable to predict that under appropriate selection conditions, the change could take place in days or weeks, rather than decades required for classical Darwinian mutation and selection," and "these rapid changes may allow the coral holobiont to use nutrients more efficiently, prevent colonization by specific pathogens and avoid death during bleaching by providing carbon and energy from photosynthetic prokaryotes," of which they say there is "a metabolically active, diverse pool" in most corals.

Another example of adaptation to stress comes from studies of corals that exhibit a "zonation" of their symbiont taxa with depth, where symbiont algae that are less tolerant of intense solar radiation grow on corals at greater depths below the ocean surface (Rowan and Knowlton, 1995; Rowan et al., 1997). Researchers also have demonstrated zooxanthellae in corals possess a number of light-quenching mechanisms that can be employed to reduce the negative impacts of excess light (Hoegh-Guldberg and Jones, 1999; Ralph et al., 1999). Both the coral host and its symbionts also have the capacity to produce amino acids that act as natural "sunscreens" (Hoegh-Guldberg, 1999); and they can regulate their enzyme activities to enhance internal scavenging systems that remove noxious oxygen radicals produced in coral tissues as a result of high light intensities (Dykens and Shick, 1984; Lesser et al., 1990; Matta and Trench, 1991; Shick et al., 1996).

Another means corals can use to lessen the stress of solar irradiance is coral tissue retraction. Brown et al. (1994) studied the phenomenon in the scleractinian coral Coeloseris mayeri at coral reefs in Phuket, Thailand by examining the retraction and recovery of coral tissues over a tidal cycle. They found extreme tissue retraction occurred approximately 85 minutes after initial sub-aerial coral exposure. Tissue retraction did not involve any reduction in chlorophyll concentration or algae symbiont abundance; the tissues expanded over the coral skeletons to pre-retraction conditions following the return of the tide. The adaptive benefits of tissue retraction, the authors write, "include increased albedo, leading to a reduction in absorbed solar energy of 10%, ... and possible avoidance of photochemical damage or photoinhibition at high solar irradiance."

Nakamura and van Woesik (2001) evaluated the bleaching of large and small coral colonies along the western coast of Okinawa, Japan during the summers of 1998 and 2001, arguing small coral colonies should survive thermal and light stress more readily than large coral colonies based on mass transfer theory, which suggests rates of passive diffusion are more rapid for small colonies than for large colonies. Bena and van Woesik (2004) offer still another reason why large coral colonies may suffer more than small colonies during environmental conditions conducive to bleaching: Small Acropora recruits "contain high concentrations of fluorescent proteins (Papina et al., 2002), which have photoprotective properties (Salih et al., 2000)," and "a high concentration of photo-protective pigments in early life, when planulae are near the surface and as newly settled recruits, may facilitate survival during this phase as well as during stress events involving both high irradiance and thermal anomalies (van Woesik, 2000)."

In addition to the adaptive phenomena described above, Earth appears to possess a natural "heat vent" over the tropics that suppresses the intensity of temperature and/or solar radiation to which corals are exposed whenever dangerously high water temperatures are approached. According to Hoegh-Guldberg (1999), 29.2°C is the threshold water temperature above which significant bleaching can be expected to occur in many tropical corals. As Sud et al. (1999) have demonstrated, deep atmospheric convection is typically initiated whenever sea surface temperatures (SSTs) reach a value of about 28°C, so that an upper SST on the order of 30°C is rarely exceeded. As SSTs reach 28–29°C, the cloud-base air mass is charged with sufficient moist static energy for the clouds to reach the upper troposphere. At this point, the billowing cloud cover reduces the amount of solar radiation received at the surface of the sea, while cool and dry downdrafts produced by the moist convection tend to promote ocean surface cooling by increasing sensible and latent heat fluxes at the air-sea interface that cause temperatures there to decline. This "thermostat-like control," as Sud et al. describe it, tends "to ventilate the tropical ocean efficiently and help contain the SST between 28–30°C," which is essentially a fluctuating temperature band of ±1°C centered on the bleaching threshold temperature of 29.2°C identified by Hoegh-Guldberg.

Other intriguing observations indicate a natural phenomenon of this nature. Satheesh and Ramanathan (2000), for example, determined polluted air from south and southeast Asia absorbs enough solar radiation over the northern Indian Ocean during the dry monsoon season to heat the atmosphere there by 1–3°C per day at solar noon, thereby greatly reducing

the intensity of solar radiation received at the surface of the sea. Ackerman *et al*. (2000), however, calculated this atmospheric heating would decrease cloud-layer relative humidity and reduce boundary-layer mixing, thereby leading to a 25 to 50% drop in daytime cloud cover relative to that of an aerosol-free atmosphere, which could negate the surface cooling effect suggested by Satheesh and Ramanathan. In a test of this hypothesis based on data obtained from the Extended Edited Cloud Report Archive, Norris (2001) determined daytime low-level ocean cloud cover (which tends to cool the water surface) not only did not decrease from the 1950s to 1990s, it increased, in both the Northern and Southern Hemispheres and at essentially all hours of the day.

Norris remarks, "the observed all-hours increase in low-level cloud cover over the time period when soot aerosol has presumably greatly increased argues against a dominant effect of soot solar absorption contributing to cloud 'burn-off.'" He says "other processes must be compensating," one of which could be the phenomenon Sud *et al* described.

Another process is the "adaptive infrared iris" phenomenon Lindzen *et al*. (2001) described. Working with upper-level cloudiness data from the Japanese Geostationary Meteorological Satellite and SST data from the National Centers for Environmental Prediction, the atmospheric scientists found a strong inverse relationship between upper-level cloud area and the mean SST of cloudy regions, such that the area of cirrus cloud coverage (which tends to warm the planet) normalized by a measure of the area of cumulus coverage (which tends to cool the planet) decreased about 22 percent for each 1°C increase in the SST of the cloudy regions.

"Essentially," the scientists write, "the cloudy-moist region appears to act as an infrared adaptive iris that opens up and closes down the regions free of upper-level clouds, which more effectively permit infrared cooling, in such a manner as to resist changes in tropical surface temperatures." So powerful is this phenomenon, Lindzen *et al*. say they are confident it could "more than cancel all the positive feedbacks in the more sensitive current climate models" routinely used to predict the climatic consequences of projected increases in atmospheric CO_2 concentration.

Is there any real-world evidence the natural thermostat discovered by Sud *et al.* and Lindzen *et al.*. has been instrumental in preventing coral bleaching? Mumby *et al*. (2001) examined long-term meteorological records from the vicinity of the Society Islands, which provide what they call "the first empirical evidence that local patterns of cloud cover may influence the susceptibility of reefs to mass bleaching and subsequent coral mortality during periods of anomalously high SST." Regarding the great El Niño of 1998, Mumby and his colleagues determined SSTs in the Society Islands sector of French Polynesia were above the 29.2°C bleaching threshold for a longer period of time (two months) than in all prior bleaching years of the historical record. Mass coral bleaching, which was extensive in certain other areas, was found to be "extremely mild in the Society Islands" and "patchy at a scale of 100s of km."

What provided the coral relief from extreme sun and heat? As Mumby and his associates write, "exceptionally high cloud cover significantly reduced the number of sun hours during the summer of 1998," much as one would have expected Earth's natural thermostat to have done in the face of such anomalously high SSTs. The marine scientists also note extensive spotty patterns of cloud cover, besides saving most of the coral they studied, "may partly account for spatial patchiness in bleaching intensity and/or bleaching-induced mortality in other areas."

Although the natural thermostat cannot protect all of Earth's corals from life-threatening bleaching during all periods of anomalously high SSTs, it apparently protects enough of them enough of the time to ensure sufficiently large numbers of corals survive and grow, since living reefs have persisted over the eons in spite of the continuing recurrence of ever-present environmental threats. That may be how it has always been, although a host of unprecedented anthropogenic forces of site-specific origin might be weakening the abilities of some species to tolerate the thermal and solar stresses they have successfully weathered in the past.

Smith *et al*. (2005) note "photoinhibition of photosynthesis and photodamage to photosystem II of the zooxanthellae, with the consequent increase in the production of damaging reactive oxygen species (ROS), have been implicated as the cause of thermal bleaching (Brown, 1997; Fitt *et al*., 2001; Lesser, 2004; Tchernov *et al*., 2004)." They also report the "thermal bleaching of many corals is ultimately the result of the destruction of photosynthetic pigments by ROS," and the production by the zooxanthellae of one particular ROS, hydrogen peroxide, "may be a signal that triggers a response in the host cell to eject the zooxanthellae or shed the host cell from the coral."

These facts resonate with other findings presented in this volume (see Section 7.3, Health Effects of CO_2) and suggest the ongoing rise in the air's CO_2

content may ultimately provide the solution to the worldwide problem of heat-induced coral bleaching. This concept originates from research conducted in the terrestrial realm, which reveals, Ren *et al*. (2001) write, "elevated CO_2 can enhance the capacity of plants to resist stress-induced oxidative damage."

In the case of ozone pollution, the primary problems occur in the leaf mesophyll, where ozone dissolves into the wet surfaces of exposed cell walls. There, reactions of ozone with water and solutes in the apoplasm lead to the formation of several ROS, including hydrogen peroxide (H_2O_2), hydroperoxide, superoxide, hydroxyl radicals, and singlet oxygen (Foyer *et al*., 1994; Kangasjarvi *et al*., 1994; Wohlgemuth *et al*., 2002), all of which promote oxygen toxicity (Podila *et al*., 2001).

In a free-air CO_2 enrichment (FACE) study of this phenomenon in aspen and paper birch seedlings exposed to ambient air, ozone-enriched air, CO_2-enriched air, or air enriched with both ozone and CO_2, Oksanen *et al*. (2003) found H_2O_2 accumulation occurred only "in ozone-exposed leaves and not in the presence of elevated CO_2," adding "CO_2 enrichment appears to alleviate chloroplastic oxidative stress." Similarly, in a study of mature holm and white oak trees that had been growing near natural CO_2 springs in central Italy for 30 to 50 years, Schwanz and Polle (1998) found they exhibited significant reductions in their amounts of lipid peroxidation.

Yu *et al*. (2004) sought to ascertain whether the ROS-fighting properties of elevated CO_2 might also operate in the aquatic realm. They grew the marine microalgae *Platymonas subcordiformis* in the laboratory at ambient levels of atmospheric CO_2 and UV-B radiation flux density, and at elevated levels of 5,000 ppm CO_2 and/or UV-B radiation characteristic of what would result from a 25% stratospheric ozone depletion under clear sky conditions in summer. They found the elevated UV-B treatment significantly decreased microalgal dry weight and photosynthetic rate, whereas the elevated CO_2 treatment enhanced dry weight and photosynthetic rate. They also report elevated UV-B significantly increased the production of the toxic superoxide anion and hydrogen peroxide, as well as malonyldialdehyde, which is an end product of lipid peroxidation, whereas elevated CO_2 did just the opposite. In the treatment consisting of both elevated UV-B and elevated CO_2, the concentrations of these three substances were lower than those observed in the elevated UV-B and ambient CO_2 treatment.

Yu *et al*. say their results suggest "CO_2 enrichment could reduce oxidative stress of reactive oxygen species to *P. subcordiformis*, and reduce the lipid peroxidation damage of UV-B to *P. subcordiformis*." They note, "CO_2 enrichment showed a protective effect against the oxidative damage of UV-B-induced stress," and, therefore, elevated CO_2 can enhance "the capacity of stress resistance." They conclude, "algae grown under high CO_2 would better overcome the adverse impact of environmental stress factors that act via generation of activated oxygen species."

Smith *et al*. (2005) write, "thermal bleaching of many corals is ultimately the result of the destruction of photosynthetic pigments by ROS," and as Oksanen *et al*. (2003) observe, "CO_2 enrichment appears to alleviate chloroplastic oxidative stress." It is thus clear some as-yet-undefined level of atmospheric CO_2 enrichment could completely counter coral thermal bleaching. In addition, since the presence of hydrogen peroxide, as Smith *et al*. (2005) write, "may be a signal that triggers a response in the host cell to eject the zooxanthellae or shed the host cell from the coral," and as Yu *et al*. (2004) write, "CO_2 enrichment could reduce ... lipid peroxidation damage," it readily follows some degree of atmospheric CO_2 enrichment should cause host cells not to eject their zooxanthellae.

6.1.2.3 Resilience of Corals

The studies reviewed in this section examine observational evidence for the resilience of corals in responding to stress events that routinely occur in nature. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings.

- Corals have been around for a very long time, experiencing climatic conditions that have changed dramatically, from conditions both warmer and colder than the present.

- Many researchers have documented rapid recoveries of corals following recent mass bleaching/mortality events, and such recoveries have occurred on time scales previously assumed to be nearly impossible.

- A growing body of research indicates coral resilience is the rule, not the exception, and these findings are at odds with IPCC's projections of future coral demise.

As illustrated in the preceding section (6.1.2.2 Responses to Temperature-Related Stresses), numerous studies attest to the ability of corals to adapt and evolve in response to temperature-related stresses. Nevertheless, there have been many recorded instances where the severity of coral bleaching from temperature-related stresses was great enough to cause mass mortality of corals, and these occurrences have led IPCC to conclude corals are among the most vulnerable species of marine life, saying it "is *very likely* that coral reef ecosystems will not survive changes in sea temperature beyond an additional increase of 1°C." (p. 35 of Chapter 30. The Ocean, Working Group II, IPCC *Fifth Assessment Report*, dated March 28, 2013).

Corals, however, have been around for a very long time, experiencing climatic conditions that have changed dramatically, from conditions both warmer and colder than the present, suggesting they are much more resilient than IPCC claims.

The earliest coral reefs date to the Palaeozoic Era, more than 450 million years ago (Hill, 1956). The scleractinian corals, the major builders of the reefs of today (Achituv and Dubinsky, 1990), appeared in the mid-Triassic some 240 million years later (Hill, 1956), when Earth was considerably warmer than it is today (Chadwick-Furman, 1996). Although reef-building ceased for a time after the extinctions at the

end of the Triassic, the Scleractinia came back during the Jurassic (Newell, 1971; Veron, 1995) and continued to exhibit great robustness throughout the Cretaceous, even when temperatures were as much as 8–15°C higher (Chadwick-Furman, 1996; Veizer *et al.*, 1999), and atmospheric CO_2 concentrations two to seven times higher (Berner and Kothavala, 2001), than they are today.

At the end of the Cretaceous, 70% of the genera and one-third of the families of scleractinian corals disappeared (Veron, 1995) in the greatest biospheric extinction event in geological history, which may have been caused by a large asteroid impact (Alvarez *et al.*, 1980; 1984). They developed again, however, throughout the Cenozoic, particularly during the Oligocene and Miocene (Chadwick-Furman, 1996). Throughout the past two million years of the Pleistocene, they survived at least 17 glacial-interglacial cycles of dramatic climate change and sea-level fluctuation, successfully adapting, over and over again, to these enormous environmental challenges (Pandolfi, 1999). According to Benzie (1999), this evidence suggests "coral reef communities are relatively resilient, have survived previous global climate change, and appear likely to survive future changes."

Such resilience helps explain why many researchers have documented rapid recoveries of corals following recent mass bleaching/mortality events, on time scales previously assumed to be nearly impossible. As more research is conducted on this topic, it appears coral resilience is the rule, not the exception. These findings are vastly at odds with IPCC's projections of future coral demise.

An early example of such resilience was observed after the widespread bleaching of corals in the Indian and Pacific Oceans during the peak warmth of the 1998 El Niño, the deadly effects of which were described at the time as the most extensive ever seen. Many of the devastated corals were not expected to recover (Normile, 2000). But barely a year later many of the reefs were in fact recovering, with large amounts of new coral found in what had been made to look like "graveyards" by the prior year's marine heat wave. Normile quotes Terry Done of the Institute of Marine Science in Cape Ferguson as saying these real-world observations forced many people to admit coral reefs are indeed "more resilient than we had thought." Since that admission, many more studies have illustrated similar recoveries as scientists have investigated and tracked coral recoveries.

Kayanne *et al.* (2002) assessed coral cover within the reef flat of Shiraho Reef, Ishigaki Island (situated at the southernmost end of the Ryukyus Islands of Japan) just before, during, and six times after an unprecedented bleaching event that began in early July 1998 and ended in early October of that year. They note "massive *Porites* were susceptible to bleaching, but regained their algae after the bleaching and sustained their coverage." Branching *Porites*, *Montipora,* and *Acropora* corals experienced significant mortality of 41.1%, 55.4%, and 82.4%, respectively, and approximately two-thirds of the surviving corals were completely or partly bleached. Nevertheless, coverage of large patches of the branching *Montipora* coral, initially reduced by 66%, recovered to pre-bleaching levels after two years.

Kayanne *et al.* note "the recovery of corals to their pre-bleaching levels has been inferred to take from 10 to 30 years for damaged coral populations and from 5 to 10 years for bleached corals that do not die (Hoegh-Guldberg, 1999; Wilkinson *et al.*, 1999)." Shiraho Reef, they report, "is recovering at an unexpectedly fast rate." The authors conclude, "even susceptible species have a high potential to regain zooxanthellae after bleaching or to recover after mortality."

Adjeroud *et al.* (2005) initiated a monitoring program on 13 islands (eight atolls and five high volcanic islands) in four of the five archipelagoes of French Polynesia, to document the effects of natural perturbations on coral assemblages. For the period covered by their report (1992–2002), these reefs were subjected to three major coral bleaching events (1994, 1998, 2002) and three cyclones (1997), and before this period the sites had experienced an additional seven bleaching events and 15 cyclones as well as several *Acanthaster planci* outbreaks.

They found the impacts of the bleaching events varied among the different study locations. They observed three temporal trends: "(1) ten sites where coral cover decreased in relation to the occurrence of major disturbances; (2) nine sites where coral cover increased, despite the occurrence of disturbances affecting seven of them; and (3) a site where no significant variation in coral cover was found." They report, "an interannual survey of reef communities at Tiahura, Moorea, showed that the mortality of coral colonies following a bleaching event was decreasing with successive events, even if the latter have the same intensity (Adjeroud *et al.*, 2002)."

The seven French scientists say the "spatial and temporal variability of the impacts observed at several scales during the present and previous surveys may reflect an acclimation and/or adaptation of local populations," and "coral colonies and/or their

endosymbiotic zooxanthellae may be phenotypically (acclimation) and possibly genotypically (adaptation) resistant to bleaching events," citing Rowan *et al*. (1997), Hoegh-Guldberg (1999), Kinzie *et al*. (2001), and Coles and Brown (2003) in support of this conclusion.

Pratchett *et al*. (2013) developed a history of variations in coral bleaching among four key genera of reef-building corals (*Acropora*, *Montipora*, *Pocillopora,* and *Porites*) in Moorea, focusing on four mass-bleaching events that occurred there in 1991, 1994, 2002, and 2007. They documented the history of the bleaching susceptibility of each of the four coral genera in each of the four events, finding "*Acropora* and *Montipora* consistently bleached in far greater proportions than *Pocillopora* and *Porites*." They also found "an apparent and sustained decline in the proportion of colonies that bleached during successive bleaching events, especially for *Acropora* and Montipora." In 2007, for example, only 77% of *Acropora* colonies bleached compared with 98% in 1991. They acknowledge "temporal variation in the proportion of coral colonies bleached may be attributable to differences in environmental conditions among years" but also state, "alternately, the sustained declines in bleaching incidence among highly susceptible corals may be indicative of acclimation or adaptation." Pratchett *et al*. suggest it may be "that gradual removal of highly susceptible genotypes (through selective mortality of individuals, populations, and/or species) is producing a coral assemblage that is more resistant to sustained and ongoing ocean warming," which further suggests "there is some capacity for adaptation, which will delay devastating effects of global climate change."

Golbuu *et al*. (2007) examined recovery rates of coral communities on the Palauan reef complex of Micronesia (7°30'N, 134°30'E) at two depths (3 and 10 m) at several sites (nine outer-reef wave-exposed sites, four on the east coast and five on the west coast; two patch reef sites; and two sheltered-bay sites) three, four, and seven years after the 1998 El Niño-Southern Oscillation (ENSO)-induced bleaching event. The nine researchers report, "coral populations recovered rapidly on the reefs of Palau," but "recovery trajectories changed over time and were habitat and depth-dependent," noting "seven years after the bleaching event, some reefs supported >30% coral cover, and some habitats supported >40% coral cover." They observe "recovery within the bays at 3 m was mostly a consequence of growth of remnant (surviving) coral colonies, while recovery on the exposed slopes was mostly likely a consequence of

both remnant regrowth and sexual recruitment events at 10 m, and more a consequence of recruitment at 3 m."

Guzman and Cortes (2007) studied coral reefs of the eastern Pacific Ocean that "suffered unprecedented mass mortality at a regional scale as a consequence of the anomalous sea warming during the 1982–1983 El Niño." At Cocos Island (5°32'N, 87°04'W), they found in a survey of three representative reefs, which they conducted in 1987, the remaining live coral cover was only 3% what it had been before the great El Niño four years earlier (Guzman and Cortes, 1992). Based on this finding and the similar observations of other scientists at other reefs, they predicted "the recovery of the reefs' framework would take centuries, and recovery of live coral cover, decades."

In 2002, nearly 20 years after the disastrous coral-killing warming, they returned to see how accurate their prediction had been, quantifying "the live coral cover and species composition of five reefs, including the three previously assessed in 1987." The two researchers report overall mean live coral cover increased nearly fivefold, from 2.99% in 1987 to 14.87% in 2002, at the three sites studied during both periods, and the mean live coral cover of all five sites studied in 2002 was 22.7%. They found "most new recruits and adults belonged to the main reef building species from pre–1982 ENSO, *Porites lobata*, suggesting that a disturbance as outstanding as El Niño was not sufficient to change the role or composition of the dominant species."

The 1998 El Niño-induced bleaching episode severely affected most Indian Ocean reefs, with the Maldives suffering 90% coral mortality in their central atolls. Before this mass mortality, Lasagna *et al*. (2008) write, "hard coral cover was generally between 30 and 60%, often reaching 100% in shallow water." One year later, they report, "coral cover had decreased to less than 8%, and reefs were dominated by algae."

In April 2006, Lasagna *et al*. "re-examined the status of the Maldivian reefs, focusing on their benthic composition to evaluate the possible change in dominance from hard corals to non-constructional organisms such as soft corals, algae or sponges," which have been predicted to replace hard corals after major bleaching episodes. The seven Italian scientists report, "eight years after the 1998 coral mass mortality, hard coral cover varied from 12% to 37%," and "cover of soft corals, algae and sponges was comparatively low (approximately 7% on average)." They say "a recent inventory of coral species showed

that their number is larger than that known before 1998 (Pichon and Benzoni, 2007)."

McClanahan *et al.* (2009) conducted surveys of coral reefs in northern Tanzania "in 2004/5 with the aim of comparing them over an ~8-year period during a time of increased efforts at fisheries management and the 1998 El Niño Southern Oscillation (ENSO) and Indian Ocean Dipole coral mortality event that caused 45% mortality in northern Tanzania and much of the Indian Ocean." The Kenyan, Swedish, Tanzanian, and U.S. researchers report their repeated surveys "indicate general stability of these reefs over time," and "in the context of the high bleaching and mortality of western Indian Ocean reefs after 1998 (Goreau *et al.*, 2000; McClanahan *et al.*, 2007), the general stability and improvement of these reefs six to seven years after the largest ENSO in recent history (McPhaden, 1999) indicates reefs with considerable resilience to climate change."

Because "all reefs exhibited some resilience and ecological stability and even improvements during this time of climate and management change," McClanahan *et al.* conclude this observation "creates considerably more optimism for poor countries, such as Tanzania, to effectively manage their reefs in an environment of climate change." They conclude, "Tanzanian and possibly many other reefs that exhibit similar environmental conditions have the ability to recover from large-scale climatic and human disturbances."

Scopelitis *et al.* (2009) sought to determine the responses of corals of Saint-Leu Reef on la Reunion (a mountainous volcanic island of the Mascarene Archipelago in the Southwest Indian Ocean) to major devastating events that occurred there over the prior 35 years (between 1973 and 2007), including a category 5 cyclone (Firinga, of 29 January 1989). These events "caused 99% coral cover loss (Naim *et al.*, 1997)." A severe coral bleaching event in March 2002 followed on the heels of cyclone Dina of January 2002, and other bleaching episodes occurred in 1983, March–April 1987, and February 2003.

Scopelitis *et al.* studied vertical images of the reef provided by five aerial photographs taken in 1973, 1978, 1989, 1997, and 2003, along with two Quick-bird satellite images taken in 2002 and 2006, as well as periodic quantitative *in situ* observations of parts of the reef-top that could be used to document ecological and substratum characteristics that produce the color and texture observable in the photos and satellite images. From these observations they constructed a history of changes in the reef's coral community over a period of 35 years (1973–2007).

"Despite the multiple disturbance events," the six scientists write, "the coral community distribution and composition in 2006 on Saint-Leu Reef did not display major differences compared to 1973." This pattern of recurrent recovery is truly remarkable, especially since "in the wake of cyclone Firinga, Saint-Leu Reef phase-shifted and became algae-dominated for a period of five years," and even more impressive given that no corals had survived an unnamed cyclone of 27 January 1948. Such findings, the Australian and French researchers write, indicate "a high degree of coral resilience at the site, led by rapid recovery of compact branching corals."

According to Crabbe (2009), "coral reefs throughout the world are under severe challenges from a variety of environmental factors including overfishing, destructive fishing practices, coral bleaching, ocean acidification, sea-level rise, algal blooms, agricultural run-off, coastal and resort development, marine pollution, increasing coral diseases, invasive species, and hurricane/cyclone damage."

Crabbe employed a number of tools to analyze the resilience of the fringing reefs around Discovery Bay, Jamaica, documenting the responses of their populations "to a number of environmental stressors, in particular hurricanes and the mass bleaching event of 2005," which he describes as "by far the major acute influence on the reef sites." The UK researcher reports "there was a reduction in numbers of colonies in the smallest size class for all the species at all the sites in 2006, after the mass bleaching of 2005, with subsequent increases for all species at all sites in 2007 and 2008." At Dairy Bull Reef, he notes, "live coral cover increased from $13 \pm 5\%$ in 2006 to $20 \pm 9\%$ in 2007 and $31 \pm 7\%$ in 2008," and "live *Acropora* species increased from $2 \pm 2\%$ in 2006 to $10 \pm 4\%$ in 2007 and $22 \pm 7\%$ in 2008."

The UK researcher concludes his results "indicate good levels of coral resilience on the fringing reefs around Discovery Bay in Jamaica," even after having "suffered from long term human-induced chronic stressors, such as overfishing and land development," along with "die-off of the long-spined sea urchin" and "coral disease." Crabbe states he and a colleague "found a variety of clades of zooxanthellae, including clade C, in corals at Dairy Bull Reef (Crabbe and Carlin, 2007)," and "the potential for symbiont shuffl-ing, as we have found in 111 colonies of *Acropora* species from the Ningaloo Reef, Australia (Crabbe and Carlin, 2009), may be a factor in their recovery," citing Stat *et al.* (2008).

In early 2006, mass bleaching of corals on

inshore reefs of the Keppel Islands in the southern Great Barrier Reef (GBR) caused high coral mortality, with severe bleaching affecting 77–95% of coral colonies (Weeks *et al.*, 2008; Jones *et al.*, 2008). This event, Diaz-Pulido *et al.* (2009) write, was followed by "an extraordinary bloom of the brown seaweed *Lobophora variegata*," which was "unprecedented in magnitude on the GBR" and "exacerbated coral mortality by overgrowing stressed coral tissue." After the natural seasonal decline in *L. variegata*, which in some places had increased its cover by 200–300% by August 2006, "the cover of branching *Acropora* corals at most sites showed an extremely rapid recovery," the Australian researchers write, "reaching pre-bleaching levels by December 2006–April 2007 ca 12–14 months after the onset of bleaching."

"Unexpectedly," as they describe it, "this rapid reversal did not involve reestablishment of corals by recruitment of coral larvae, as often assumed, but depended on several ecological mechanisms previously underestimated." Most interesting in this regard was "the 'phoenix effect' in which apparently dead coral branches regenerate live tissue (Krupp *et al.*, 1993; Jokiel *et al.*, 1993; Riegl and Piller, 2001)." This "remnant surviving coral tissue," Diaz-Pulido *et al.* continue, "rapidly expanded upwards along the dead coral branches and actively overgrew *L. variegata*, as well as a range of other algal types, including filamentous algal turfs, fleshy seaweeds and crustose coralline algae," resulting in "a 'seaweed sandwich' with algae engulfed between new and old layers of [coral] skeleton."

Noting reefs of the Keppel Islands "have shown rapid recovery of coral dominance, despite repeated coral bleaching events (1998, 2002, and 2006), severe flood plumes (e.g. 1991, 2008), and dense algal over-growth," Diaz-Pulido *et al.* conclude these and other reefs that are "able to rapidly recover abundant corals may serve as key refugia, or sources of larvae for reef recovery at broader scales," and the phenomena they document in their research "may well be critical to the overall resilience and persistence of coral reef ecosystems globally."

Bruno *et al.* (2009) recognized additional resili-ence of corals against algal growth that often ensues after a bleaching event, noting one of the great concerns of marine scientists is "coral reefs are moving toward or are locked into a seaweed-dominated state." Bruno *et al.* "analyzed 3,581 quan-titative surveys of 1,851 reefs performed between 1996 and 2006 to determine the frequency, geo-graphical extent, and degree of macroalgal dominance

of coral reefs and of coral to macroalgal phase shifts around the world."

The five marine researchers found "the replace-ment of corals by macroalgae as the dominant benthic functional group is less common and less geo-graphically extensive than assumed," noting "only 4% of reefs were dominated by macroalgae (i.e., >50% cover)." Across the Indo-Pacific, where regional averages of macroalgal cover were 9–12%, they found "macroalgae only dominated 1% of the surveyed reefs." In addition, "between 1996 and 2006, phase shift severity decreased in the Caribbean, did not change in the Florida Keys and Indo-Pacific, and increased slightly on the Great Barrier Reef."

Bruno *et al.* state "coral reef ecosystems appear to be more resistant to macroalgal blooms than assum-ed," and "the mismatch between descriptions of reef degradation in the literature and patterns in nature was caused by the generalization of a relatively small number of examples." They conclude their analysis suggests "the macroalgae problem has been exag-gerated," and "overall," there has been "no general recent trend (i.e., post–1995) toward macroalgal dominance." They write, "macroalgal cover may currently be close to the historical baseline across most of the world."

Zapata *et al.* (2010) developed an extended history from data they obtained over the period 1998–2004 from 20 permanent transects at two sites on one of the largest and best developed coral reefs in the Colombian Pacific (La Azufrada reef on Gorgona Island), plus data obtained there even earlier by others. The four Colombian researchers report comparisons with previous studies showed the reef at La Azufrada returned to "pre-disturbance (1979) levels of coral cover within a 10-year period after the 1982–83 El Niño, which caused 85% mortality," and subsequently, "the effects of the 1997–98 El Niño, indicated by the difference in overall live coral cover between 1998 and 1999, were minor (<6% reduction)." They report "despite recurrent natural disturbances, live coral cover in 2004 was as high as that existing before 1982 at La Azufrada." Zapata *et al.* conclude "the recent history of La Azufrada reef since coral reef studies began at Gorgona Island three decades ago (Prahl *et al.*, 1979; Glynn *et al.*, 1982) suggests a remarkable ability of this reef to recover from past perturbations," which are of the type (extreme El Niño-driven temperature increases leading to coral bleaching) IPCC claims should be especially deadly and from which coral recovery should not be expected.

According to van Woesik *et al.* (2011), "over the

past three decades, thermal stress events have damaged corals globally," but few studies "have tracked the recovery process or assessed whether winners in the short term are also winners in the long term." They repeatedly evaluated (1997, 1999, 2000, 2001, 2004, 2007, 2010) a coral assemblage on the southeastern reef of Sesoko Island at the Tropical Biosphere Research Center of the University of the Ryukyus, Okinawa, Japan (26°38'N, 127°52'E), which experienced significant thermal stress events in 1998 and 2001.

The four researchers report, "by 2007, species richness had recovered to ~13 species per m^2, which was similar to species richness in 1997," and "hard coral cover increased from 3% in 2001 to 47% in 2010." They also found "species composition had undergone change," as "some species were thermally tolerant and increased in relative abundance through time," some "increased in relative abundance through the thermal stress and remained constant thereafter," and some "were neither winners nor losers through time."

Van Woesik *et al.* conclude the ecosystem they studied was "able to absorb the thermal stressors without undergoing change to a less desirable state," citing the similar findings of Holling (1973) and Scheffer and Carpenter (2003). They note "*Acropora* populations had fully recovered seven years after an extreme thermal-stress event in Palau (Golbuu *et al.*, 2007)," and in the Arabian Gulf, "Riegl and Purkis (2009) showed that *Acropora* assemblages could recover from thermal-stress cycles occurring every fifteen years."

Marimuthu *et al.* (2013) investigated the recovery of the corals in the Andaman and Nicobar Islands in the eastern part of the Bay of Bengal following a significant warming event in summer 2010. At the time, sea surface temperatures (SSTs) rose to about 34°C, resulting in the bleaching of 74 to 77% of the corals surrounding Havelock Island and Port Blair Bay, respectively. Marimuthu *et al.* utilized pre-bleaching population data obtained by the line inter-cept transect (LIT) method of English *et al.* (1997) in July 2010, along with post-bleaching data they collected in January 2011 for the most severely affected corals, which included *Acropora cerealis, A. humilis, Montipora* sp., *Favia pallida, Diploastrea* sp., *Goniopora* sp., *Fungia concinna, Gardinero-series* sp., *Porites* sp., *Favites abdita,* and *Lobo-phyllia robusta.* They found "the observed post bleaching recovery [January 2011] of coral cover was 21.1% at Port Blair Bay and 13.29% at Havelock Island," and "once the sea water temperature resumed back to the normal condition, most of the corals where found recovered."

Gilmour *et al.* (2013) note, "coral reef recovery from major disturbance is hypothesized to depend on the arrival of propagules from nearby undisturbed reefs," and, therefore, "reefs isolated by distance or current patterns are thought to be highly vulnerable to catastrophic disturbance." In a test of this hypothesis, Gilmour *et al.* set out to "document the recovery of coral assemblages at Australia's largest oceanic reef system, where changes in assemblage structure and key demographic parameters were quantified for 16 years, through a regime of disturbances beginning with a catastrophic mass bleaching event in 1998." The authors focused on "the Scott system of reefs, which is surrounded by oceanic waters on the edge of Western Australia's continental shelf" and is "more than 250 km from the mainland and other reefs in the region, and more than 1000 km from a major center of urbanization."

The five Australian researchers report finding "for 6 years, recruitment rates were <6% of those prior to the disturbance," and "on the basis of these rates of change," they say "recovery was projected to take decades." Within just 12 years, "coral cover, recruitment, generic diversity, and community structure were again similar to the pre-bleaching years." The coral recovery "may have been even faster if not for a series of more moderate disturbances, including two cyclones, an outbreak of disease, and a second bleaching."

Gilmour *et al.* say their results demonstrate "even corals with a negligible supply of larvae from outside can recover relatively quickly from disturbances in the absence of chronic human pressures." They suggest "addressing local pressures, such as pollution and overfishing, is as important to the recovery of coral reefs as the establishment of networks of marine protected areas." They conclude, "managing local pressures to promote resilience will be critical to preventing the global degradation of coral reefs," which is true of several other damaging phenomena, many of which have particular application to Australia's Great Barrier Reef. These include rising nutrient levels caused by runoff from agricultural activity on land; outbreaks of the coral-devouring crown-of-thorns starfish; the barbed hooks and scything nets used in fishing; tourists and the developers who build resorts and marinas for them; increased sediment levels; the nets of prawn trawlers stirring up the growing load of sediments; the 6–10 tons of "bycatch" for each ton of prawns netted that are caught and die, which dramatically changes the

composition of reef life; sea life depleted to the point of exhaustion by over-fishing; huge catamarans and dive boats that take thousands of visitors to the Barrier Reef each day and dump their sewage in the sea on the way home; the live reef-fish trade; fishermen using dynamite and cyanide; coral diseases; and pollution.

Mondal *et al*. (2013) studied the fringing reefs off Little Andaman Island at the juncture of the Bay of Bengal and the Andaman Sea. A number of such reefs were essentially destroyed when a 2004 tsunami swept across them with devastating consequences. Five years later in 2009, however, 34 species of scleractinian corals had reappeared (Sawall *et al*., 2010). But the next year brought a massive bleaching event caused by a dramatic increase in sea surface temperatures above their normal average ranges (Mondal and Raghunathan, 2011), after which Mondal *et al*. (2013) found "the bleached corals were transformed mostly into dead ones."

In February 2012 the three Indian researchers dove to depths of up to 35 meters to identify and record what species of scleractinian corals they encountered at three locations around Little Andaman Island. They employed the line intercept transect method (Bradbury *et al*., 1886) with a series of 20-meter transects randomly placed at intervals of 10 meters, with three replicates of the procedure carried out at depths of 5, 10, 15, 20, 25, 30, and 35 meters. They discovered 124 species of youthful scleractinian corals, 90 more than the 34 species detected by Sawall *et al*. in 2009. Mondal *et al*. report the minimum value of the Shannon-Weaver Diversity Index was 5.09, which they state "is above the optimum hypothetical value," whereas the minimum value of Simpson's Density Index was 0.94, which they report "is very near to the maximum value which is most advantageous."

In light of these observations and because "bleaching was the only physiological process which happened in between 2009 and 2012," Mondal *et al*. conclude "bleaching is a prime regulator for the settlement of new recruitment of scleractinian corals which leads to diversified reef area," further noting "the adaptive features of bleaching can be seen as a mechanism that enables the exchange of symbionts in a better fit of the holobiont to a changed environment," citing Graham *et al*. (2011).

According to Miranda *et al*. (2013), sub-lethal bleaching effects "occur when corals do not experience mortality after bleaching, but rather undergo a temporary loss of zooxanthellae and/or of their photosynthetic pigments, with later recovery." This implies, they write, "corals have an adaptive capacity or resistance to seasonal changes in environmental conditions," as suggested by Buddemeir and Fautin (1993), Hennige *et al*. (2010), and Hughes *et al*. (2011).

The three Brazilian researchers note "thermal anomalies on the Brazilian coast have been monitored by NOAA satellite imaging since 1998." They also observe, "there have been many reports of bleaching events occurring in association with ocean warming events," but "only Dutra *et al*. (2000) reported observations of the reefs after the occurrence of the beaching phenomenon." They studied the effects of bleaching in the corals of Caramuanas reef—comprised of three main flat reef banks (13°07'S, 38°43'W; 13°07'S, 38°44'W; 13°08'S, 38°44'W)—by comparing them during and immediately after the thermal anomalies related to the ENSO event of 2010 in terms of "frequency and severity of bleaching, live coral cover, number of colonies, class size, disease occurrence and mortality rate," based on samples taken at 12 fixed transects in three reef locations.

Miranda *et al*. found, "after this bleaching event, neither the rate of mortality nor the number of colonies with disease increased; the size class structure of the most abundant species did not vary; and the number of live colonies and live coral cover also remained the same." They report, "the reef showed certain resilience to the perturbations caused by the 2010 ENSO event." In further support of their findings, they write, "the sub-lethal effects of bleaching in Brazilian corals have been observed previously," noting, "in 1998, the northern littoral of Bahia experienced a bleaching event that affected up to 60% of the coral community, which after one year have completely recovered," as reported by Dutra *et al*. (2000).

Miranda *et al*. point out, "the Brazilian zooxanthellate coral fauna is characterized by endemic species, with some reminiscent of a Tertiary coral fauna that may be adapted to these inhospitable environment conditions," citing Leao *et al*. (2003). They cite as some examples various species of the genus *Mussismilia*, as these species had "the lowest percent of bleached colonies," adding, "those that bleached completely recovered during this investigation." With respect to potential policy implications of their findings, the Brazilian biologists suggest "eliminating or reducing anthropogenic effects on this reef may increase its resistance and resilience to bleaching, allowing its maintenance," so "the Caramuanas reef could then act as a reserve of species and genes for this geographic region."

Earth's corals likely will be able to cope with any further increases in water temperatures, anthropogenic or natural. Corals have survived such warmth and worse many times in the past, including the Medieval Warm Period, Roman Warm Period, and Holocene Optimum, as well as numerous times during prior interglacial periods. There is no reason to think they cannot do so again if the need arises.

6.1.2.4 Sea-level Rise

The studies reviewed in this section examine the threat potentially large increases in sea level may pose to corals. The key findings are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- The warming-induced sea-level rise predicted for the coming century—which could be greatly exaggerated if predictions of CO_2-induced global warming are wrong—falls well within the range of typical coral vertical extension rates and can be less than half the rate of certain branching corals.

- Most coral reefs are known to have responded successfully to the sea-level rises that occurred between 14,000 and 6,000 years ago, which were more than twice as rapid as what is being predicted for the coming century.

- Earth's oceans have undergone, and their coral reefs survived, at least 17 major cycles of sea-level rise and fall during the Pleistocene, the most recent low phase of which ended 18,000 years ago with a global sea level some 120–135 meters below where it is today.

- Even if reef vertical growth rates could not keep up with rising sea levels, that would not spell their doom, as "propagules of the species could keep pace and settle at suitable depths each generation."

- Rising sea levels likely would benefit many coral reefs. Over the past 6,000 years, relatively stable sea levels have limited upward reef growth, resulting in the development of extensive reef flats. Rising sea levels likely would release them from this vertical constraint.

Some researchers claim CO_2-induced global warming will melt large portions of planetary ice, thereby raising sea levels at a rate faster than corals can adjust to, while reducing the amount of life-sustaining light

that reaches coral algal symbionts. Such concerns are overblown and unlikely to occur, as discussed in the studies reviewed below.

The approximate 30- to 60-cm warming-induced sea-level rise that is predicted for the coming century—which could turn out to be greatly exaggerated if predictions of CO_2-induced global warming are wrong—falls well within the range (2 to 6 mm per year) of typical coral vertical extension rates, which exhibited a modal value of 7 to 8 mm per year during the Holocene and can be more than double that value in certain branching corals (Hopley and Kinsey, 1988; Done, 1999). Moreover, most coral reefs are known to have responded successfully to the sea-level rises that occurred between 14,000 and 6,000 years ago, which were accompanied by large changes in "CO_2 concentrations, ... rainfall, cloud cover, storms and currents" (Wilkinson, 1996), and which were more than twice as rapid as what is being predicted for the coming century (Digerfeldt and Hendry, 1987).

Earth's oceans have undergone, and their coral reefs have survived (Chadwick-Furman, 1996), at least 17 major cycles of sea-level rise and fall during the Pleistocene, the most recent low phase of which ended 18,000 years ago with a global sea level some 120–135 meters below where it is now (Grigg and Epp, 1989). And most coral reefs handle increases in sea level, even rapid increases, much better than decreases (White *et al.*, 1998).

Even if reef vertical growth rates could not keep up with rising sea levels, that would not spell their doom. One of the important characteristics of essentially all reef cnidarians is their ability to produce free-swimming planulae, spores, or dispersive larval stages. Kinzie (1999) notes, "no matter how quickly sea level might rise, propagules of the species could keep pace and settle at suitable depths each generation," thereby creating what he calls jump-up reefs that "might well contain most of the species present in the original community." Done (1999) notes "coral communities have a history of tracking their preferred environmental niche which may suggest that as an entity, they will be predisposed to 'adapt' to prospective changes in environment over the next century," citing precedents that clearly demonstrate "coral communities have historically had a good capacity to track their re-distributed preferred physical niches."

As Kinzie and Buddemeier (1996) recount, coral reefs have survived many periods of "massive environmental changes" throughout the geologic record. Reefs are survivors, they state, "because they do not simply tolerate environmental changes" but "exhibit an impressive array of acclimations" that allow them to deal with a variety of challenges to their continued existence in any given area. It is highly unlikely anticipated increases in sea level would spell the doom of Earth's corals.

Rising sea levels may actually have a *positive* effect on coral reefs (Roberts, 1993). Over the past 6,000 years, relatively stable sea levels have limited upward reef growth, resulting in the development of extensive reef flats. As Buddemeier and Smith (1988) and Wilkinson (1996) have noted, the sea-level rises predicted to result from CO_2-induced global warming should be beneficial, permitting increased growth in these growth-restricted areas. As Chadwick-Furman (1996) noted, "many coral reefs have already reached their upward limit of growth at present sea level (Buddemeier, 1992), and may be released from this vertical constraint by a rise in sea level." She also notes rising sea levels may allow more water to circulate between segregated lagoons and outer reef slopes, which could "increase the exchange of coral propagules between reef habitats and lead to higher coral diversity in inner reef areas." She, too, concludes "coral reefs are likely to survive predicted rates of global change."

6.1.3 Crustaceans

The studies reviewed in this section examine the impact of rising temperatures on crustacean species. The key findings, which challenge the alarming and negative projections of IPCC, are presented in the bullet points below, followed by an expanded discussion of those findings. (Citations for passages in quotation marks in the bullet points are included in the main body of the section.)

- The larval form of the kelp crab is capable of adapting to both higher and lower temperatures than those at which it may have lived for long periods in the past.

- At higher temperatures, red king crab (*Paralithodes camtschaticus*) experienced "accelerated growth" and a "positive, indirect effect on survival," as "larger size associated with high temperature could provide for earlier refuge in size from the typical fish and invertebrate predators."

- A modest warming would prove advantageous to hymenosomatid crabs, increasing larval growth and survival rates, as well as fecundity.

- European green crabs (*Carcinus maenas*) on the west coast of North America have demonstrated phenotypic thermal tolerance and adaptation.

- *Palaemonetes varians*, a shallow-water brackish shrimp, "shows genuine acclimation capacities" due to the plasticity inherent in the organism's critical thermal limit and heat shock response to temperature.

- Some Branchiopod crustaceans display "substantial physiological plasticity or important adaptive variation," which enables them "to better cope with environmental change."

- "Copepod diversity, especially in extra-tropical regions, is likely to increase with climate change as their large-scale distributions respond to climate warming," because of a "strong positive correlation between diversity and temperature."

Storch *et al.* (2009) note, "temperature is often invoked as the main determinant of distribution ranges and boundaries for marine and terrestrial species," and the larval stages of many marine species "are more vulnerable to thermal and osmotic stresses than adults." They explored the rigidity of this temperature determinant of livable range for the Chilean kelp crab (*Taliepus dentatus*) in its most temperature-sensitive larval state. They studied stage zoea I larvae of two populations of the crab—one from Southern Chile (SC, 43°54'S) and one from Central Chile (CC, 33°29'S)—measuring "temperature-dependent activity, oxygen consumption, cardiac performance, body mass and the carbon and nitrogen composition in order to (1) examine thermal effects from organismal to cellular levels, and (2) compare the thermal tolerance of larvae from two environmental temperature regimes."

The six researchers report, "the thermal tolerance window of zoea from SC was found to be shifted to lower temperatures when compared with those from CC"; that is, the thermal tolerance window of zoea from CC was found to be shifted to higher temperatures when compared with those from SC. The Chilean and German scientists conclude "the small but clear shift between thermal tolerance windows between populations suggests an optimization of reaction norms and local adaptation in larvae of *T. dentatus*," noting "this differentiation allows the species to cover a wider range of distribution than when restricted to one and the same thermal window for all populations," which suggests the larval form of

the kelp crab is capable of adapting to both higher and lower temperatures than those at which it may have lived for long periods in the past.

Stoner *et al*. (2010) write, "temperature is a dominant environmental factor that mediates the behavior, physiology, growth, survival, distribution, and recruitment of ectothermic animals living in temperate and high latitudes." They investigated how the growth and survival of the red king crab (RKC: *Paralithodes camtschaticus*) "may be affected by warming trends expected in Alaska," since the RKC was once that state's "most economically valuable crustacean fishery." The authors reared RKC in "four temperature treatments ranging from 1.5 to 12°C for a period of 60 days, both individually and in low-density populations," measuring various physiological processes and properties throughout this period.

The three researchers report "temperature had no significant effect on survival of RKC," and "there was no consistent difference in survival between individually cultured crabs and those in populations." Growth, they found, "was very slow at 1.5°C, and increased rapidly with temperature with both a contracted inter-molt period and small increase in growth increment." In addition, "20% of the crabs held at 1.5°C never molted, while more than 90% of the crabs in 12°C reached juvenile state 4 or higher." Overall, "growth increased as an exponential function of temperature, with slightly higher growth rates observed in populations than for isolated individuals." They found "no evidence that culturing RKC juveniles at elevated temperatures led to a decrease in condition or nutritional status."

Stoner *et al*. conclude the "accelerated growth" they observed in the RKC raised at the highest temperature might have a "positive, indirect effect on survival," as "larger size associated with high temperature could provide for earlier refuge in size from the typical fish and invertebrate predators on RKC."

Van den Brink *et al*. (2012) note "hymenosomatid crabs of the genus *Halicarcinus* have a reproductive strategy involving a terminal, pubertal moult where reproduction begins only when growth has ceased." This strategy, they explain, "allows females to maximize their reproductive output during a comparatively short (approximately six month) adult life span by producing broods continuously and successively, without the need for the female to suspend reproduction for moulting," citing Van den Brink and McLay (2009, 2010). Van den Brink *et al*. investigated the effect of temperature on brood development for "three intertidal hymenosomatid crabs: *Halicarcinus cookii*, *H. varius* and *H. innominatus*," which

they collected from intertidal habitats around the Kaikoura Peninsula of New Zealand.

The results yielded three main findings. First, "if temperatures rise 2°C as predicted, each of the three species could produce one extra brood per female lifetime," which the authors say "would result in the production of over 1000 extra larvae per female resulting in a 10–15% increase in fecundity" that could "result in a single female producing 10–50 extra surviving offspring per lifetime." Second, "an increase in temperature is also likely to increase larval growth rates ... resulting in shorter development times," which "may also increase survival rates to final instars and eventually adults, thus potentially increasing the size of the population." Third, "the current six month peak breeding season in the three *Halicarcinus* species may increase as temperatures rise," which "may allow the three *Halicarcinus* crabs more time to carry eggs and therefore produce even more offspring per lifetime." These findings indicate a modest warming would prove extremely beneficial to hymenosomatid crabs.

Kelley *et al*. (2011) note, "measuring variation in physiological traits over broad spatial and temporal scales in an effort to investigate the ecological impacts of these traits (Chown *et al*., 2004)" can "aid in predicting how species or communities will respond to climate change," citing Baker *et al*. (2004), Harley *et al*. (2006), Hassol (2004), Helmuth *et al*. (2002, 2005), Kennedy *et al*. (2002), Parmesan (2006), Parmesan and Yohe (2003), Portner *et al*. (2001), and Stillman (2003). Employing this approach in their study of the European green crab (*Carcinus maenas*), Kelley *et al*. measured the upper lethal thermal thresholds of two populations of the invasive species living at the southern and northern limits of its current range on the west coast of North America— Sea Drift Lagoon, Stinson Beach California (CA; 37°54'27.82"N), and Pipestem Inlet, Vancouver Island, British Columbia (BC; 49°02.3'N). The two sites are separated by 1,200 km of coastline—where "ambient sea surface temperature in the northern part of the North American west coast range is 5 to 10°C lower, depending on the time of year, than near the southern range limit." The species' expansion from its initial introduction at the south end of its range to its current northern end occurred over a period of about 20 years.

The three U.S. scientists determined the warm-adapted southern CA group of crabs had the highest level of organismal thermotolerance and the greatest degree of heat shock protein 70 (Hsp70) production. They also found carapace widths of male and female

C. maenas individuals from CA were significantly smaller than those in BC. Kelley *et al*. say these findings "provide evidence that the northeastern Pacific population of *C. maenas* has incurred a shift in thermal tolerance compared to its southern counterpart," and "thermal adaptation at the level of the phenotype is a likely cause due to the short timescale of the invasion and the genetic connectivity of the two populations."

The authors state that over just two decades "it is possible that a large, northern cold-water phenotype may have already arisen," which further suggests the reverse of this phenomenon also could have occurred over the same length of time if the driving force for phenotypic change had arisen due to the crabs migrating from a cooler to a warmer environment, or, by further inference, that it could have occurred during a period of equivalent climatic warming in the same physical setting without any relocation. This is yet another example of a species demonstrating a capacity to cope with projected global warming, without the need to migrate.

Ravaux *et al*. (2012) point out "all organisms possess some capacity to modify their behavioral, physiological or morphological characteristics in response to changes in environmental temperature" via a phenomenon they characterize as thermal acclimation, citing Angilletta (2009). This special case of phenotypic plasticity would be of great significance to all organisms in a warming world. Ravaux *et al*. studied *Palaemonetes varians*, a shallow-water brackish shrimp native to Western Europe, assessing both cold- and warm-acclimated specimens collected from the Bay of Mont Saint-Michel (France), the plasticity of a common index of thermal tolerance, the critical thermal maximum (CT_{max}), and the plasticity of a widespread and conserved molecular response to stress, known simply as heat shock response (HSR).

The seven scientists determined *P. varians* "shows genuine acclimation capacities" due to the plasticity inherent in the organism's thermal limit (CT_{max}) and its heat shock response (*hsp*70 induction temperature). Ravaux *et al*. conclude *P. varians* "is readily able to expand its thermal range since it can shift its thermal maximum to higher temperatures and also mobilize the HSR over a wide range of temperatures above those experienced in nature." They state the shrimp "is potentially capable of expanding its upper thermal range," which suggests it may not have to migrate toward cooler regions in a potentially warming world of the future.

Pinceel *et al*. (2013) studied the ability of large branchiopod crustaceans to phenotypically adapt, constructing "a molecular phylogeny based on a data set which includes about 85% of the *Branchinella* species currently known to science, as well as a number of recently discovered lineages." They discovered "substantial physiological plasticity or important adaptive variation present in some species, potentially enabling them to better cope with environmental change."

Letessier *et al*. (2011) modeled the influence of a suite of physical, chemical, and biological variables on euphausiid species abundance. Euphausiids are small, pelagic, shrimplike crustaceans of the order Euphausiacea; the authors say they constitute "an important component of the pelagic realm," where they "graze directly on phytoplankton and provide a food source for a range of predators including birds, seals, baleen whales and many commercially important fish species," citing Verity *et al*. (2002). The authors used a generalized additive model running environmental changes based on IPCC A1B climate scenario to make predictions of future species abundance changes in the Pacific and Atlantic Oceans, which they sub-divided into cells having east-to-west lengths of 300 km and north-to-south lengths of 200 km.

Letessier *et al*. found "the main drivers of species abundance, in order of decreasing importance, were sea surface temperature (SST, explaining 29.53% of species variability), salinity (20.29%), longitude (-15.01%, species abundance decreased from West to East), distance to coast (10.99%) and dissolved silicate concentration (9.03%)." The three UK researchers say their results suggest "the present broad patterns apparent in species abundance (low in high latitudes, high in intermediate latitudes and intermediate in the tropics) will become less pronounced in a warming ocean," and eventually, "species abundance will be enhanced within intermediate-to-high latitudes (30°N to 60°N and 30°S to 60°S) and diminished in the tropics (20°N to 20°S)." These changes, they write, are "consistent with changes already observed to be occurring in terrestrial systems in Europe and America," citing Rosenzweig *et al*. (2008), and with "already-observed changes in zooplankton assemblages in the North Atlantic (i.e., communities shifting north)," as reported by Beaugrand *et al*. (2002), Beaugrand and Ibanez (2004), and Richardson and Schoeman (2004). Considered in their entirety, such shifts in euphausiid species abundance may be viewed as positive developments, especially in light of the three scientists' finding that both the Atlantic and Pacific

Oceans "will on average see an increase in species abundance per cell."

Rombouts *et al*. (2009) studied marine copepods—small ocean crustaceans that form a key trophic link between phytoplankton and fish. Some are planktonic and drift in sea water, but more are benthic and live on the ocean floor. Rombouts *et al*. developed the first global description of geographical variation in the diversity of marine copepods in relation to 10 environmental variables.

They found "ocean temperature was the most important explanatory factor among all environmental variables tested, accounting for 54 percent of the variation in diversity." They report "diversity peaked at subtropical latitudes in the Northern Hemisphere and showed a plateau in the Southern Hemisphere where diversity remained high from the Equator to the beginning of the temperate regions." This pattern, they write, "is consistent with latitudinal variations found for some other marine taxa, e.g. foraminifera (Rutherford *et al*., 1999), tintinnids (Dolan *et al*., 2006) and fish (Worm *et al*., 2005; Boyce *et al*., 2008), and also in the terrestrial environment, e.g. aphids, sawflies and birds (Gaston and Blackburn, 2000)."

"Given the strong positive correlation between diversity and temperature," the six scientists conclude, "local copepod diversity, especially in extra-tropical regions, is likely to increase with climate change as their large-scale distributions respond to climate warming." This state of affairs has typically been found on land for birds, butterflies, and several other terrestrial lifeforms, as their ranges expand and overlap in response to global warming. With more territory thus available to them, their foothold on the planet becomes increasingly strong, fortifying them against forces (many of them human-induced) that might otherwise lead to their extinction.

Tremblay *et al*. (2011) compared time series of ice cover, wind forcing, and satellite-based assessments of photosynthetic carbon production in the Canadian Beaufort Shelf for the years 2002–2008 with corresponding *in situ* measurements of salinity, nutrients, new production, biological stocks, and biogenic fluxes obtained during overwintering surveys of copepods in 2003–2004 and 2007–2008. The 15 researchers report that in 2007–2008, in areas where ice was no longer present, due to enhanced seasonal warming, there was significant wind-induced upwelling of growth-promoting nitrates, which were brought up from deep and dark waters into the euphotic zone, where photosynthesis occurs. As a result of this fertilization effect, the herbivorous

copepod *Calanus glacialis*—which they say is "the key link between diatom production and apex consumers on Arctic shelves," citing Soreide *et al*. (2010)—experienced a total abundance "3 to 33 times higher than in 2003 during mid-fall and 1.6 to 13 fold higher than in 2004 during early summer." On the region's central shelf, the scientists observed "sedimentary chlorophyll *a* was over 20-fold higher than at any station not influenced by upwelling," and "benthic carbon demand was among the highest ever observed in the Arctic ocean," citing Clough *et al*. (2005). They report the "repeated instances of ice ablation and upwelling during fall 2007 and summer 2008 multiplied the production of ice algae, phyto-plankton, zooplankton and benthos by 2 to 6 fold."
